The basic operation of a computer or microprocessor is governed by the control and timing unit (CTU) which generates the signals necessary to coordinate, synchronise and control the movement and processing of all information within the system. A simple external clock usually drives the unit, and this provides a time-reference signal from which the CTU generates the timing and control signals for the various logic subsystems in the computer. Modern high-performance processors may include a separate clock management subsystem which generates multi-phase timing sequences for use by the CTU.

The control and timing unit is responsible for controlling the main operational cycle of the processor which is known as the 'instruction cycle'. The instruction cycle can be split

CPU register identity	Programmer's model	Function
PC	Program counter	Code memory reference pointer
Status Register SR or Condition Code CC or Flag F	Status register	ALU status at end of execution phase
CPU address registers	Operand (1) addr.	Data memory reference mechanism
(Number may vary and instruction-type and address-mode constraints may apply)	Operand (2) addr.	
	Resultand addr.	
CPU data registers	Accumulator	Accumulators or CPU memory registers
(Number and function may vary and instruction-type constraints may apply)	Accumulator	

Figure 15.8 Programmer's model

into two distinct phases, the instruction fetch and the execution of the instruction. During the instruction fetch the address of the next instruction is obtained from the program-counter mechanism and transferred to the memory address register (MAR). A memory reference operation is then performed on the code part or code segment of memory to read the opcode which is the first part of an instruction. The opcode data are transferred via the memory buffer register (MBR) to the instruction register where it is decoded and then input to the CTU. The program-counter is then updated to point to the next part of the instruction or to the next instruction.

The opcode identifies any further memory reference operations which are required to complete the instruction 'fetch'. The control unit uses the updated program counter to make reference to successive addresses in the code part of memory to fetch any further parts of the instruction, such as immediate data values or the addresses of the operands and the address of the resultand. This information is transferred to various temporary registers in the CPU for use during the 'execute' cycle. At the end of the instruction 'fetch', the CPU will contain all the information it requires to control the execution of the instruction and the program-counter will be pointing to the next instruction to be fetched (assuming that the execution cycle does not compute a new program-counter address). The various logic units used during the instruction 'fetch' cycle are shown in Figure 15.9 in which the memory and input/output discriminator M/I/O is used to distinguish between memory reference operations and any operations involving peripheral systems which may use the same address and data bus.

The opcode also defines the sequence of operations necessary to execute the instruction. During the execution part of the instruction cycle the control and timing unit will synchronise the transfer of data within the system and control the operation of the ALU. The control unit will access operand data by transferring the operand addresses from the temporary registers to the memory address register to perform memory reference operations. In practice, many processors have a complex data reference pointer which will compute the address of the data object using not only

the temporary register but also base or segment registers, offset registers, and index registers according to the addressing mode specified in the instruction. If the computer has a memory-to-memory architecture, then operand data can be transferred direct from immediate access memory to the arithmetic logic unit and resultands can be returned direct to storage in immediate access memory. However, if the computer has a register-to-register architecture, then the operand data is normally transferred to a CPU register before being processed by the arithmetic logic unit and resultand data is held in the accumulator or transferred to another CPU register. The register-to-register architecture has distinct performance advantages, particularly when used with a multiple-instruction pipeline CTU, as in modern reduced instruction set (RISC) processors.

### 15.4.5 Arithmetic logic unit

The actual data processing operations are performed by the ALU, which is a general-purpose logic system and can normally perform logical, arithmetic and bit manipulation operations. The ALU operates under the control of the control and timing unit and its function is defined by the current instruction held in the instruction register. The ALU can perform both monadic (single operand) and dyadic (two operand) operations and, therefore, has two input data paths. It generates status information in the status register and has an output data path for the resultand. Depending on the architecture of the processor, the operand data inputs may be from either immediate access memory registers or CPU data registers. The resultand is usually output to a special register, known as the accumulator, which is normally a multi-function register which can participate fully in the processing operations. In some systems the accumulator is used to store one of the operands before a processing operation and is subsequently used to store the resultand. This technique removes the need to have two operand registers and may increase the operational speed of the processor. However, the need to minimise the number of CPU registers is no longer a major design objective and many modern microprocessors have a number of CPU registers of advanced design which can act as operand registers or accumulators.

The ALU also contains the status register which is also known as a *flag register* or *condition-code register*. This register consists of a number of flip flops (flags) whose state reflects the result or state of the processing element at the end of the previous processing operation. This is illustrated in Figure 15.10 which shows in schematic form the structure of a typical ALU and the other logical systems associated with the execution part of the instruction cycle.

### 15.4.6 Memory unit

The memory unit provides storage for program code and data. Computers commonly use two types of memory, fast immediate-access memory and backing store memory, which have different roles and functions.

The immediate-access memory is considered to be the primary memory unit of a computer, it is used to store program code and the data associated with the program so that it may be readily accessed during the execution of the program. Read only memory (ROM) devices may be used to store information which does not alter, such as program code or constant data, and random-access read-write memory (RAM) devices are used to store data which may be altered, such as the value of variables. The immediate

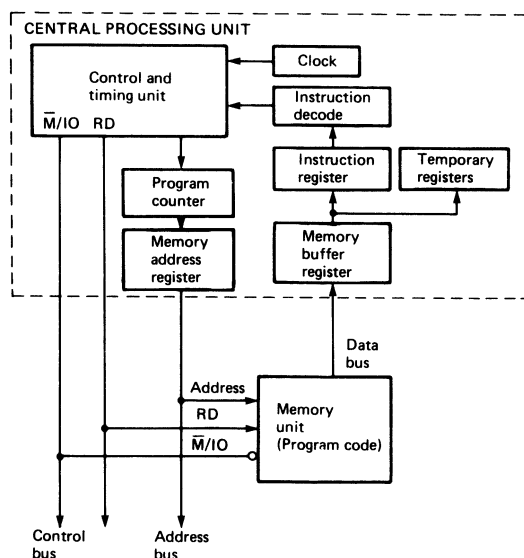

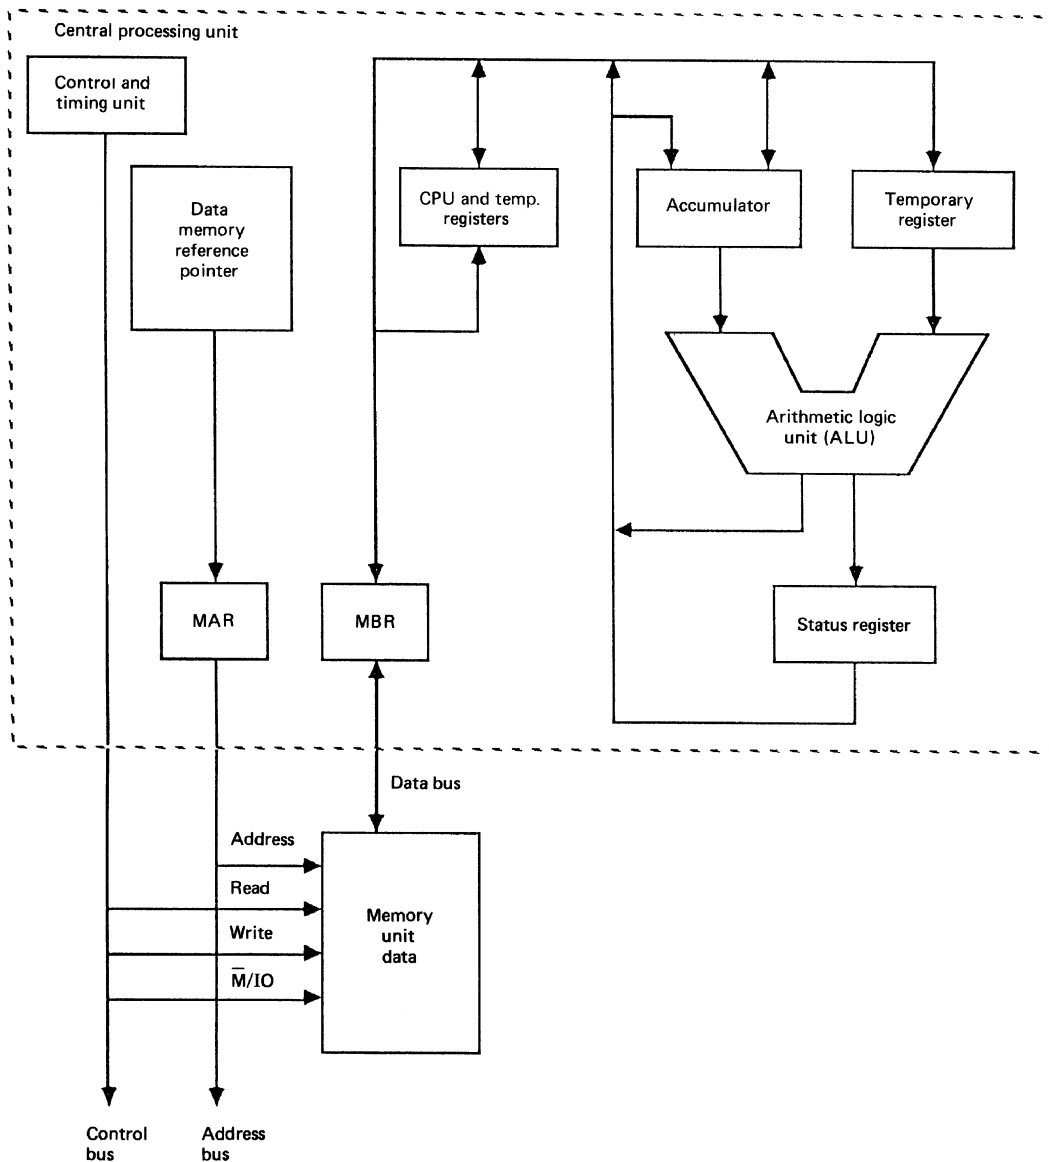

Figure 15.9 Instruction 'fetch' logic structure

**Figure 15.10** Instruction 'execution' logic structure

access memory is normally constructed using semiconductor memory devices. Typically, large memories are built using dynamic RAM memory devices which provide 'high-density' storage at relatively low cost.

The immediate-access memory is normally limited in size by the computer architecture. For example, simple microprocessors may have a 16-bit memory address and this limits the size of the immediate-access memory to 64k registers or elements. While a  $64\text{k} \times 8$ -bit memory is often sufficient for embedded applications such as dedicated control systems, larger memories are often required to support general-purpose applications software. Typically, modern microprocessors use 32-bit effective memory addressing and commonly have a 128 M byte or 256 M byte memory which is sufficient to run modern operating systems and

applications software. However, the performance of memory-intensive applications, such as image processing, computer aided design (CAD), and interactive computer games, may benefit from larger memories. Therefore, more advanced microprocessors have the capability to physically address 1 G or more of memory.

Many computers have facilities for using an area of memory as a stack. This is a block of RAM memory which is used on a last-in/first-out (LIFO) basis for storing context information, such as the values of the program-counter, status register, and other CPU registers, or for storing data such as the parameters passed to subroutines. This facility is particularly useful for storing addresses and register contents during subroutine operations or during the context switches which take place following an interrupt.

**Figure 15.11** Stack layout in RAM memory

A stack is organised by a stack pointer, which is a CPU register holding the address of the last item placed on to the stack, also called the ‘top-of-the-stack’. Instructions are provided which automatically decrement the stack pointer before data is stored (PUSH) or automatically increment the stack pointer after data is retrieved (POP) from the stack. A stack grows downwards in the store as shown in Figure 15.11.

Stacks can be used to implement nested subroutine calls by simply putting return addresses and CPU register contents on to the top of the stack during successive calls. Recursive subroutine calls can be implemented in a similar manner provided parameters are passed to the subroutine on the stack and local variables are stored on the stack at each level of call. Typically, the parameters are pushed onto the stack before the subroutine call; following the call the parameters are accessed by the subroutine using indirect addressing (using any CPU address register other than the stack pointer so that the stack pointer is available for the next recursive call). Results can be returned using the same technique. The stack can be employed in a similar fashion to store register and address information following an interrupt, including multiple and re-entrant interrupts.

Large immediate-access memories are relatively expensive to implement and are unsuited to the long-term storage of large program or data files. Most computers are therefore equipped with auxiliary or backing stores which are normally sequential access storage systems such as magnetic memory hard discs, and removable sequential stores such as optical storage discs, 650 M byte compact discs or CDs (such as write-once, read-only CD-R or read-write CD-RW discs), or 4.7 G byte digital video discs or DVDs (such as write-once, read-only DVD-R or read-write DVD-RW discs). These systems provide economic storage for the large volumes of data which are commonly used in database or image processing applications. Most computers are still equipped with a floppy disc drive, though this legacy technology is increasingly irrelevant for backing store purposes and is usually reserved for system start-up (or boot-up) during installation or fault recovery. Magnetic tape cartridges still provide economic storage for backing up large-scale systems such as servers.

### 15.4.7 Interrupts

In many applications the computer must respond rapidly when an external event occurs. This is usually achieved by an interrupt facility. The CPU is provided with a special input, the interrupt control line, which is used to notify the processor of the occurrence of an asynchronous external event. When the event occurs, e.g. a key is depressed or a switch is closed, the interrupt control line is driven to a specified logical state and the CPU is interrupted.

On detection of an interrupt, the processor carries out a sequence of operations that transfers control to a special form of subroutine, called the ‘interrupt handler’ or ‘interrupt service routine’, which is located at a pre-determined

address in memory. The actions taken to invoke an interrupt service program vary from computer to computer, but in general terms the following sequence occurs:

- (1) At the end of the current instruction the contents of the program counter and the status register are automatically stored in the stack and the interrupt line is disabled.
- (2) The program counter is loaded with the address of an interrupt service routine, either directly or following interrogation of the interrupt source to determine the identity of the service routine so that the CPU can be vectored to one of a number of interrupt entry addresses appropriate to the particular interrupt.
- (3) The interrupt service program is entered. Care should be taken to ensure that the interrupt service program does not alter the context of the interrupted program. Therefore, the CPU registers needed by the service routine are stored in the stack, this may be an automatic hardware facility or may be performed by the interrupt handler software.
- (4) When the interrupt service program is complete, the context of the interrupted program is restored (by restoring the contents of registers saved in the stack) and control is returned to the interrupted program by restoring the contents of the status register and the program-counter. Also, interrupts are re-enabled if this has not already been done as part of the interrupt service above.

### 15.4.8 Input/output

The role of the input/output subsystem is to interface the computer to external logic devices. There are several ways of controlling input and output. Normally, data are input or output under program control at prescribed points in a program. In an event-driven environment, data can be input or output in response to an interrupt under the control of an interrupt service program. However, in both cases, the speed of data transfer is governed by the interface logic and by the speed of the input/output control program which executes in the CPU. In high-speed applications the restrictions due to the control program can be removed if the external logic circuits can access the immediate-access memory directly using a suitable access mechanism and input/output protocol.

#### 15.4.8.1 Program controlled input/output

There are two commonly used methods for connecting input and output systems to a processor for program or interrupt controlled input/output. The most elegant technique treats all input and output ports as if they were memory registers in the memory unit. The input and output ports are connected to the address, data and control bus structures as if they were memory elements and are designed to operate to the same electrical and functional specification as a memory register. Data can then be output using a memory reference ‘write’ instruction at the output address, or input using a memory reference ‘read’ instruction at the input address. This method, which is known as *memory-mapped input/output*, is used in a wide range of processors. It gives fast input and output and is compatible with other software data-transfer instructions.

An alternative approach connects all inputs and outputs to a separate input/output bus structure which normally consists of a limited number of address lines and the usual

control signals. In bus-orientated systems a subset of the memory address lines is used and an additional memory or input/output discriminator signal ( $M'/IO$ ) is used to generate unambiguous addresses. Input/output-mapped input/output is not compatible with memory reference operations and special instructions such as IN or OUT are often used to distinguish this mode of operation.

Serial communications are usually interfaced using a universal asynchronous receiver and transmitter device (USART) which contains a serial-to-parallel receiver buffer, a parallel-to-serial transmitter buffer, a mode control register, and a status register which indicates valid communications. The data, control, and status register are accessed using either memory-mapped or input-output mapped techniques according to the architecture of the processor.

#### 15.4.8.2 Interrupt-driven input/output

An interrupt can be used to force a processor to suspend its current task and execute an interrupt service program, as described in Section 15.4.7. Interrupt driven input/output is implemented by connecting the control logic of the external device to an interrupt line so that the device can demand the CPU's attention. Following the generation of an interrupt, the CPU is forced to respond immediately and execute a program which services the input or output requirements of the interrupting device. Interrupt-driven input/output maximises the utilisation of the external device, but causes suspension of the current task. Interrupt-driven input/output is commonly used to interface intermittent inputs such as keyboards. However, in some embedded applications it is undesirable to interrupt an executing task, and the preferred approach is to regularly inspect (or poll) an external device for the availability of an input.

#### 15.4.8.3 Direct memory access

The use of direct memory access (DMA) allows an external device to transmit data directly into the computer memory without involving the CPU. The CPU is provided with control facilities which allow the DMA controller (external to the CPU) to gain control of the CPU data bus. The DMA controller must provide a memory address, the data, and bus control signals to effect a data transfer. The DMA controller then transfers data directly over the bus to or from the memory. DMA transfers are commonly used to send blocks of data, rather than individual items of data, between backing stores or peripheral devices and memory. The controller contains a counter to increment the memory address and count the number of transfers made within the data block. The DMA process is also referred to as *cycle-stealing*, since it proceeds simultaneously with program execution, the only effect being that the instruction execution time is increased by the number of memory cycles used when a transfer is in progress.

The relative merits of DMA over other means of input/output is that it is fast, uses the minimum amount of computer time per data word transferred and operates autonomously. The loss of instruction execution time is not usually significant unless a very large number of devices are under DMA control. The major disadvantage of DMA is that the computer program is not explicitly aware of changes in data or the completion of a DMA transfer and it is usually necessary to make the DMA controller invoke an interrupt to inform the CPU that a data block transfer is complete.

### 15.4.9 Microprocessors

Advances in microelectronics and computing science have provided the technologies necessary to construct the complete central processing unit of a computer on a single integrated circuit; this device was called a microprocessor. The microprocessor, which was developed in 1971, realised a step change in the cost, performance, power consumption and reliability of a minimum computer system. Further advances in VLSI design led to the development of integrated circuits containing both the CPU and the memory unit; the so-called single chip computer. In effect, these advances had resulted in the miniaturisation of the computer.

The microprocessor can also be viewed as an advanced programmable logic device. Special microprocessors and other advanced programmable systems have been developed to carry out specific computational functions. These processors are often designed to work in conjunction with a general CPU and are known as co-processors. A number of devices such as fast floating-point arithmetic units, communication or local area network co-processors, and multimedia units such as audio processors and graphics and video display generators, are available and can be used in the design of powerful processor architectures. To prevent such high-bandwidth processing elements making significant demands on immediate-access memory, they are often provided with separate application-specific memories as in the case of video display subsystems. A typical system architecture of this type is shown in *Figure 15.12* which illustrates the use of programmable systems including microprocessors in the design of an advanced information processing system.

## 15.5 Processor instruction sets

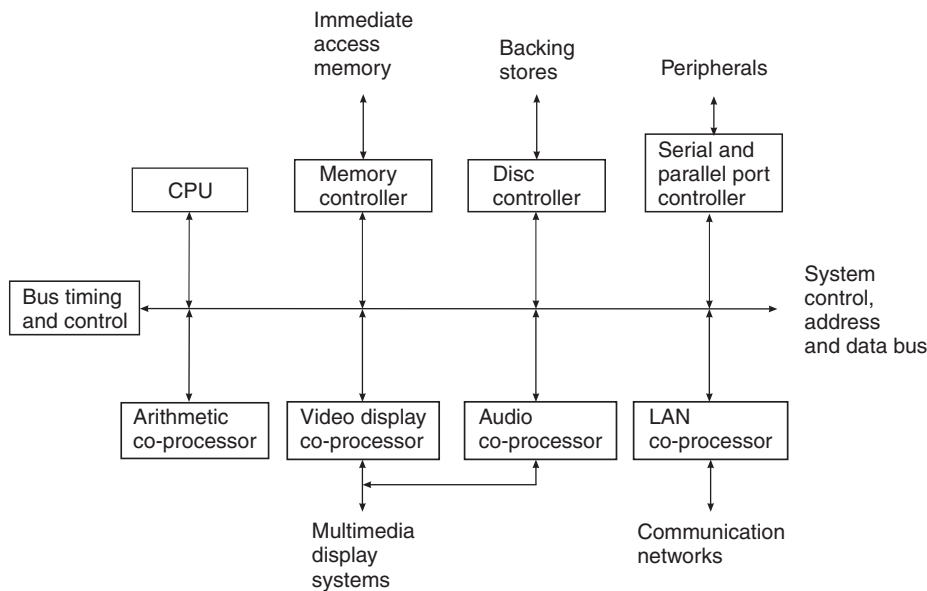

Most general-purpose computers or microprocessors are designed to execute sequences of instructions or more complex programs of instructions which prescribe the actions necessary to input, store, and process data, and output computed results. The instruction set of a processor defines the machine code operations, which the processor can perform. However, the range of instructions available with a particular processor depends to a considerable extent on the design objectives of the particular manufacturer. The range and capability of the instruction set provided may have a considerable influence on the choice of a computer for a particular application task.

### 15.5.1 Types of instruction

Although there is no standardisation of computer instructions, most processors provide primitive operations or instructions for the following.

#### 15.5.1.1 Program flow control

The sequence in which instructions are executed is defined implicitly by the program which comprises an ordered list of instructions held in successive memory locations. Unconditional branch or jump instructions can be used to jump to a program in another part of memory. Also, repetitive or loop structures can be formed by jumping back to an instruction which has already been processed. However, the true power of a programmable system is provided by conditional instructions. The flags in the status register can be used as qualifiers for conditional branches, either on their own, as in 'branch if zero', or in combinations as in 'branch if greater than' or 'branch if less than or equal'.

**Figure 15.12** A multiprocessor system architecture

When computing decisions (selecting between alternative sequences of code) conditional branch or jump instructions are used to determine whether to continue the present sequence or jump to the start of an alternative sequence. Similarly, conditional jumps can be used to form conditional exits from repetitive structures.

Although most processors are unable to implement directly the flow control constructs found in high-level programming languages, the implicit sequence, unconditional branch and conditional branch instructions form the primitives from which constructs such as ‘if-then-else’, ‘while-do’, and ‘repeat-until’ can be formed.

#### 15.5.1.2 Data-flow including input and output

Data-transfer instructions, such as MOVE, can be used to input external data to a CPU data register or an immediate-access memory register, to transfer data between such registers, and to output data from such registers to the outside world. Although these instructions do not necessarily make use of the ALU and may not alter the status register, they can be classed as data processing instructions in the sense that they assign values to the variables (registers).

#### 15.5.1.3 Data-processing instructions involving the ALU

Most processors provide a range of arithmetic instructions including addition, subtraction, multiplication and division. These instructions are used in mathematical applications including the data ‘sorting’ operations used in data base applications. Simple processors often implement these operations using two’s complement integer arithmetic. More complex algorithms involving floating point arithmetic can be programmed using these primitive operations. However, these programs often make intensive use of the processor and are relatively slow and it is common to enhance the performance of such processors by adding arithmetic co-processors. More advanced processors have

powerful built-in arithmetic capabilities including floating point arithmetic units.

Most processors can also implement logic operations such as NOT, AND, OR, and EXCLUSIVE OR (XOR) which are implemented ‘bit-wise’ by performing the operation simultaneously on each corresponding pair of bits in the operands. These operations are used to perform the ‘compare’ or ‘find’ operations used in database applications. Many processors can also implement shift/rotate instructions which involve moving all the bits in a computer word either to the right or the left. There are several possible form of shift, such as arithmetic and logical shifts and logical rotations. (Few conventional high-level languages give direct access to primitives for physical bit-level manipulation.)

#### 15.5.1.4 Machine control

These instructions control the mode of operation of the processor. Many machine control instructions, such as START/RESTART, HALT, STOP have a profound influence on the behaviour of the processor. Similarly, in event driven systems, machine control instructions such as INTERRUPT ENABLE/DISABLE and interrupt priority control instructions affect the ability of the processor to respond to external stimuli. Therefore, some processors classify certain machine control instructions as ‘privileged instructions’ which can only be used if the processor is in a special ‘systems’ or ‘supervisor’ mode that is used by systems programmers. (Few conventional high-level programming languages give direct access to machine-level primitives for machine or interrupt control.)

### 15.5.2 Data objects and data types

At machine level textual, numerical and logical information is represented by codes of binary digits and the processor is not able to infer the context of any particular binary data

object. Thus, the concept of *data typing*, in the high-level sense, does not exist at machine level.

A processor handles such data in terms of the contents of registers. Thus low-level primitive instructions transfer and process data by reference to the architecture and registers of the processor, such as input/output device registers, CPU data registers and/or accumulators, and immediate-access memory registers. Data typing at machine level is restricted to specifying the length of a data object. Most low-level assembly languages provide assembler directives which allow the programmer to declare data objects by length, assign symbolic names (identifiers) to the objects, and provide initialising values for variables. When an assembly language source program is translated into machine code, the assembler enforces the data-type rules on the usage of the declared data objects and allocates storage space at machine level for all data objects.

Although limiting, low-level data types provide the building blocks for accommodating (storing and processing) the more complex data types normally associated with high-level programming languages. However, the efficient use of high-level data types also depends on the availability of suitable addressing mechanisms for accessing data objects.

### 15.5.3 Instruction formats

Each computer instruction is stored in memory as binary numbers and can be considered to comprise a number of fields:

- (1) *Operation code (op-code)*: this part of the instruction identifies the type of operation which is to be performed (such as 'add' or 'jump'), the number and addressing mode of the operands, and the addressing mode of the resultand (if any).
- (2) *Operand field*: this specifies either an immediate data value (if immediate addressing) or the address of the operand on which the instruction operation is to be performed. The processor's data memory reference mechanism will use the address information in conjunction with the addressing mode to compute the effective address (physical address) of the operand.
- (3) *Resultand field*: this specifies the address of the resultand (corresponding to the addressing mode used). In some processors, the resultand address is, by default, the same as that of one of the operands, and when the instruction is executed the resultand overwrites the operand concerned.

The format of a typical instruction, such as ADD, for a memory-to-memory architecture processor in which the operands and resultands reside in immediate access memory is shown in *Figure 15.13*. This type of instruction format has the potential to generate multi-word instructions. For example, a 16-bit microprocessor may have a 16-bit op-code and either a 16, 20, 24 or 32 bit memory addressing capability. The resulting instruction would be long and the corresponding instruction fetch would require many memory reference operations, which is inefficient. Many CPU architectures force the resultand to overwrite one of the operands, this gives some gain in efficiency since the resultand address is, implicitly, the same as one of the operands. The format of a typical instruction of this type is shown in *Figure 15.14*.

In practice, many processors have a register-to-register architecture where the operands and resultands are stored in CPU data registers, which being few in number can be

Op-code	Operand 1 field	Operand 2 field	Resultand field
---------	-----------------	-----------------	-----------------

**Figure 15.13** Instruction format—explicit resultand

Op-code	Operand 1 field	Operand 2 field and implicit resultand field
---------	-----------------	--

**Figure 15.14** Instruction format—implicit resultand

addressed using very short direct addresses. This gives some gain in efficiency, although separate MOVE instructions are required to load data from memory into the CPU registers (the LOAD operations) and to return results to memory (the STORE operation). The so-called LOAD-STORE architecture, or register-to-register architecture processor, is the default architecture for modern reduced instruction set (RISC) processors. These processors commonly have a CPU register file comprising 32 general-purpose 32-bits registers that can act as source registers for operands and accumulators for resultands.

### 15.5.4 Addressing data objects

During the execution of an instruction, operands are fetched from the addresses indicated in the operand field of the instruction, and resultands are returned to the address shown in the resultand field of the instruction. A number of different methods of addressing operands have been developed. These address modes are used to introduce flexibility by decoupling the logical address from the physical address, to extend the address range of the memory that can be accessed from an instruction, and to provide support at a primitive level for the addressing mechanisms required in advanced data structures. The data-memory reference system is used to generate the physical address of a data object from knowledge of the addressing mode and the values in the operand field of the instruction and any associated address registers.

The address modes commonly encountered for accessing operands are as follows.

#### 15.5.4.1 Immediate addressing

In this mode, the actual value of the operand is included in the instruction, i.e. the operand address field is a literal. This allows rapid access to the operand, but the value of the operand is fixed by the program code. The operand may be a data object, such as an integer constant, or an address object. Typically, it is used to load small integer constants into a register. (To avoid repeatedly using immediate addressing to load the commonly used value zero into CPU registers, many RISC processors have one CPU 'register' permanently hardwired to the value zero.)

#### 15.5.4.2 Direct addressing

In this mode the value in the operand address field is the address of the operand. There are two main variants of direct addressing. In *CPU register direct addressing* the address of the CPU register is given, as an explicit value,

in the address field of the instruction. Since most CPUs have a small number of CPU registers, the address field is restricted and this allows single word instructions. CPU Register direct addressing is fast because the instruction is short and the operands are already held in the CPU. It is used extensively in register-to-register architecture processors, including RISC processors. In *memory direct addressing* the immediate access memory address of the operand is given, as an explicit value, in the address field of the instruction. In limited-word-length computers this means that only a small area of memory can be assessed directly. Also, this addressing mode is inflexible because the address is embedded in the program code. It is commonly used to access address constants, such as input/output ports.

#### 15.5.4.3 Indirect addressing

In this mode, the operand field of the instruction identifies an address register (usually a CPU register) which holds the address of the operand. The address register must be initialised before use. In effect, the address-register acts as a 'pointer' to the operand. This removes the need for the instruction to specify the absolute address, which introduces flexibility. It also allows the operand to be accessed by a one-word instruction. If the address register has accumulator capabilities and can participate in arithmetic operations, then the indirect address or pointer can be manipulated to give access to complex data structures. For example, the indirect address could be incremented during successive passes through a loop of instructions.

Some processors have special mechanisms which allow an indirect register to be decremented or incremented immediately before use (e.g. pre-decrement) or immediately following use (e.g. post-increment). Such pointers can be used as stack pointers which are automatically updated to point to the 'top-of-stack' following a PUSH or POP operation.

#### 15.5.4.4 Indexed addressing

Indexing is used to address sequential data structures. The effective address of a data object in the structure is formed from the sum of two components; the address of (the start of) the data structure and the index or offset of the object relative to the start of the structure. The data-memory reference mechanism computes the effective address as the instruction is executed.

Indexed addressing is normally implemented using two CPU registers. An address-register is used (as in indirect addressing) to point to the start of the data structure (the address of the first object the structure) and a second register, known as the *index register*, holds the offset address of the data object. The index register usually has an accumulator capability such that the index can be readily modified or incremented. Modern processors often have a number of address registers which can be used as pointers to data structures and a number of index registers. An indexed addressing instruction for such a processor would specify both the pointer and index register.

#### 15.5.4.5 Base and (relative) offset addressing

In this system of addressing, an address register is used as a 'base pointer' and points to the segment of memory allocated to the data associated with a program. All references to data objects are made relative to the base address. The data memory reference mechanism automatically adds the

base address of data segment when calculating the effective address of a data object. Thus, in this system, direct addresses, indirect address, and indexed addresses are assumed to be relative to the base address. Thus all relative addresses associated with the operand data can be calculated when the program is compiled or assembled and do not require further alteration when the program is located. This has the significant advantage that, as far as references to data objects are concerned, the data segment can be relocated easily because the executable program code remains unchanged and only the value of the base pointer has to be altered.

### 15.5.5 Addressing program code

The program-counter points to the location of the current instruction and is incremented as each instruction is executed in sequence. However, the value in the program-counter is overwritten during unconditional and conditional branch or jump instructions. In effect, the operand of branch and jump instructions may modify the value of the program counter. Branch and jump instructions employ a variety of addressing modes:

#### 15.5.5.1 Direct addressing

The value in the operand field of the instruction is the destination address of the branch or jump.

#### 15.5.5.2 Indirect addressing

The operand field of the instruction identifies an address-register which holds the destination address of the branch or jump.

#### 15.5.5.3 Relative addressing

The value in the operand field is interpreted as a positive or negative binary number which is added to the current contents of the program-counter to determine the destination address of the branch or jump. This is usually quite efficient because most destination addresses will be fairly close to the instruction being executed. Since the offset of the relative address is independent of the location of the code, the offset can be determined as a constant when the program is assembled or compiled and does not need to be altered when the program is located. This has the significant advantage that, as far as references to code locations are concerned, the executable program code can be relocated and only the initial value of the program counter has to be changed.

## 15.6 Program structures

Certain program structures occur so frequently in program design that it is worth looking at methods for implementing them both at high-level and at assembly or machine level. The implementations use both unconditional and conditional jumps.

### 15.6.1 Selection

The '*if-then-else*' selective construct is used to select between two alternative instructions (or processes). This high-level

construct specifies the alternative processes and the conditions under which they can be executed, for example:

```
if x > 0 then P1 else P2;
```

The decision part of this construct is implemented at machine level by two distinct instructions:

- (1) the evaluation of the conditional expression, which must be a relational operation that returns a Boolean result. When this is computed, the result is reflected by the setting or resetting of one or more flags in the ALU status register.
- (2) the conditional branch which uses the relevant flags in the status register as operands. When the conditional branch instruction is executed it passes program flow control to the selected process (i.e. if the condition is true then branch to P1 else continue with P2). Note that in the low level implementation an unconditional branch instruction has to be inserted at the end of the 'else process' P2 to allow both alternative processes to be stored in sequential memory, as shown in *Figure 15.15*.

## 15.6.2 Repetition

Consider a process which must be executed several times. If the number of iterations is known, then a 'for' loop would be indicated; otherwise the loop structure could be implemented using either as a 'while...do' or a 'repeat...until' construct. The 'repeat...until' construct should be used if the process is to be executed at least once, otherwise the 'while...do' construct, which allows the possibility of an exit before the process is executed, should be used. Since both the 'for' and 'repeat...until' constructs can be derived from the 'while...do' construct, the 'while...do' construct is

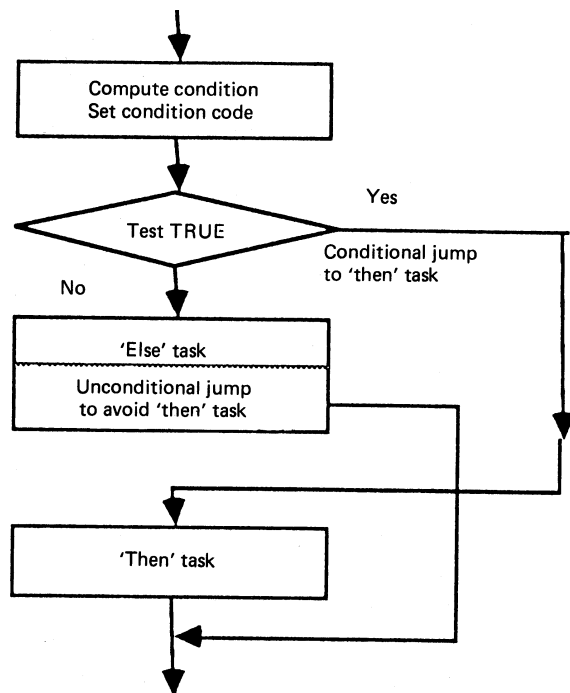

Figure 15.15 'If-then-else' construct

the primitive and is found in all high-level sequential and concurrent programming languages.

### 15.6.2.1 'Repeat-until' construct

This repetitive construct allows a process to be executed at least once. The number of times the process is executed depends on a value of a control variable, for example:

```
count := number;
repeat
  P1
until count <= 0 do;
```

where the process P1 must update the loop control variable, as in:

```
count := count - 1;
```

Implementation of the 'repeat-until' construct at low-level requires an explicit loop control mechanism, with initialisation and termination phases. The 'repeat-until' construct tests the exit condition at the end of the loop as shown in *Figure 15.16*.

### 15.6.2.2 'While-do' construct

This construct provides for a process not to be executed, or to be executed one or more times. The number of times the process is executed depends on a value of a control variable, for example:

```
count := number;
while count >= 0 do
  P1;
```

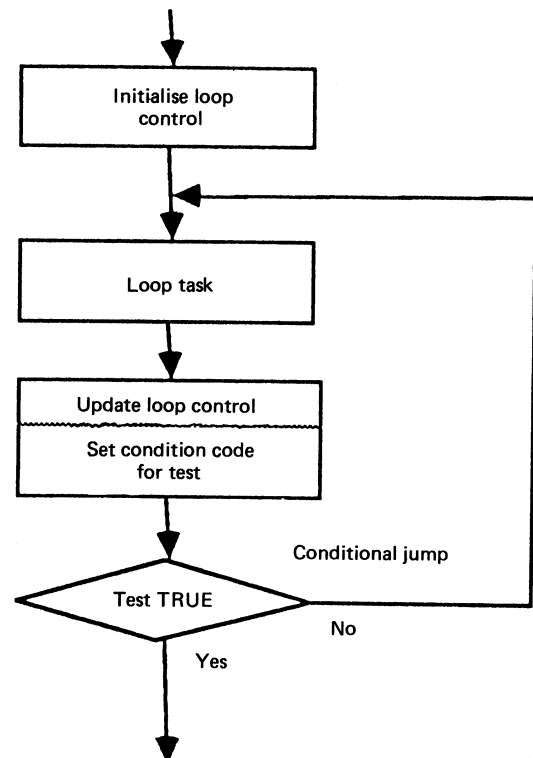

Figure 15.16 'Repeat-until' construct

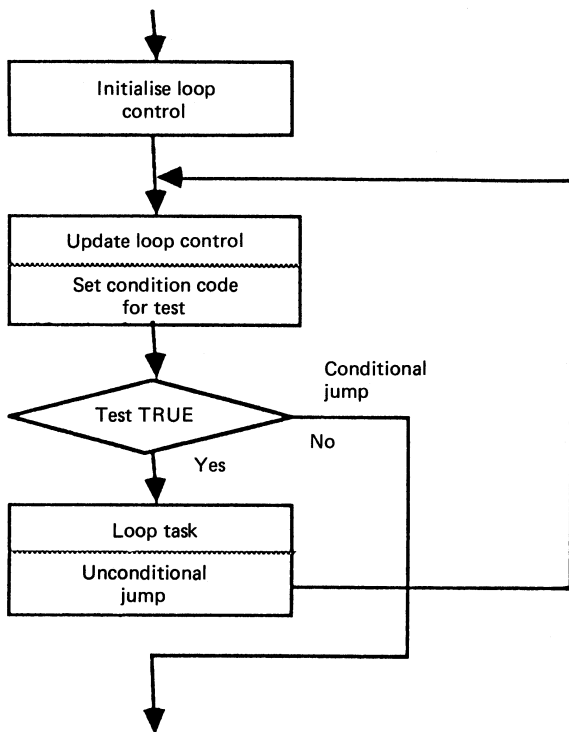

Figure 15.17 'While-do' construct

where the process P1 must update the loop control variable, as in:

```
count := count - 1;
```

Implementation of the 'while-do' construct at low-level requires an explicit loop control mechanism, with initialisation and termination phases. The terminating condition must be evaluated at the start of the loop. The general form of the 'while-do' construct is shown in Figure 15.17.

## 15.7 Reduced instruction set computers (RISC)

### 15.7.1 The reduced instruction set concept

The evolution in processor design during the 1980s and early 1990s led to increasingly complex processor architectures. The emerging 32-bit architectures accommodated a good range of data types and a wide range of instruction types and addressing modes. In addition, the flexible instructions often allowed the user a free choice of the addressing mode for the operands which resulted in many permutations of (variable-length) instructions. Such processors were characterised by the complexity of their instruction sets, the complex sequences necessary to 'fetch' the variable-length instructions, and the complex and very large instruction-decode logic. These processors were known as complex instruction set computers (CISC) processors.

Analysis of the actual use of these processors showed that the instruction set complexity often exceeded the needs of

many applications. Many users simply preferred to use a familiar and well understood subset of the data types, addressing modes, and instructions. In addition, it was found that common programming constructs, such as conditional expressions, were often formed using simple relational operations, such as 'equals' and simple and short constants, such as 'zero'. Similarly, program branches often had a short relative offset that could be accommodated using short (16-bit) relative addressing. This led to the notion of developing high-performance processors with a reduced set of appropriate instructions.

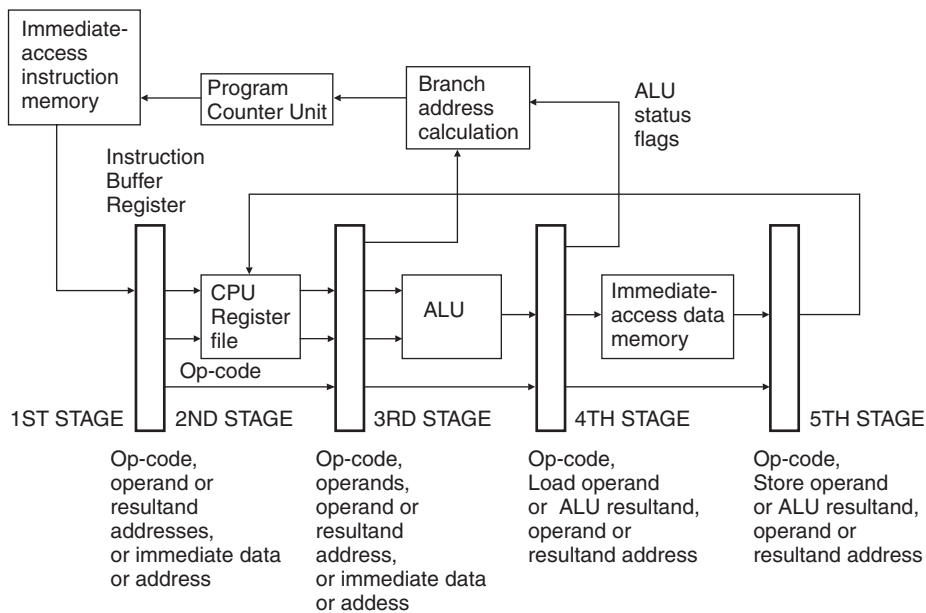

### 15.7.2 The reduced instruction set (RISC) processor

The reduced instruction set computer (RISC) processor has a relatively simple register-to-register architecture which focuses on a CPU register file of, say, 32 general purpose 32-bit registers. Each register may hold data or addresses and can provide source operands and/or act as an accumulator for resultands. Since data can not be transferred directly between immediate-access memory and the ALU, simple data transfer (LOAD) instructions are used to transfer operand data from immediate-access memory to CPU registers so that it can be processed subsequently by the ALU. Similarly, simple data transfer (STORE) instructions must be used to transfer result data from CPU registers to immediate-access memory. Thus, if  $X$ ,  $Y$ , and  $Z$  are stored in immediate-access memory, the high level expression  $X := Y + Z$  must be implemented using four separate instructions.

$R1 := Y$	LOAD operation, load CPU register R1 with Y from memory
$R2 := Z$	LOAD operation, load CPU register R2 with Z from memory
$R3 = R1 + R2$	ALU operation, write into CPU register R3 sum $R1 + R2$
$X := R3$	STORE operation, store CPU register R1 as X in memory.

The apparent disadvantage of using four low-level instructions to implement one higher-level memory-to-memory instruction is partially offset by the simple format of the RISC instructions. Register-to-register architecture processors have relatively short instructions since there is at most only one immediate-access memory reference operation (to load or store an operand) per instruction. This leads to the notion of using fixed-length instructions. A typical 32-bit RISC processor with 32 CPU registers will use a 32-bit fixed length instruction with, say, a 6-bit op-code, 5-bit direct addressing of CPU registers, and relative (base and offset) addressing of immediate-access memory using 16-bit relative addresses or immediate data. Thus LOAD and STORE instructions may consist of the 6-bit op-code, a 5-bit CPU register address for the operand or resultand, and an immediate-access memory address comprising a 5-bit base (register) address and a 16-bit relative offset. Similarly, an ALU instruction may comprise the 6-bit op-code, and either three 5-bit CPU register addresses (plus scope for instruction extensions), or two 5-bit CPU register addresses and a 16-bit immediate-data object. The use of a 32-bit instruction, which can be 'fetched' in a single memory reference operation, results in a fast instruction cycle and much simplified instruction decoder logic. The performance of RISC processors is further enhanced by the use of multi-stage instruction-pipelines.

**Figure 15.18** Simplified instruction pipeline

### 15.7.3 Instruction pipelines

The conventional instruction ‘fetch’ and ‘execute’ cycle imposes speed constraints on a processor. The primary problem is the time taken to access immediate-access memory, both to ‘fetch’ the instruction and to read operands during LOAD instructions, or to write operands during STORE instructions. In each case the processor ALU is idle (not processing data) while the memory reference operation is taking place. This limitation can be overcome, to a large extent, by the notion of pipelining.

The basic idea of pipelining is to partition the processor into autonomous operational or functional units that can operate concurrently, (such as instruction ‘fetch’ from immediate-access memory, program counter update, CPU register-file read, ALU operation, write operation on immediate-access data memory, read operation on immediate-access memory read, CPU register-file write). Typically, this allows the process of ‘fetching’, decoding and executing an instruction to be split into the following stages.

- (1) Instruction ‘fetch’ and program counter update.
- (2) Operand read from CPU register file.
- (3) ALU operation or effective address calculation (for LOAD and STORE).
- (4) Immediate-access data memory read (for LOAD) or write (for STORE).
- (5) Resultand (ALU operations) or operand (for LOAD) write to CPU register file.

In effect, the traditional instruction register is replaced by a pipeline of instruction buffers each of which store the information (opcode, CPU register addresses, memory reference address, operands, resultands, ALU status) necessary to carry out subsequent phases of the instruction cycle for each instruction, *Figure 15.18*. Thus, such a pipeline will normally contain five sequential instructions, and each stage of the pipeline will have the information and resources required to autonomously implement its stage of the instruction cycle. In addition, each stage includes at most

one immediate-access memory reference operation, thus allowing fast (average) instruction throughput.

In practice, the pipeline speed-up is restricted by physical resource constraints (resource hazards) and temporal data access constraints (data hazards). For example, if the instruction memory and data memory share the same address and data bus (as in von Neumann architecture processors), then an immediate-access data memory reference operation for an instruction in stage (4) of the above pipeline can not take place concurrently with the instruction ‘fetch’ operation for a successor instruction in stage (1) of the pipeline, and a resource hazard occurs. This results in the need to stall the pipeline (with respect to the successor instructions) until the data buses are free. This problem can be overcome at some cost by adding resources, such as separate instruction and data memories (as in Harvard architecture processors). Data hazards typically occur when an instruction attempts to use the results of a preceding instruction, but due to pipelining the results are unavailable. For example, the results of the preceding instruction in the pipeline may still be being computed or may not have been written back into the CPU register file at the point at which they are required as operands by the successor instruction. Such problems can be solved either by invoking pipeline stalls or by designing additional fast-track data paths which make results available direct from the ALU. Data hazards may occur in sequences of data processing operations, or in flow control operations when branches may be conditional on data generated by previous instructions.

A related problem affecting the performance of pipelined processors arises when computing decisions, such as IF-THEN-ELSE constructs, that involve alternative sequences. The instruction pipeline usually operates on the assumption that the instructions form a natural sequence, and no allowance is made for the presence of alternative sequences. Consequently, when the condition governing the branch-decision is computed (in stage (4) of the above pipeline), presumed-sequence instructions are already being processed in stages (1), (2) and (3) of the pipeline. If the

branch is taken, the presumed-sequence instructions have to be deleted (or 'flushed') from the pipeline and the 'branch-taken' instructions 'fetched' and processed.

Modern RISC processors use many techniques to overcome these performance restrictions. Multi-stage pipelines may be used (up to 20 stages) to maximise concurrency. Multiple pipelines may be used to accommodate both of the alternative sequences for a decision, and this removes the delay associated with flushing and re-filling a pipeline. Persistent data (regularly used data objects) may be maintained in the CPU register file to reduce the need for multiple LOAD and STORE operations. First and second level high-speed access cache memories may be used for instructions and data to overcome the delay associated with accessing immediate-access memory. In all cases, the processor design process involves compromise between performance, complexity and cost. General purpose microprocessors and workstations often seek to maximise performance. Alternatively, in embedded applications, performance and complexity are often costly in terms of silicon area or 'real estate'. In an interesting development, proprietary embedded RISC processors are now available in a range of variants so that the designer can choose the level of performance, complexity, word length, and silicon area.

## 15.8 Software design

The process of software development involves turning the specification of the task to be performed into a program in a form which the processor can directly execute. The starting point for the design of such a system is the derivation of the system requirements specification. The specification should state what the system should do in a formal and precise manner. However, the requirements specification should not state how the task should be carried out or how it should be implemented.

The design procedure is normally a 'top-down' approach in which the requirements specification is translated into a design by a process of elaboration. The description of what the system should do is elaborated until the description comprises a set of easily implemented activities. In most design methods, the formal system specification will be analysed and decomposed on a functional basis. Careful consideration should be given to determining when to take decisions that bind or constrain the design, such as the choice of programming notation or processing architecture.

The design procedure often consists of a compromise between taking an early decision to map the problem onto a known implementation, such as a particular high-performance architecture, or delaying such decisions to retain the freedom of choice in design and implementation. It is desirable that the process of analysis is not subject to implementation constraints before the analysis has revealed the characteristics of the problem. This is particularly important if the designer is to exploit fully the advantages that can be obtained by using modern programming notations and processing hardware.

In applications which involve safety functions or have implications for safety, the system must perform in a reliable and safe manner. Ideally, the designer should prove the correctness of the design and the design should be translated into an implementation using proven translators. Finally, the implementation should be verified to show that it is fit for its intended use. However, current formal proof techniques require high levels of skill; they are also lengthy and are not efficient for complex systems.

### 15.8.1 Program development

The design and development of the computer programs or software is not a trivial task. Even a relatively simple program can have a sophisticated logical structure. Large software systems can have considerable complexity and special software engineering and management techniques have been developed to ensure that such systems can be designed and developed to the required quality within a specified time-scale and budget. The methods place considerable emphasis on the need to document relevant aspects of a system design including the test phase, they also address the important problem of maintaining a system throughout its lifecycle. They also provide a range of computer-aided software engineering tools to support the design activity.

Good software design techniques, such as structured programming, are used to produce readable, reliable and understandable programs. A restricted set of programming constructs or processes is allowed: sequential processes, selection, and repetition (see Section 15.6). Each such process has a single input and output and can be readily documented, tested and understood. Complex processes can be decomposed into a hierarchy of simpler sub-processes, each of which can be declared as subprograms or procedures to hide unnecessary detail. This improves the legibility of a program and helps the problem of managing complexity.

The structured programming approach leads naturally to a modular approach to program construction. The program is divided into modules, each comprising separate code and data. The data within any module is local to that module and communication between the modules has to be declared and is strictly controlled. This limits the interaction between modules and helps prevent error migration. It also encourages the documentation of module interfaces and inter-module actions; an understanding of this is essential when a program is modified.

### 15.8.2 Assembly languages

Programming languages may be either high-level and oriented to the solution of a particular class of problems, or low-level and oriented towards the architecture of a particular machine.

Assembly-language allows the designer to program in terms of the machine instructions that a specific processor can perform. Since binary machine-code instructions are difficult to understand directly, assembly-language programs are expressed in a symbolic notation. There is a one-to-one correspondence between each assembly-language instruction and a machine-code instruction.

Assembly-language programs have to be written in terms of the specific processor's instruction set and architecture, such as its CPU registers, memory locations, and input/output device registers. Also, memory storage has to be allocated explicitly for data objects using primitive data types. Assembly-language uses mnemonics for each machine level instruction. The mnemonics are usually specific to one processor or a family of processors and are chosen such that the function of the instruction is fairly obvious (e.g. ADD, SUB, MOV, etc.). In addition, the user has to define symbolic names for data objects such as variables (memory addresses), data constants, and labels (code locations).

The low-level code is translated into machine-code by a simple process of transliteration, this is usually carried out by a program known as an *assembler*. The assembler checks the syntax and usage of each of the instructions in the source text (the 'source code'), and produces cross-references for any jump, branch, or data access instructions.

The output of the assembler (the 'object code') can then be 'linked' with any library routines or external subroutines which are called from the program, and 'located' by inserting into the file the absolute addresses of the memory locations where the program code and data will be loaded in the target system.

The unstructured nature of assembly-language programs increases the problem of testing such software. It is made even more difficult because testing conventionally takes place at machine level, rather than at the level of the symbolic assembly language. Normally, the software is executed on a simulator, or on a target processor equipped with a monitor program, with facilities for memory and CPU register examination, and for the insertion of breakpoints which allow the programmer to inspect and change memory or register contents at specified points in the program. Such testing requires skill, care and good management if it is to produce usable results.

Assembly-language programming, which requires a detailed understanding of instruction sets and processor architecture, is normally only necessary in applications where it is critical that the processing models and programming constructs used in the design are supported properly at machine level. Typical examples are compilers, the kernels of operating systems, interface software including interrupt handling, and certain aspects of real-time software. This is the province of the 'systems programmer' rather than the 'applications programmer'.

Knowledge of assembly language programming is not essential for general applications programming. Specifically, due to the lack of high-level constructs, assembly-language programs normally comprise an intimate mix of low-level program flow-control instructions and architecture-dependent data-processing instructions. Such programs are often difficult to design or comprehend. Thus, a programmer is advised to always use the highest level programming language appropriate for an application.

### 15.8.3 High-level languages

Instead of writing the programs in the assembly language of a processor, a high-level language can be used. The advantages to writing programs in a high-level language are as follows:

- (1) *Hardware independence*: the language is independent of the implementation hardware and can be compiled for a range of target processors.
- (2) *High-level notation*: the language comprises unambiguous statements which are often close to those used to express problems in natural language. This aids comprehension and increases the speed of programming.
- (3) *Structured code*: most high-level languages support structured programming and modular program construction.
- (4) *Data types*: most high-level languages support a wide range of data types which allow checks on expression validity to be applied by the compiler.
- (5) *Maintenance*: clear program and data structures give easier program maintenance.

Few conventional high-level languages give direct access to machine-level primitives that are used for physical input and output, bit-level manipulation, machine control, and interrupts. Therefore, programs written in conventional high-level languages are normally restricted to using idealised input and output (e.g. to files) and are run in a protected environment provided by the operating system. However, this is not always sufficient for 'systems' programmers

who are concerned with how the software, including the operating system and user programs, operates and performs and how it interfaces with the outside world. Thus, the programming languages used by systems programmers, such as 'C', typically include both high-level constructs and machine-level primitives.

A high-level language program is prepared as a source text file using a text editor (or using a word processing facility capable of producing a text file in the required format). The high-level language program is translated into an object program (i.e. nearly executable machine code) by a compiler. At the start of the compilation process, the compiler will check the syntax of the source program and any errors detected will be reported. During the compilation process, each construct or statement in the source program is translated into one or more lines of object code. The compiler may require several passes to convert the source program into the object code. Also, error checking may be included within the object code to detect run-time errors, such as array bounds exceeding predefined limits.

The compiler must be informed of the identity of the processor on which the compiled program is to run, so that it can produce processor-specific object code. Normally, the object code is generated for the processor on which the compiler runs. However, in the case of microprocessor systems, it is common to prepare programs on larger computers with better software engineering support facilities and to compile the source program for the intended target processor (this is known as cross-compilation).

The object code produced by the compiler requires linking, locating and loading before it can be executed,

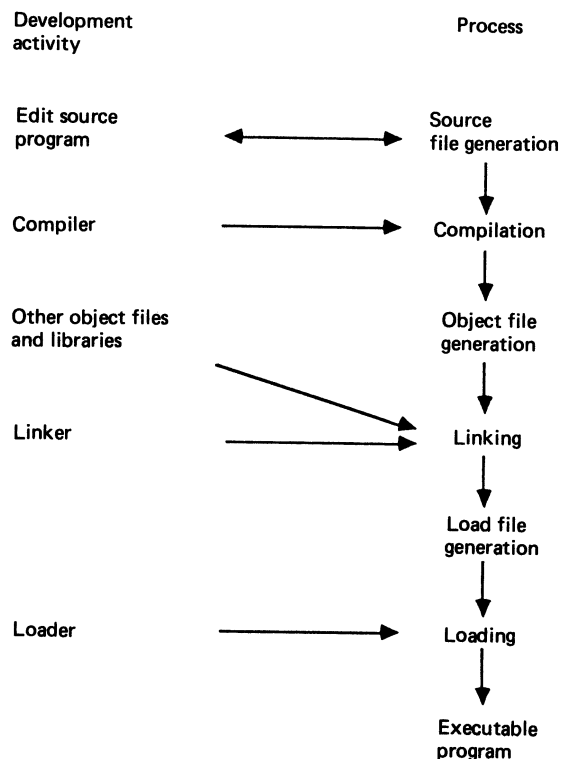

Figure 15.19 Stages in program development

as shown in *Figure 15.19*. The linker resolves all external references in the object code, such as references to library subroutines or other program modules held as object files, and combines all these modules into a single executable program. It also locates the program by adjusting the addresses all data memory references (variables) and code location references (labels) to the values of locations at which the code and data will be loaded. (In the case of relocatable code and data, it simply calculates the correct base addresses.) Finally, the linked object modules are loaded into memory at a defined location by the loader ready for execution. (For ease of communication, the object program is often downline loaded into the target processor in HEX form, and converted into binary by the loader during the loading process.) When the program is loaded, it is resident in memory in the target machine ready for execution.

### 15.8.4 Real-time processes

Many engineering systems, such as embedded computer real-time systems, are required to maintain synchronism with an asynchronous external system, or to respond to stimuli from such a system, within a finite and specified delay. In real-time programming there is a primary need for a mechanism for handling the concept of time. Real-time sequential programming languages include an additional primitive construct that allows the formal inclusion of time.

An application is said to be 'time-critical' if it must perform activities and produce responses at times dictated by an external environment. Typically in real-time control, a precise time-window is specified during which sensors need be sampled, a satisfactory control response computed, and output values sent to actuators. This schedule may re-occur periodically, or be initiated at irregular intervals by stimuli from the external system. Failure to perform the required functions in time is a fault; this may lead to system failure and may be hazardous.

The software for a time-critical application will comprise processes that must be properly synchronised with each other and with the external system. Synchronism with the external system is usually imposed by a 'real-time clock' driven schedule; these times will not be dictated by the optimum use of computing resources. To ensure that component processes do not overrun, it is common to place (critical) timing requirements on software execution and to provide a 'time-out' mechanism to warn of timing violations.

It is conventional to monitor the performance of a time-critical application process. Traditionally, this is done using a real-time time-lapse counter built as an external circuit. The counter is preset to trip after a pre-determined time and is initiated to run concurrently with the time-critical process. The first process to complete causes the other to abort. The mechanism is known as a 'watch-dog' timer.

If the application process has been properly designed, it will produce results well before the maximum allowed time and the 'watch-dog' timer will be aborted. The expiry of a 'watch-dog' timer or 'trip' indicates the presence of a fault (which may be a software design fault or a transient or permanent malfunction of the system) and appropriate fault recovery activities should be invoked. It is therefore necessary to set the pre-determined trip period to somewhat less than the time-critical time so that fault recovery can take place and the system can still provide a timely and satisfactory response.

### 15.8.5 Embedded real-time operating systems (RTOS)

A number of proprietary real-time operating systems (RTOS) are available for use in embedded microprocessor systems. These operating systems typically provide input/output handling, deterministic real-time task scheduling, watchdog facilities, and default behaviour under fault conditions. They are also characterised by having modest memory requirements. Significantly, these operating systems are targeted at a range of processors including conventional microprocessors, commercial off-the-shelf (COTS) microcomputers, embedded controllers (microprocessors with built-in analogue and digital signal acquisition and output generation), and the more recently introduced system-on-chip (SoC) systems with on-chip embedded processors.

## 15.9 Embedded systems

Many products have computers, microprocessors, or microcontrollers hidden or embedded within them. Some devices, such as digital organisers or personal digital assistants (PDAs), resemble small computers and the user may be provided with limited programming facilities for the embedded processor. In the case of other products, such as video games machines or consoles, it is fairly obvious that the device contains embedded processors and video display generators, even though the user is given little or no facility for programming the device. A much wider range of products contains embedded processors that are hidden or invisible to the user. For example embedded processors are commonly found in the following: cellular or mobile telephones, automobile electronics (such as engine management, braking systems, active suspension, intelligent sensing for lights or windscreen wipers, navigation systems, and both in-car and in-seat entertainment systems), office automation products (such as faxes, scanners, printers, copiers or duplicators, multimedia display projectors, computer network switches), domestic appliances (such as washing machines, dishwashers, tumble driers, cookers or ovens, microwave cookers, food blenders and processors, weigh scales, and vacuum cleaners), home entertainment units (such as radios, televisions, satellite receivers, digital set-top boxes, video cassette recorders, digital video disc (DVD) players, and hi-fi units), photographic equipment (such as film and digital cameras, analogue and digital video cameras) and personal or 'wearable' electronics (such as portable radios and CD players, MP3 players, watches, and fitness monitors). The trend is to increase significantly the sophistication of such systems, including user adaptation or personalisation, and to increase very significantly the data handling and processing requirements of the embedded processor. This is leading to the development of extremely powerful processors that are designed specifically for embedded applications, including small battery-powered products.

### 15.9.1 Embedded processors

The designer of embedded systems can choose from a wide range of processors. Classical microcontrollers, with integrated analogue inputs and outputs, are often used in control applications for domestic appliances or automotive systems. Specialist microcontrollers have been developed for applications such as electric motor control, or servo control. Traditional microprocessors or RISC processors may be used as stand alone devices within a more complex design.

Increasingly, the trend is to minimise the number of components in an embedded system. Traditionally, conventional microprocessors tend to be poorly suited to integration within, say, an FPGA since they are relatively complex and are not scalable (i.e. smaller versions can not be readily generated), although these constraints may become less important as the size of FPGAs increase. RISC processors are much better suited to integration because they have powerful ALUs, small instruction sets and instruction decoders, and are scalable in terms of word-length, concurrent resource, instruction pipeline, and clock speed. Embedded RISC processors are readily available as intellectual property (IP) cores.

Traditionally, IP cores have taken the form of hardware description language (HDL) software macros, which a designer incorporates within an application-specific design. However, the performance of such IP cores is layout dependent, and very careful design is necessary to achieve good speeds. Therefore, the preferred method of deriving high-performance designs is to use a proprietary 'hard' IP core that provides guaranteed performance (i.e. an IP core that has been pre-mapped into a fixed and full-tested hardware layout on the intended FPGA target). The second advantage of using proprietary 'hard' IP core RISC processors is that they are usually fully supported by proprietary embedded real-time operating system (RTOS) software and software tools for writing applications (such as editors and compilers). Thus the embedded systems design approach typically involves:

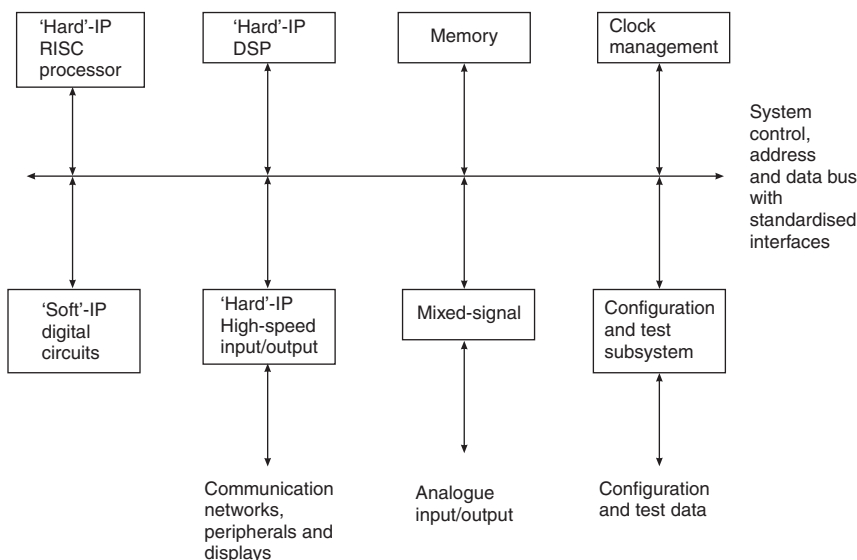

- (1) Determining the application's processing requirements and selecting a proprietary 'hard' IP RISC processor of appropriate performance, complexity, word length, and silicon area.
- (2) Selecting a proprietary embedded RTOS that supports the processor.
- (3) Developing application-specific software for software-implemented functions.
- (4) Developing digital designs for any hardware-implemented functions and interfaces.

### 15.9.2 System on chip (SoC) design

The increase in size of VLSI logic circuits has led to a new generation of reconfigurable FPGA devices that provide a platform for 'hard' IP cores and are large enough to contain a complete high-performance digital processing system within a chip. These FPGAs are commonly called System on Chip (SoC) devices. An SoC device can be configured to include both 'hard' and 'soft' IP cores, plus user-designed digital circuits, *Figure 15.20*. At the heart of most SoC designs are an embedded proprietary RISC processor and a block of RAM memory (for the software that runs on the processor). This allows the designer to partition a design into those parts that will be implemented as software executing on the embedded processor (under an appropriate embedded RTOS) and those parts that will be implemented in hardware as high-speed application-specific logic circuits. This design approach, known as co-design or co-ware, has the significant advantage that established and high-performance parts of the design can be committed to application-specific hardware, and more adventurous parts of the design or low-speed functions can be committed to easily changed software.

The high-performance hardware implemented application-specific logic circuits may make extensive use of both 'hard'- and 'soft'- IP cores. In particular, SoC devices commonly provide co-processor support for digital signal processing, typically using a proprietary 'hard' IP digital signal processor (DSP). Alternatively, specific algorithms may be implemented using either 'hard'- or 'soft'- IP digital signal processing circuits. Similarly, signal acquisition may be facilitated using mixed-signal (digital/analogue) components such as analogue-to-digital (A/D) or digital-to-analogue (D/A) converters. The problem of interfacing such major components is eased by the on-chip provision of advanced data highways or buses, standardised bus interfaces (for the major components such as the RISC/DSP processors and the memory), sophisticated clock generators, and a clock management unit.

Reconfigurable FPGA

**Figure 15.20** Typical system-on-chip (SoC) configuration

External interfacing is facilitated by the use of 'hard' IP cores that support a wide range of high-bandwidth interface standards (for high-speed serial and parallel interfaces, including either system- or source-synchronous parallel interfaces). This is an area of on-going development, and both the SoC vendors and third-party IP providers are developing IP cores to support the ever widening range of communications protocols and interface standards found in the embedded systems market.

Modern SoC devices and the co-design approach, (involving embedded RTOS software, 'soft'- and 'hard'-IP cores, and bespoke digital design), provides a manageable and flexible route to embedded systems design. It may also change the relative roles of the hardware and software

designer in the development of SoC designs. The reconfigurable SoC devices can be deployed in a wide range of applications and the common-platform nature of the devices helps avoid the non-recurring costs associated with fully bespoke designs. The extensive use of 'hard'- and 'soft'-IP from SoC vendors and third party suppliers minimises risk and facilitates time-to-market which gives competitive advantage. However, it also involves entering into IP license arrangements for both product development and deployment. It will be interesting to see whether the rapidly decreasing SoC product design cycles are complemented by corresponding decreases in the time, complexity, and cost of negotiating multi-party IP license agreements.

## 16.1 Introduction

### 16.1.1 The computer in control

A computer can be considered as a device that follows predetermined instructions to manipulate input data in order to produce new output data as summarised on *Figure 16.1(a)*. Early computer systems tended to be based on commercial functions; payroll, accountancy, banking and similar activities. The operations tended to be batch processes; a daily update of stores stock for example.

A computer can also be used as part of a control system as *Figure 16.1(b)*. The input data will be the operator's commands and signals from the plant (limit switches, flows, temperatures). The output data are control actions to the plant and status displays to the operator. The instructions will define what action is to be taken as the input data (from both the plant and the operator) changes.

The first industrial computer application was probably a system installed in an oil refinery in Port Arthur USA in 1959. The reliability and mean time between failure of computers at this time meant that little actual control was performed by the computer, and its role approximated to a simple monitoring subsystem.

### 16.1.2 Requirements for industrial control

Industrial control has rather different requirements than other computer applications. It is worth examining these in some detail.

A conventional computer takes data, usually from a keyboard, and outputs data to a screen or printer. The data being manipulated will generally be characters or numbers (e.g. item names and quantities held in a stores stock list).

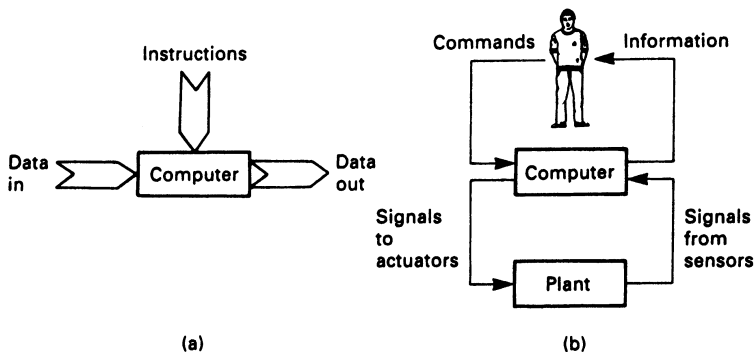

An industrial control computer is very different. Its inputs come from a vast number of devices. Although some of these will be numeric (flows, temperature, pressures and similar analog signals) the majority will be single bit, on/off, digital signals representing valves, limit switches, motor contactors etc.

There will also be a similar large amount of digital and analog output signals. A very small control system may have connections to about twenty input and output signals; figures of over two hundred connections are quite common on medium sized systems.

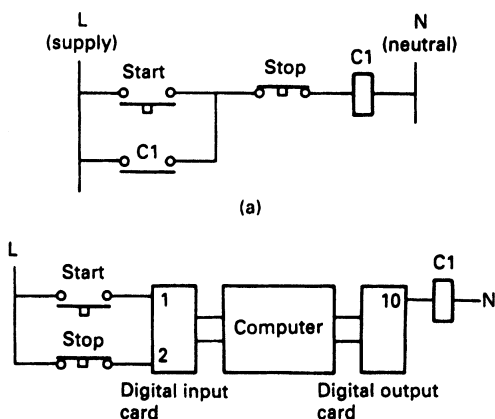

Although it is possible to connect this quantity of signals into a conventional machine, it requires non-standard connections and external boxes. Similarly, although programming for a large amount of input and output signals can be done in Pascal, BASIC or C, the languages are being used for a purpose for which they were not really designed, and the result can be very ungainly.

In *Figure 16.2(a)*, for example, we have a simple motor starter. This could be connected as a computer driven circuit as *Figure 16.2(b)*. The two inputs are identified by addresses 1 and 2, with the output (the relay starter) being given the address 10.

If we assume a program function bitread ( $N$ ) exists which gives the state (on/off) of address  $N$ , and a function bitwrite ( $M$ , var) which sends the state of program variable var to address  $M$ , we could give the actions of *Figure 16.2* by

**Figure 16.1** The computer as part of an industrial control system: (a) a simple overview of a computer; (b) the computer as part of a control system

**Figure 16.2** Comparison of hardwire and computer based systems: (a) hardwire motor starter; (b) computer based motor starter

```
repeat
    start:= bitread(1);
    stop:= bitread(2);
    run:= ((start) or (run)) & stop;
    bitwrite (10,run);
until hellfreezesover
```

where start, stop and run are one bit variables. The program is not very clear, however, and we have just three connections.

An industrial control program rarely stays the same for the whole of its life. There are always modifications to cover changes in the operations of the plant. These changes will be made by plant maintenance staff, and must be made with minimal (preferably none) interruptions to the plant production. Adding a second stop button and a second start button into *Figure 16.2* would not be a simple task.

In general, computer control is done in real time, i.e. the computer has to respond to random events as they occur. An operator expects a motor to start (and more important to stop!) within a fraction of a second of a button being pressed. Although commercial computing needs fast computers, it is unlikely that the difference between a one second and two second computation time for a spreadsheet would be noticed by the user. Such a difference would be unacceptable for industrial control.

Time itself is often part of the control strategy (e.g. start air fan, wait 10secs for air purge, open pilot gas valve, wait 0.5s, start ignition spark, wait 2.5s, if flame present open main gas valve). Such sequences are difficult to write with conventional languages.

Most control faults are caused by external items (limit switches, solenoids and similar devices) and not by failures within the central control itself. The permission to start a plant, for example, could rely on signals involving cooling water flows, lubrication pressure and temperatures all being within allowable ranges. For quick fault finding the maintenance staff must be able to monitor the action of the computer program whilst it is running. If, as is quite common, there are ten interlock signals which allow a motor to start, the maintenance staff will need to be able to check these quickly in the event of a fault. With a conventional computer, this could only be achieved with yet more complex programming.

The power supply in an industrial site is shared with many antisocial loads; large motors stopping and starting, thyristor drives which put spikes on signals and harmonic frequencies onto the mains supply. To a human these are perceived as light flicker; to a computer they can result in storage corruption or even machine failure.

An industrial computer must therefore be able to live with a 'dirty' mains supply, and should also be capable of responding sensibly following a total supply interruption. Some outputs must go back to the state they were in before the loss of supply, others will need to turn off or on until an operator takes corrective action. The designer must have the facility to define what happens when the system powers up from cold.

The final considerations are environmental. A large mainframe computer generally sits in an air conditioned room at a steady 20°C with carefully controlled humidity. A desk top PC will normally live in a fairly constant office environment because human beings do not work well at extremes. An industrial computer, however, will probably have to operate away from people in a normal electrical

substation with temperatures as low as -10°C after a winter shutdown, and possibly over 40°C in the height of summer. Even worse, these temperature variations lead to a constant expansion and contraction of components which can lead to early failure if the design has not taken this factor into account.

To these temperature changes must be added dust and dirt. Very few industrial processes are clean, and the dust gets everywhere. The dust will work itself into connectors, and if these are not of a highest quality, intermittent faults will occur which can be very difficult to find.

In most computer applications, a programming error or a machine fault can often be humorous (bills and reminders for 0p) or at worse expensive and embarrassing. When a computer controlling a plant fails, or a programmer misunderstands the plants operation, the result could be injuries or fatalities. It behoves everyone to take extreme care with the design.

Our requirements for industrial control computers are very demanding, and it is worth summarising them:

- They should be designed to survive in an industrial environment with all that this implies for temperature, dirt and poor quality mains supply.
- They should be capable of dealing with bit form digital input/output signals at the usual voltages encountered in industry (24 V d.c. to 240 V a.c.) plus analog input/output signals. The expansion of the I/O should be simple and straightforward.
- The programming language should be understandable by maintenance staff (such as electricians) who have no computer training. Programming changes should be easy to perform in a constantly changing plant.
- It must be possible to monitor the plant operation whilst it is running to assist fault finding. It should be appreciated that most faults will be in external equipment such as plant mounted limit switches, actuators and sensors, and it should be possible to observe the action of these from the control computer.
- The system should operate sufficiently fast for real-time control. In practice, 'sufficiently fast' means a response time of around 0.1 sec, but this can vary dependent on the application and the controller used.
- The user should be protected from computer jargon.
- Safety must be a prime consideration.

### 16.1.3 Enter the PLC

In the late 1960s the American motor car manufacturer General Motors was interested in the application of computers to replace the relay sequencing used in the control of its automated car plants. In 1969 it produced a specification for an industrial computer similar to that outlined at the end of the previous section.

Two independent companies, Bedford Associates (later called Modicon) and Allen Bradley (now owned by Rockwell) responded to General Motors specifications. Each produced a computer system similar to *Figure 16.3* which bore little resemblance to the commercial mini-computers of the day.

The computer itself, called the central processor, was designed to live in an industrial environment, and was connected to the outside world via racks into which input, or output cards could be plugged.

Each input or output card could connect to 16 signals. A typical rack would contain eight cards and the processor could connect to eight racks, allowing connection to 1024

**Figure 16.3** The component parts of an early PLC system

devices. It is very important to appreciate that the card allocations were the user's choice, allowing great flexibility.

The most radical idea, however, was a programming language based on a relay schematic diagram, with inputs (from limit switches, pushbuttons, etc.) represented by relay contacts, and outputs (to solenoids, motor starters, lamps, etc.) represented by relay coils. *Figure 16.4(a)* shows a simple hydraulic cylinder which can be extended or retracted by pushbuttons. Its stroke is set by limit switches which open at the end of travel, and the solenoids can only be operated if the hydraulic pump is running. This would be controlled by the computer program of *Figure 16.4(b)* which is identical to the relay circuit needed to control the cylinder. These programs look like the rungs on a ladder, and were consequently called 'Ladder Diagrams'.

The program was entered via a programming terminal with keys showing relay symbols (normally open/normally closed contacts, coils, timers, counters, parallel branches, etc.), with which a maintenance electrician would be familiar. *Figure 16.5* shows the programmer's keyboard for an early PLC. The meaning of the majority of the keys should be obvious to any maintenance electrician. The program, shown exactly on the screen as *Figure 16.4(b)*, would highlight energised contacts and coils allowing the programming terminal to be used for simple faultfinding.

The name given to these machines was *Programmable Controllers* or PCs. The name *Programmable Logic Controller* or PLC was also used, but this is, strictly, a registered trade mark of the Allen Bradley Company, now part of Rockwell. Unfortunately in more recent times the letters PC have come to be used for Personal Computer, and confusingly the worlds of programmable controllers and personal computers overlap where portable and lap-top computers are now used as programming terminals. To avoid confusion, we shall use PLC for a programmable controller and PC for a personal computer.

#### 16.1.4 The advantages of PLC control

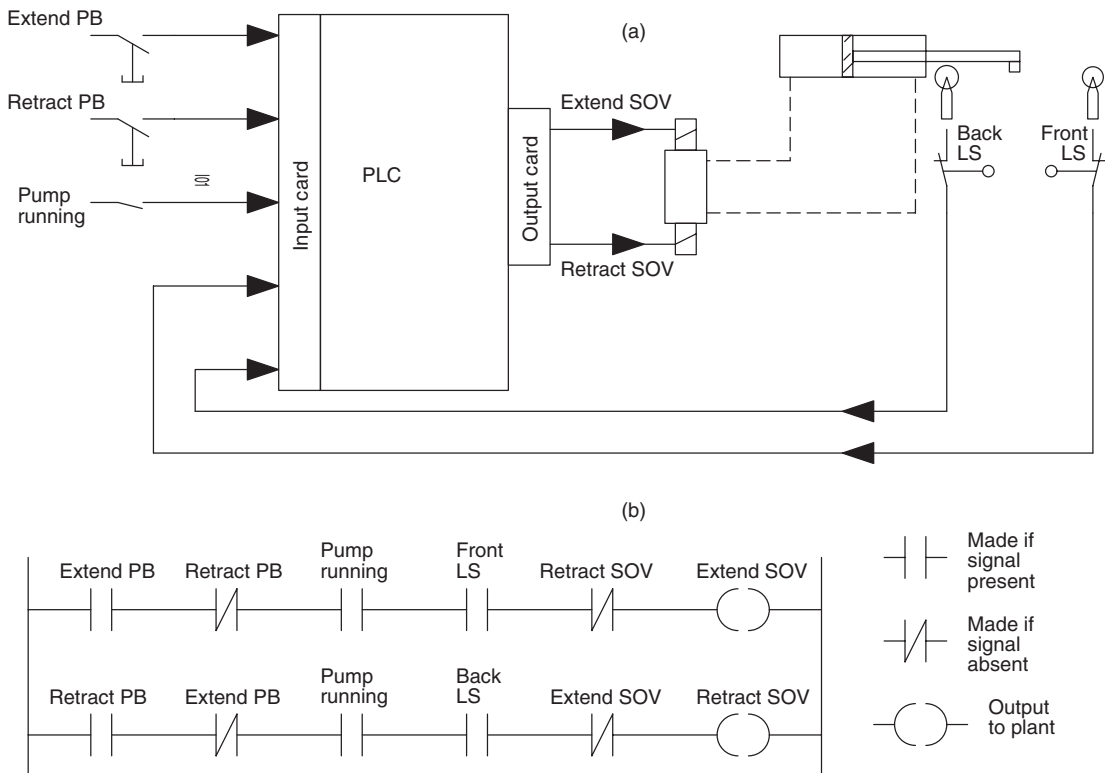

Any control system goes through several stages from conception to a working plant.

The first stage is *Design* when the required plant is studied and the control strategies decided. With conventional systems every 'i' must be dotted before construction can start. With a PLC system all that is needed is a possibly (usually!) vague idea of the size of the machine and the I/O requirements (so many inputs and outputs). The cost of the input and output cards are cheap at this stage, so a healthy spare capacity can be built in to allow for the inevitable omissions and future developments.

Next comes *Construction*. With conventional schemes, every job is a 'one-off' with inevitable delays and costs. A PLC system is simply bolted together from standard parts.

The next stage is *Installation*, a tedious and expensive business as sensors, actuators, limit switches and operator controls are cabled. A distributed PLC system (discussed in Section 16.5) using serial links and pre-built and tested desks can simplify installation and bring huge cost benefits. The majority of the PLC program is usually written at this stage.

Finally comes *Commissioning*, and this is where the real advantages are found. No plant ever works first time. Human nature being what it is, there will be some oversights. (We need a limit switch to only allow feeding when the discharge valve is 'shut' or 'Whoops, didn't we say the loading valve is energised to UNLOAD on this system' and so on.) Changes to conventional systems are time consuming and expensive. Provided the designer of the PLC systems has built in spare memory capacity, spare I/O and a few spare cores in multi-core cables, most changes can be made quickly and relatively cheaply. An added bonus is that all changes are inherently recorded in the PLC's program and commissioning modifications do not go unrecorded.

**Figure 16.4** A simple PLC application: (a) a hydraulic cylinder controlled by a PLC; (b) the 'Ladder Diagram' program used to control the cylinder

There is an additional fifth stage called *Maintenance* which starts once the plant is working and is handed over to production. All plants have faults, and most tend to spend the majority of their time in some form of failure mode. A PLC system provides a very powerful tool for assisting with fault diagnosis.

A plant is also subject to many changes during its life to speed production, ease breakdowns or because of changes in its requirements. A PLC system can be changed so easily that modifications are simple and the PLC program will automatically document the changes that have been made.

known as CEGELEC and is part of a French group in which Alstom are a major shareholder.

- The ASEA Master System, now manufactured by the ABB company formed by the merger of ASEA and Brown Boveri. The Master system has features more akin to a conventional computer system and its programming language has some interesting and powerful features.

The above four PLCs are shown on *Figure 16.6*. Many PLC systems are now very small and as an example of this bottom end of the market we shall also consider the Japanese Mitsubishi F2-40.

## 16.2 The programmable controller

### 16.2.1 Modern PLC systems

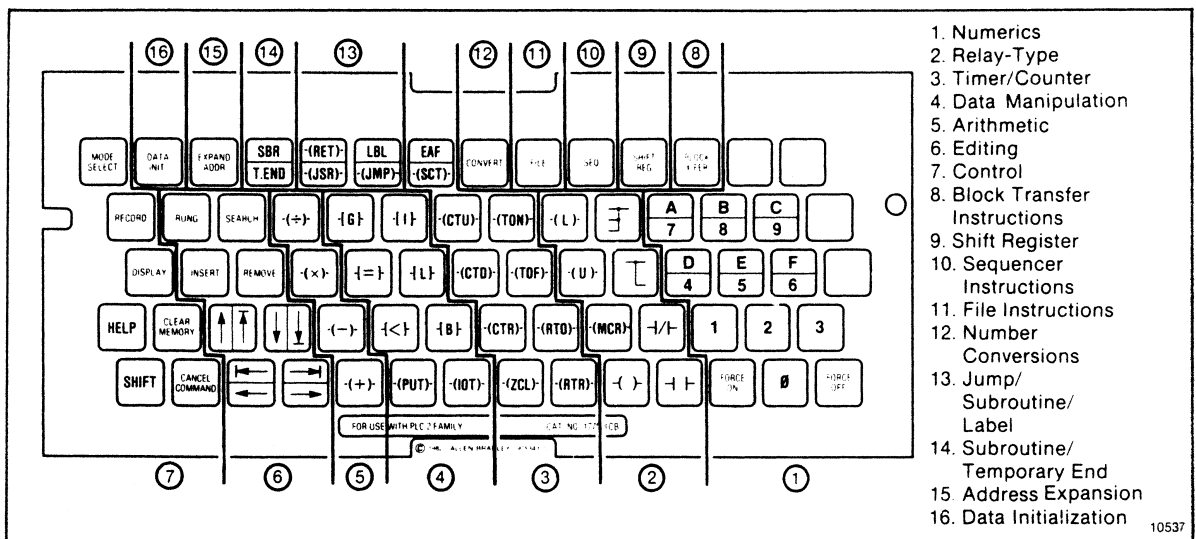

This chapter is written around five manufacturers' ranges:

- The Allen Bradley PLC-5 series. Allen Bradley, now owned by Rockwell, were one of the original PLC originators (and actually has the US copyright on the name PLC). They have been responsible for much of the development of the ideas used in PLCs and have succeeded in maintaining a fair degree of upward compatibility from their earliest machine without restricting the features of the latest.
- The Siemens Simatic 55 range which is probably the commonest PLC in mainland Europe.
- The British GEM-80, originally designed by GEC from a long association with industrial computers dating back to English Electric. This part of GEC is now

### 16.2.2 I/O connections

Internally a computer usually operates at 5 V d.c. The external devices (solenoids, motor starters, limit switches, etc.) operate at voltages up to 110 V a.c. The mixing of these two voltages will cause irreparable damage to the PLC electronics. A less obvious problem can occur from electrical 'noise' introduced into the PLC from voltage spikes, caused by interference on signals lines, or from load currents flowing in a.c. neutral or d.c. return lines. Differences in earth potential between the PLC cubicle and outside plant can also cause problems.

There are obviously very good reasons for separating the plant supplies from the PLC supplies with some form of barrier to ensure that the PLC cannot be adversely affected by anything happening on the plant. Even a cable fault putting 415 V a.c. onto a d.c. input would only damage the input card; the PLC itself (and the other cards in the system) would not suffer.

1. Numerics—provides addresses and decimal or hexadecimal values for instructions. It also provides force instructions.
2. Relay-Type—examines and controls the status of individual bits in specified memory areas.
3. Timer/Counter—allows the user to select various time-incremented and count-incremented and decremented functions.
4. Data Manipulation—used to transfer and compare BCD or octal values in the user program.
5. Arithmetic—performs the four indicated math functions.
6. Editing—used to locate, display and change instructions in the user program.
7. Control—directs the operation of the industrial terminal and its communication with the PLC-2 family processors and peripherals. Also provides HELP information.
8. Block Transfer Instructions—used to program block transfer Instructions in block format.
9. Shift Register—used to shift a word (all 16 bits) up or down one word in the shift register file.
  - used to shift a bit in the shift register file to the left or right one position.
  - used to create FIFO stacks.
10. Sequencer Instructions—used to establish and maintain user sequencer tables.
11. File Instructions—used to establish and manipulate user files.

(d)

Figure 16.6 (continued)

This isolation is achieved by optical isolators consisting of a linked light emitting diode and photoelectric transistor. When current is passed through the diode it emits light causing the transistor to switch on. Because there is no electrical connections between the diode and the transistor, very good electrical isolation (typically 1–4 kV) is achieved.

A d.c. input can be provided as *Figure 16.7(a)*. When the push button is pressed, current will flow through D1 causing TR1 to turn on passing the signal to the PLC internal logic. Diode D2 is a light emitting diode used as a fault finding aid to show when the input signal is present. Such indicators are present on almost all PLC input and output cards. The resistor R sets the voltage range of the input. D.c. input cards are usually available for three voltage ranges; 5 V (TTL), 12–24 V, 24–50 V.

A possible a.c. input circuit is shown on *Figure 16.7(b)*. The bridge rectifier is used to convert the a.c. to full wave rectified d.c. Resistor R2 and capacitor C1 act as a filter (typically 50 ms time constant) to give a clean signal to the PLC logic. As before a neon LPI acts as an input signal indicator for fault finding, and resistor R1 sets the voltage range.

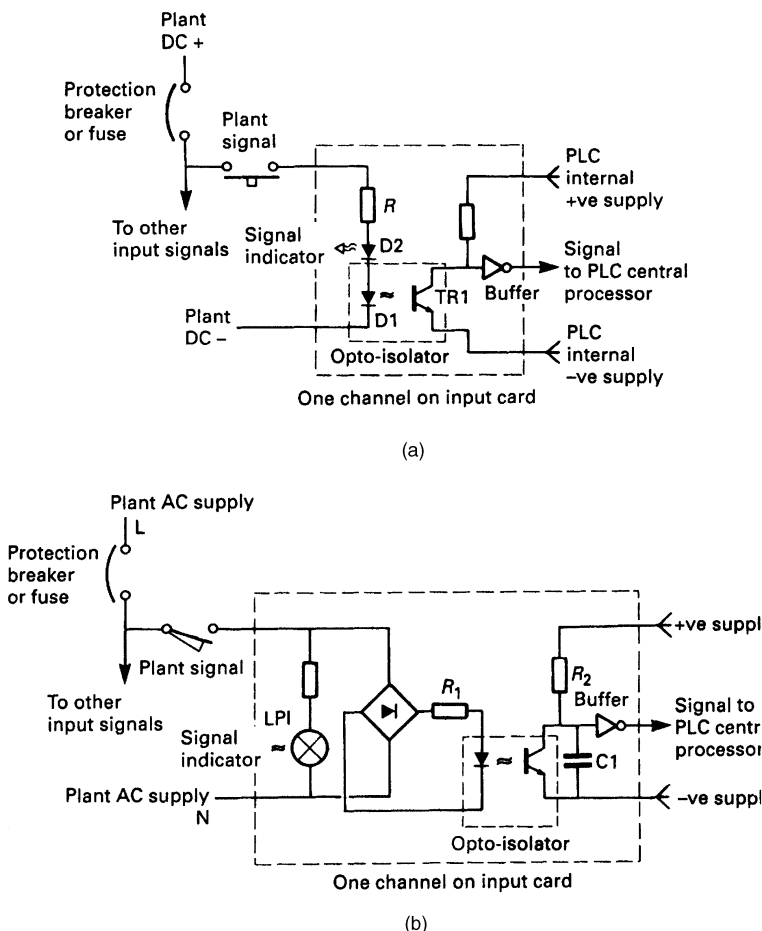

Output connections also require some form of isolation barrier to limit damage from the inevitable plant faults and to stop electrical 'noise' corrupting the processor's operations. Interference can be more of a problem on outputs because

higher currents are being controlled by the cards and the loads (solenoids and relay coils) are often inductive.

In *Figure 16.8*, eight outputs are fed from a common supply, which originates local to the PLC cubicle (but separate from the supply to the PLC itself). This arrangement is the simplest and the cheapest, to install. Each output has its own individual fuse protection on the card and a common circuit breaker. It is important to design the system so that a fault, say, on load 3 blows the fuse FS3 but does not trip the supply to the whole card shutting down every output. This is known as 'discrimination'.

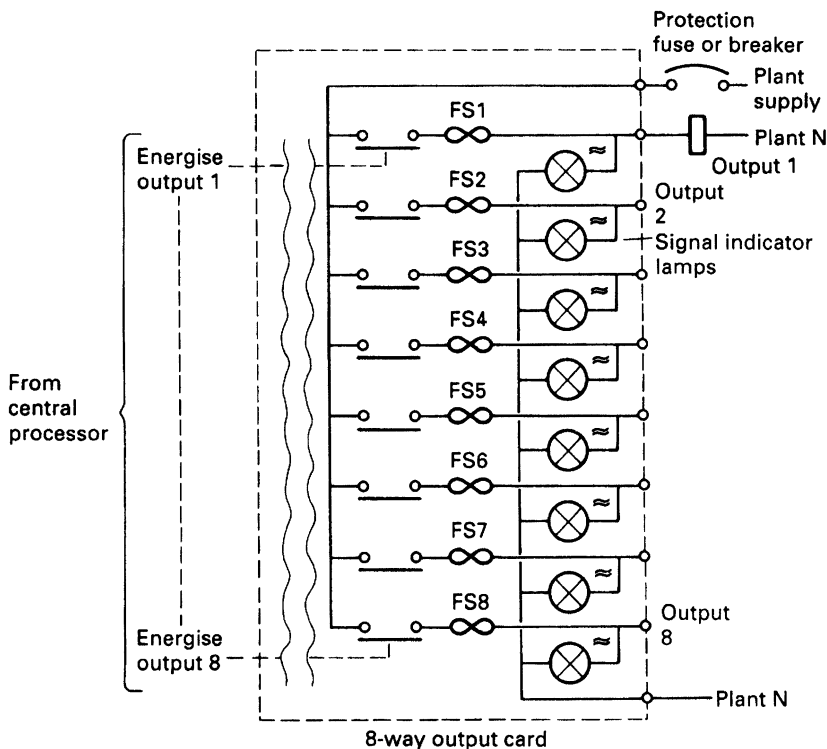

Contacts have been shown on the outputs in *Figure 16.8*. Relay outputs can be used (and do give the required isolation) but are not particularly common. A relay is an electromagnetic device with moving parts and hence a finite limited life. A purely electronic device will have greater reliability. Less obviously, though, a relay driven inductive load can generate troublesome interference and lead to early contact failure.

A transistor output circuit is shown on *Figure 16.9(a)*. Opto-isolation is again used to give the necessary separation between the plant and the PLC system. Diode D1 acts as a spike suppression diode to reduce the voltage spike encountered with inductive loads as shown on *Figure 16.9(b)*. The output state can be observed on LED1. *Figure 16.9(a)* is a

**Figure 16.7** Optical isolation of input signals: (a) d.c. input; (b) a.c. input

**Figure 16.8** Schematic of an 8 way output card with common supply

current sourcing output. If NPN transistors are used, a current sinking card can be made as *Figure 16.9(c)*.

A.c. output cards invariably use triacs, a typical circuit being shown on *Figure 16.10*. Triacs have the advantage that they can be made to turn on at zero voltage and inherently turn off at zero current in the load. The zero current turn off eliminates the spike interference caused by breaking the current through an inductive load. If possible, all a.c. loads should be driven from triacs rather than relays.

An output card will have a limit to the current it can supply, usually set by the printed circuit board tracks rather than the output devices. An individual output current will be set for each output (typically 2 A) and a total overall output (typically 6 A). Usually the total allowed for the card current is lower than the sum of the allowed individual outputs.

### 16.2.3 Remote I/O

So far we have assumed that a PLC consists of a processor unit and a collection of I/O cards mounted in local racks. Early PLCs were arranged like this, but in a large and scattered plant, all signals had to be brought back to some central point in expensive multi-core cables. This also makes commissioning and fault finding rather difficult, as signals can only be monitored effectively at a point distant from the plant device being tested.

In all but the smallest and cheapest systems, PLC manufacturers therefore provide the ability to mount I/O racks remote from the processor, and linked with simple (and cheap) screened single pair or fibre optic cable. Racks can then be mounted up to several kilometres away from the processor.

There are many benefits from this. It obviously reduces cable costs as racks can be laid out local to the plant devices and only short multi-core cable runs are needed. The long runs will only be the communication cables (which are cheap, easy to install and only have a few cores to terminate at each end) and hardwire safety signals.

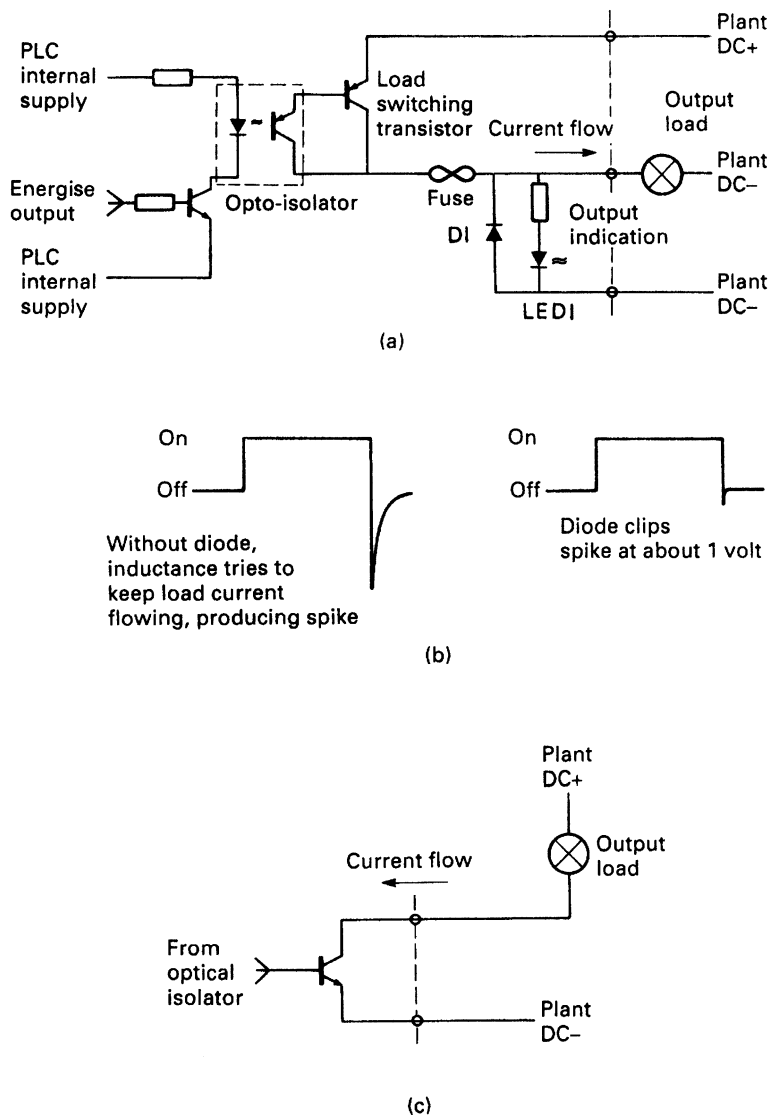

Less obviously, remote I/O allows complete plant units to be constructed, wired to a built in PLC rack, and tested off site prior to delivery and installation. Typical examples are hydraulic skids, desks and even complete control pulpits. The use of remote I/O in this way can greatly reduce installation and commissioning time and cost.

The use of serial communication for remote I/O means some form of sequential scan must be used to read input and update outputs. This scan, typically 30–50 ms, introduces a small delay in the response to signals discussed further in the following section.

If remote I/O is used, provision should be made for a program terminal to be connected local to each rack. It negates most of the benefits if the designer can only monitor the operation from a central control room several hundred metres from the plant. Fortunately, manufacturers have recognised this and most PLCs have programming terminals which can be remotely connected to the processor.

### 16.2.4 The program scan

A PLC program can be considered to behave as a permanent running loop similar to *Figure 16.11(a)*. The user's instructions are obeyed sequentially, and when the last instruction has been obeyed the operation starts again at the first instruction. A PLC does not, therefore, communicate

**Figure 16.9** D.c. output circuits: (a) isolated output circuit, current sourcing; (b) the effect of an inductive load and the reason for including diode D1; (c) current sinking output

continuously with the outside world, but acts, rather, by taking 'snapshots'.

The action of Figure 16.11(a) is called a *program scan*, and the period of the loop is called the *program scan time*. This depends on the size of the PLC program and the speed of the processor, but is typically 2–5 ms per K of program. Average scan times are usually around 10–50 ms.

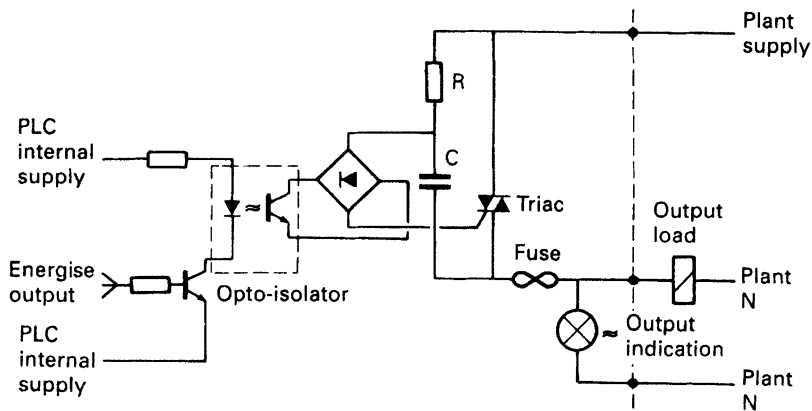

Figure 16.11(a) can be expanded to Figure 16.11(b). The PLC does NOT read inputs as needed (as implied by Figure 16.11(a)) as this would be wasteful of time. At the start of the scan it reads the state of ALL the connected inputs and stores their state in the PLC memory. When the PLC program accesses an input, it reads the input state as it was at the start of the current program scan.

As the PLC program is obeyed through the scan, it again does not change outputs instantly. An area of the PLC's memory corresponding to the outputs is changed by the

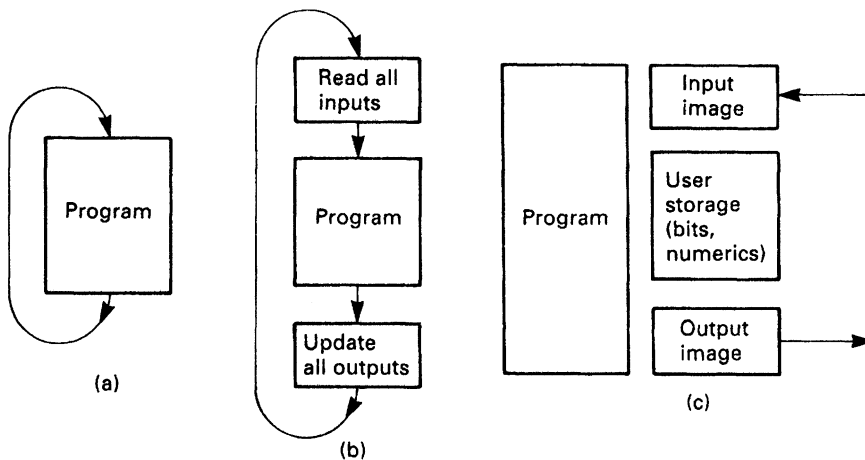

program, then ALL the outputs are updated simultaneously at the end of the scan. The action is thus:

Read Inputs,  
Scan Program,  
Update Outputs.

The PLC memory can therefore be considered to consist of four areas as shown on Figure 16.11(c). The inputs are read into an input mimic area at the start of the scan, and the outputs updated from the output mimic area at the end of the scan. There will be an area of memory reserved for internal signals which are used by the program but are not connected directly to the outside world (timers, counters, storage bits (e.g. fault signals) and so on). These three areas are often referred to as the *data table* (Allen Bradley) or the *database* (ASEA/ABB).

**Figure 16.10** A.c. isolated output. The triac switches on at zero voltage and off at zero current which minimises interference

**Figure 16.11** The program scan and memory organisation: (a) simple view of PLC operation; (b) more detailed view of PLC operation; (c) memory organisation

This data area is smaller than may be at first thought. A medium size PLC system will have around 1000 inputs and outputs. Stored as individual bits in a PLC with a 16 bit word this corresponds to just over 60 storage locations. An analog value read from the plant or written to the plant will take one word. Timers and counters take two words (one for the value, and one for the preset) and sixteen internal storage bits take just one word. The majority of the store therefore, is taken up by the fourth area, the program itself.

The program scan limits the speed of signals to which a PLC can respond. In *Figure 16.12(a)* a PLC is being used to count a series of fast pulses, with the pulse rate slower than the scan rate. The PLC counts correctly. In *Figure 16.12(b)* the pulse rate is faster than the scan rate and the PLC starts to miscount and miss pulses. In the extreme case of *Figure 16.12(c)* whole blocks of pulses are totally ignored.

In general, any input signal a PLC reads must be present for longer than the scan time; shorter pulses may be read if they happen to be present at the right time but this cannot be guaranteed. If pulse trains are being observed, the pulse frequency must be slower than  $1/(2 \times \text{scan period})$ . A PLC with a scan period of 40 ms can, in theory, just about follow a pulse train of  $1/(2 \times 0.04) = 12.5 \text{ Hz}$ . In practice other

factors such as filters on the input cards have a significant effect and it is always advisable to be conservative in speed estimates.

Less obviously, the PLC scan can cause a random 'skew' between inputs and outputs. In *Figure 16.13* an input I is to cause an 'immediate' output O. In the best case of *Figure 16.13(a)*, the input occurs just at the start of the scan, resulting in the energisation of the output one scan period later. In *Figure 16.13(b)* the input has arrived just after the inputs are read, and one whole scan is lost before the PLC 'sees' the input, and the rest of the second scan passes before the output is energised. The response can thus vary between one and two scan periods.

In the majority of applications this skew of a few tens of milliseconds is not important (it cannot be seen, for example, in the response of a plant to pushbuttons). Where fast actions are needed, however it can be crucial. If, for example, material travelling at 15 m/s is to be cut to length by a PLC with the cut being triggered by a photocell a 30 ms scan time would result in a  $0.03 \times 15000 = 450 \text{ mm}$  variation in cut length.

PLC manufacturers provide special cards (which are really small processors in their own right) for dealing with

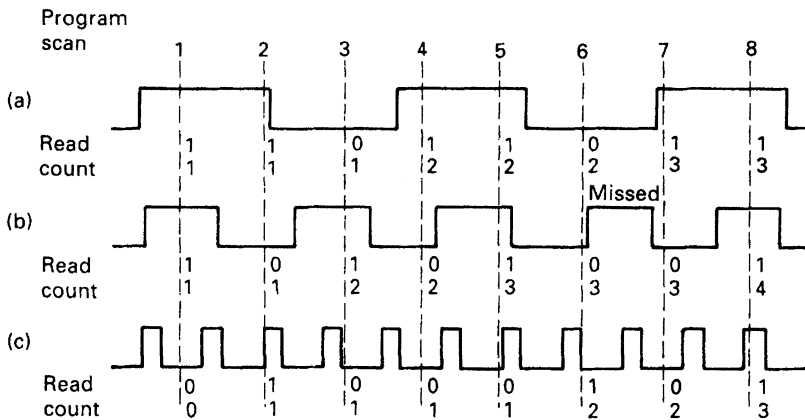

Figure 16.12 The effect of program scan on a fast pulse train

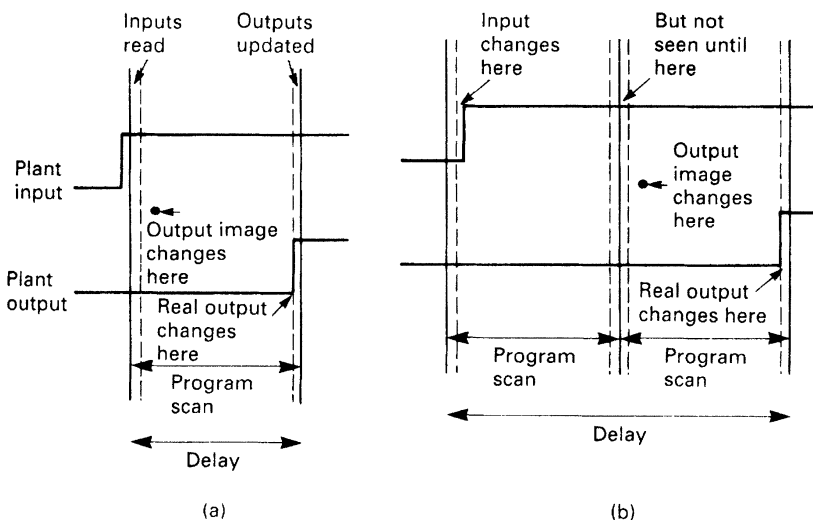

Figure 16.13 The effect of program scan on response time: (a) best case; (b) worst case

this type of high speed application. We will return to these later in Section 16.4.8.

The layout of the PLC program itself can result in undesirable delays if the program logic flows against the PLC program scan. The PLC starts at the first instruction for each scan, and works its way through the instructions in a sequential manner to the end of the program when it does its output update, then goes to read its inputs and run through the program again.

In Figure 16.14(a), an input I again causes an output O, but it goes through five steps first (it could be stepping a counter or seeing if some other required conditions are present). The program logic, however, is flowing against the scan. On the first scan the input I causes event A. On the next scan event A causes event B and so on until after 5 scans event D causes the output to energise. If the program had been arranged as Figure 16.14(b) the whole sequence would have occurred in one single scan.

The failings of Figure 16.14(a) are self-evident, but the effect can often occur when the layout of the program is not carefully planned. The effect can also be used deliberately to ensure sequences operate correctly.

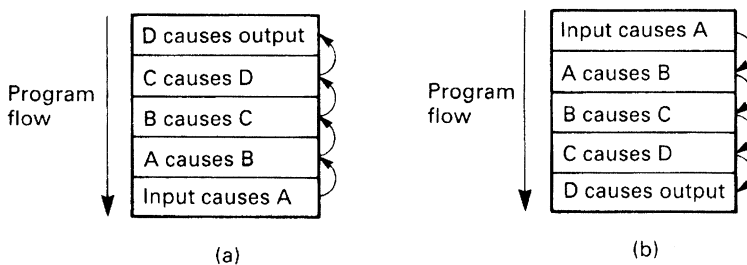

The effect of scan times can become even more complex when remote serially scanned I/O racks are present. These are generally read by an I/O scanner as Figure 16.15 but the remote I/O scan is not usually synchronised to the program scan. In this case with, say, a program scan of 30 ms and a remote I/O scan of 50 ms the fastest response to an input could be 30 ms, but the slowest response (with an input just missing the I/O scan and the I/O scan just missing the program scan and the programming scan just missing the I/O scan to update the output) could be 180 ms.

PLC manufacturers offer many facilities to reduce the effect of scan times. Typical are intelligent high speed independent I/O cards and the ability to sectionalise the program into areas with different scan rates.

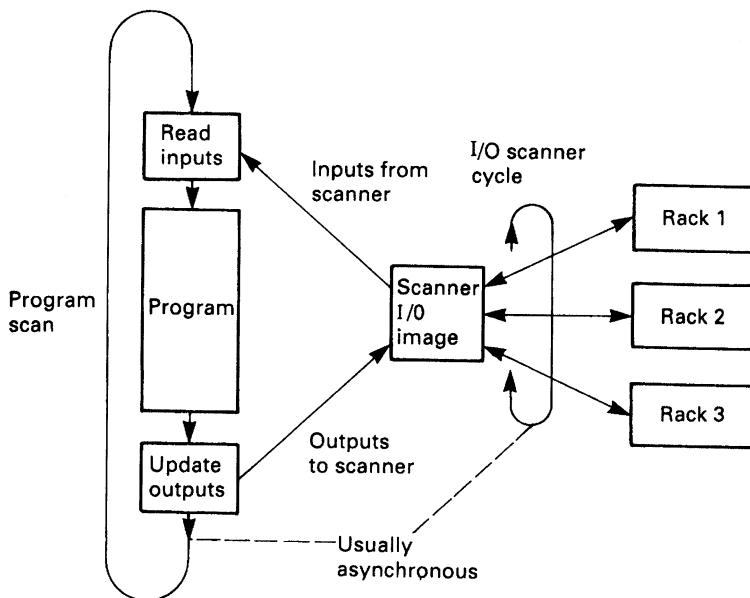

## 16.3 Programming methods

### 16.3.1 Introduction

The programming language of a PLC will be used by engineers, technicians and maintenance electricians. It should

**Figure 16.14** Compounding of program scan delays: (a) logic flows against the scan, five scan times from input to output; (b) logic flows with program scan, output occurs in same program scan as input

**Figure 16.15** The effect of remote input/output scan times. The remote I/O scan usually free-runs and is not synchronised with the program scan

therefore be based on techniques used in industry rather than techniques used in computer programming. In this section we shall look at the various ways of programming PLCs from different manufacturers.

### 16.3.2 I/O identification

The PLC program is concerned with connections to the outside plant, and these input and output devices need to be identified inside the program. Before we can examine how the program is written we will first discuss how various manufacturers treat the I/O.

The earlier Figure 16.3 showed that a medium sized PLC system consists of several racks each containing cards, with each card interfacing generally with 8, 16 or 32 devices. I/O addressing is usually based on this rack/card/bit idea.

The Allen Bradley PLC-5 family has a range of processors which can address up to 64 racks. Its medium size 5/25 can have up to 8 racks. The rack containing the processor is automatically defined as rack 0, but the designer can allocate addresses of the other racks (in the range 1–7) by set up

switches. The racks other than rack 0 connect to the processor via a remote I/O serial communications cable.

Each rack contains 16 card positions which are grouped in pairs called a 'slot'. A 16 card rack thus contains eight slots, numbered 0–7. A slot can contain one 16 way input card and one 16 way output card OR two 8 way cards usually (but not necessarily) of the same type.

The addressing for inputs is

I: Rack Slot/Bit

with bit being 2 digits. Allen Bradley use octal addressing for bits, so allowable numbers are 00–07 and 10–17. The address I: 27/14 is input 14 (octal remember) on slot 7 in rack 2.

Outputs are addressed in a similar manner:

O: Rack Slot/Bit

so O: 35/06 is output 6 in slot 5 of rack 2. Note that if 16 way cards are used an input and an output can have the same rack/slot/bit address, being distinguished only by the

I: or the O:. With 8 way cards there can be no sharing or rack/slot/bit addressing.

The digital I/O in Siemens 115 PLCs is arranged into groups of 8 bits, called a Byte. A signal is identified by its bit number (0–7) and its byte number (0–127).

Inputs are denoted

`I<byte>.<bit>`,

and outputs by

`Q<byte>.<bit>`.

`I9.4` is thus an input with bit address 4 in byte 9, and `Q63.6` is an output with bit address 6 in byte 63.

Like Allen Bradley, Siemens use card slots in one or more racks. The cards are available in 16 bit (2 byte) or 32 bit (4 byte) form. A system can be built with local racks connected via a parallel bus cable or as remote racks with a serial link.

The simplest form of addressing is fixed slot where four bytes are assigned sequentially to each slot; 0–3 to the first slot, 4–7 to the next slot and so on. Input `I12.4` is thus input bit 4 on the first byte of the card in slot 3 of the first rack. If 16 bit (2 byte) cards are used with fixed (4 byte) addressing the upper 2 bytes in each slot are lost.

In all but the simplest system the user has the ability to assign byte addresses. This is known as variable slot addressing. The first byte address and the range (2 byte for 16 bit cards or 4 byte for 32 bit cards) can be set independently for each slot by switches in the adaptor module in each rack. Although any legitimate combination can be set up, it is recommended that a logical order is used.

Siemens use different notations in different countries with multi-lingual programming terminals. A common European standard is German, where E (for Eingang or input) is used for inputs (e.g. `E4.7`) and A (for Ausgang) used for outputs (e.g. `A3.5`).

The GEM-80 again configures its I/O in terms of bits and slots within racks. The processor rack can contain 8 card positions, and additional I/O can be connected into 12 position racks local to the processor connected via ribbon cable (called Basic I/O) or remotely via a serial link.

The I/O is addressed in terms of 16 bit words, one word corresponding to one or two card positions, and the prefix A being used for inputs and B for outputs. The bit addressing runs in decimal from 0 to 15.

`A3.12` is thus input bit 12 in word 3 and

`B5.04` is output bit 4 in word 5

A word can only be an input or an output; duplication of word addresses is not allowed. I/O cards are available in 8 bit, 16 bit and 32 bit form, so one slot can be half a word, one word or two words according to the cards being used. Individual slot addresses are set by rotary switches on the back plane of each rack. The user has a more or less free choice in this allocation, but as usual it is best to use a logical sequential progression.

The ABB (originally ASEA) Master system is a more complex system than any we have discussed so far. Its organisation brings the user closer to the computer, and its language is more akin to the ideas used by programmers. If the PLCs discussed so far are taken to be represented by the home computer language BASIC, the ABB Master is analogous to PASCAL or C. This comparison is actually closer than might, at first, be thought. BASIC is quick and easy to use, but can de-generate into a web of spaghetti

programming if care is not taken. PASCAL and C are more powerful but everything has to be declared and the language forces organisation and structure on the user.

The I/O cards are NOT identified by position in the rack, but by an address set on the card by a small plug with solder links. The I/O addressing does not, therefore, relate to card position, and a card can, in theory, be moved about without changing its operation.

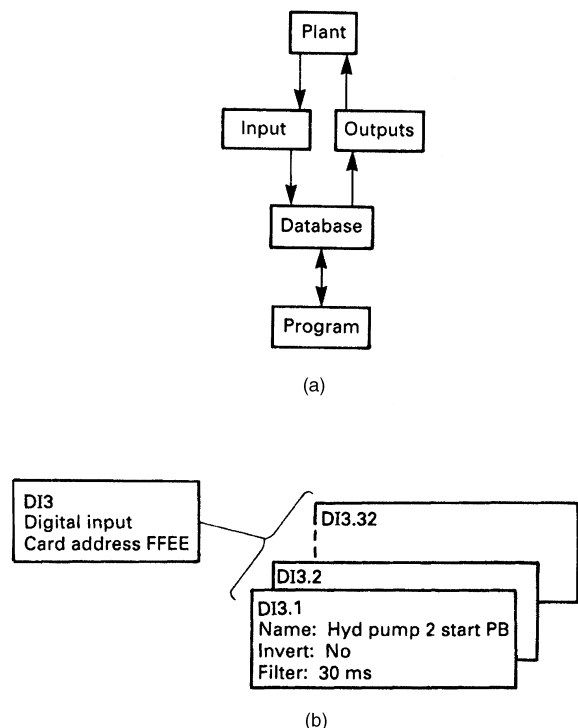

The processor memory is arranged as *Figure 16.16(a)*. The I/O is connected to a processor database, but unlike PLCs described earlier, the designer can specify different scan rates for different cards.

The designer also has considerable power over how the PLC program is organised. This is heavily modularised as we shall see later, and the user can also specify different scan rates for different modules of the program.

*Figure 16.16(b)* indicates the database for one input card. There are two levels of the definition, the top level relating to details of the board itself such as address and scan rate, then lower levels relating to details of each channel on the board such as its name and whether the signal is to be inverted. The database holds details for all the I/O which can then be referenced by the program either by its database identification (e.g. `DI3.1`) or by its unique name (e.g. `HydPump2StartPB`).

The Mitsubishi F2 range is typical of small PLCs with input/output connection, power supply and processor all contained in one unit. The smallest unit, the F2-40 M has 24 inputs and 16 outputs. (It is a characteristic of process control systems that the ratio input:outputs is generally 3:2.)

The 24 inputs are designated X400–X427 in octal notation and the 16 outputs Y430–Y447. The apparently arbitrary numbers are directly related to the storage

**Figure 16.16** The ABB Master system: (a) organisation of the memory; (b) definition of a digital input in the database

locations used to hold the image of the inputs and output. Further addresses are used in larger PLCs in the series.

### 16.3.3 Ladder logic

Early PLCs, designed for the car industry, replaced relay control schemes. The symbols used in American relay drawings,  $-$   $]$   $-$  for a normally open (NO) contact,  $-$   $]$   $-$  for a normally closed (NC) contact, and  $-$   $( )$  for a plant output, were the basis of the language. The earlier Figure 16.5 showed the keyboard for a programmer for this type of PLC; the relationship to relay symbolism is obvious.

Suppose we have a hydraulic unit, and we wish to give a healthy lamp indication when

*The Pump is running (sensed by an auxiliary contact on the pump starter).*

*There is oil in the tank (sensed by a level switch which makes for good level).*

*There is oil pressure (sensed by a pressure switch which makes for adequate pressure).*

With conventional relays, we would wire up a circuit as Figure 16.17(a).

To use a PLC, we connect the input signals to an input card, and the lamp to an output card as Figure 16.17(b). The I/O notation used is Allen Bradley.

The program to provide the function is shown on Figure 16.17(c). The line on the left can be considered to be a supply, and the line on the right a neutral. The output is represented by a coil  $-$   $( )$  and is energised when there is a route from the left-hand rail. Output  $0:22/01$  will come on when signals  $I:21/00$ ,  $I:21/01$  and  $I:21/02$  are all present.

The program is entered from a terminal with keys representing the various relay symbols. The terminal can also be used to monitor the state of the inputs and outputs, with 'energised' inputs and outputs being shown highlighted on the screen.

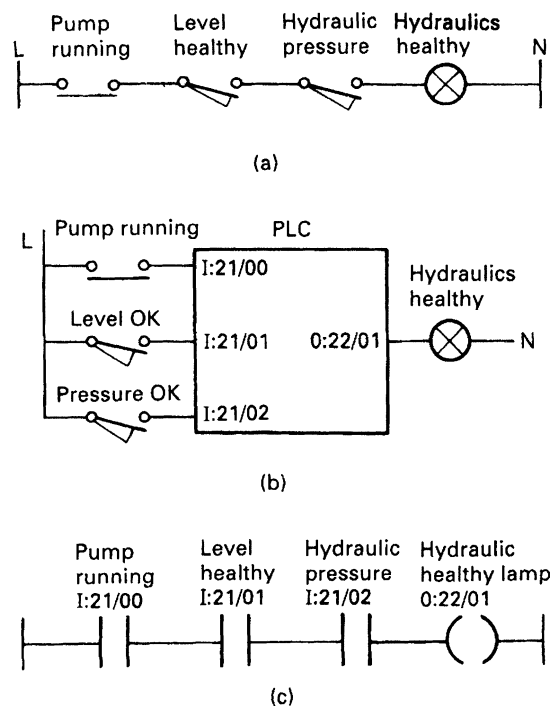

In Figure 16.18(a), a hydraulic cylinder can be extended or retracted by operation of two pushbuttons. The notation this time is for a GEM-80. It is undesirable to allow both solenoids to be operated together; this will almost certainly result in blown fuses in the supply to the output card, so some protection is needed. The program to achieve this is shown on Figure 16.18(b).

Normally closed contacts  $-$   $]$   $-$  have been used here. Output  $B2.9$ , the extend solenoid, will be energised when the extend pushbutton is pressed, providing the retract solenoid is not energised or the retract button pressed, and the extend limit switch has not been struck.

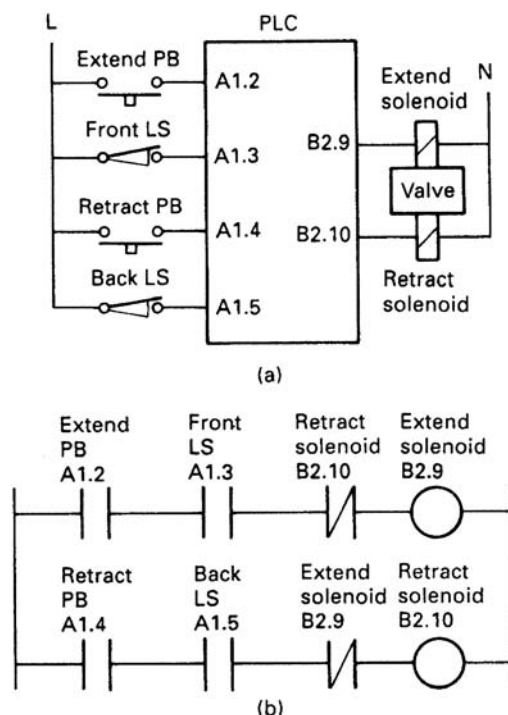

There are two points to note on Figure 16.18. Contacts can be used from outputs as well as inputs, and contacts can be used as many times as needed in the program. Figure 16.18 also shows the origin of the name 'Ladder Program'. A program in this form looks like a ladder, with each instruction statement forming a 'rung' and the power rail and neutral the supports. The term 'rung' is invariably applied to the contacts leading to one output.

Let us return to the hydraulics healthy light of Figure 16.17 and add a lamp test pushbutton (a useful feature that should be present on all panels. It not only allows lamps to be tested, but can also be used to check the PLC and the local rack are healthy). To do this we add the lamp test pushbutton to the PLC and modify the program to Figure 16.19.

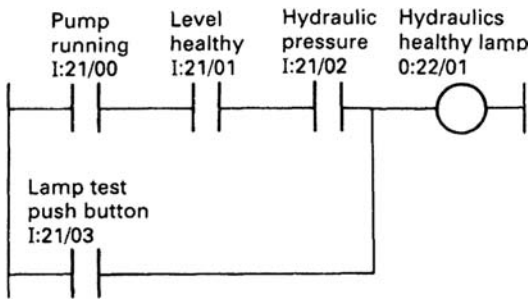

Here we have added a branch, and the output will energise if our three plant signals are all present OR the

**Figure 16.17** From a relay circuit to a PLC program: (a) basic non-PLC circuit; (b) wiring of I/O to a PLC; (c) the corresponding PLC program

**Figure 16.18** Ladder diagram in GEM-80 notation: (a) input/output connections; (b) GEM-80 ladder diagram

**Figure 16.19** Adding a lamp test pushbutton with a branch

lamp test button is pressed. The way in which the branch is programmed need not concern us here as it varies between manufacturers. Some use start branch and end branch keys (the keypad shown earlier on *Figure 16.5* uses this method, the corresponding keys can readily be identified). Others use a branch from/to approach. All are simple to use.

A further use of a branch is shown on *Figure 16.20*. This is probably the commonest control circuit, a motor starter, shown using Siemens notation. The operation is simple, pressing the start pushbutton causes the output Q8.2 to energise, and the contact of the output in the branch keeps the output energised until the stop button is pressed. The program, like its relay equivalent, remembers which button was last pressed.

There is, however, a very important point to note about the pushbutton wiring and the program. For safety, a normally closed stop button has been used giving an input signal on I12.5 when the stop button is NOT pressed. A loss of supply to the button, or a cable fault, or dirt under the contacts will cause the signal to be lost making the program think the stop PB has been pressed causing the motor to stop. If a normally open stop PB has been used, the PLC program could easily be made to work, but a fault with the stop button or its circuit could leave the motor running with the only way of stopping it being to turn off the PLC or the motor supply.

This topic is discussed further in Section 16.7.4, but note the effect on the program in *Figure 16.20*. The sense of the stop button input (I12.5) inside the program is the opposite of what would be expected in a relay circuit. The input is really acting as 'Permit to Run' rather than 'Stop'.

### 16.3.4 Logic symbols

Logic gates are widely used in digital systems (including the boards used inside PLCs). The circuits on these boards are represented by logic symbols, and these symbols can also be used to represent the operations of a PLC program. Logic symbols are used by Siemens and ABB; initially we will use Siemens notation.

The output from an AND gate, shown on *Figure 16.21(a)*, is TRUE if (and only if) all its inputs are TRUE. The operation of the gate of *Figure 16.21(a)* can be represented by the table of *Figure 16.21(b)*. In *Figure 16.21(c)* we have the hydraulics healthy lamp of *Figure 16.19* programmed using logic symbols for a Siemens PLC. The output block, denoted by equals = is energised when its input is true, so the lamp Q8.2 is energised (lit) when all the inputs to the AND gate are true.

Often a test has to be made to say a signal is NOT true. This is denoted by a small circle 'o'. In the earlier *Figure*

**Figure 16.20** A simple motor starter in Siemens notation: (a) input/output connections; (b) the ladder diagram. Note how the stop button appears in the program

16.18 we illustrated the control of a hydraulic cylinder with a program which prevented the extend and retract solenoids from being energised simultaneously. This is shown programmed with logic symbols for a Siemens PLC in *Figure 16.22*. Note the NOT inputs on each AND gate.

The output of an OR gate, Z in *Figure 16.23(a)*, is TRUE if any of its inputs are TRUE. The inverse of a signal can be tested, as before, with a small circle 'o'. The output Z of the

**Figure 16.21** PLC programming using logic symbols: (a) an AND gate; (b) truth table for a three input AND gate; (c) the healthy lamp of *Figure 16.17* using a logic symbol in Siemens notation

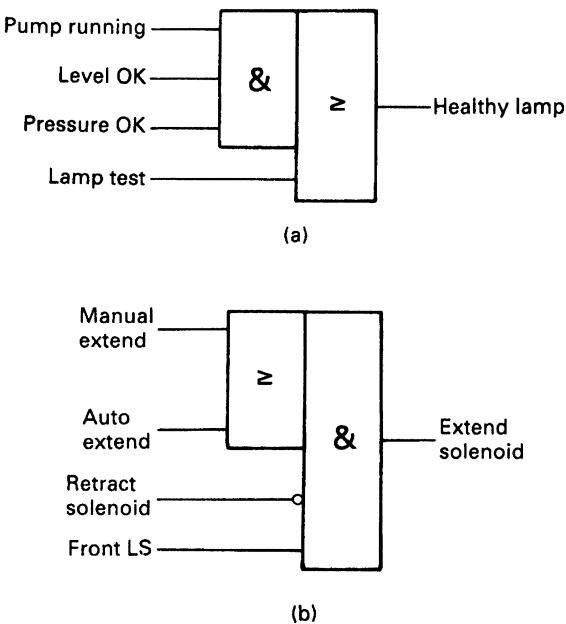

**Figure 16.22** The hydraulic cylinder of *Figure 16.18* in logic notation and Siemens addressing. Note the use of inverted inputs (denoted by small circles)

gate in *Figure 16.23(b)* is TRUE if A is TRUE or B is FALSE or C is TRUE. In *Figure 16.23(c)* we have used an OR gate to add a lamp test to our hydraulic healthy lamp. The circuit of *Figure 16.23(c)* is an AND/OR combination. The ABB Master has logic combination blocks as well as the basic gates. *Figure 16.24(a)* is the Master block corresponding to *Figure 16.23(c)* (with a Master program referring to the names in its database). Similarly, for an OR/AND combination the OR/AND block of *Figure 16.24(b)* can be used in a Master program.

16.3.5 Statement list

A statement list is a set of instructions which superficially resemble assembly language instructions for a computer. Statement lists, available on the Siemens and Mitsubishi range, are the most flexible form of programming for the experienced user but are by no means as easy to follow as ladder diagrams or logic symbols.

**Figure 16.24** ABB Master composite gates: (a) AND/OR gate (equivalent to *Figure 16.23(c)*); (b) OR/AND gate

*Figure 16.25* shows a simple operation in both ladder and logic formats for a Siemens PLC. The equivalent statement list would be:

Instruction	Operation	Address number	Comment
00	:A	I 3.7	Forward Pushbutton
01	:A	I 3.2	Front Limit OK
02	:AN	Q 4.2	Reverse Solenoid
03	:=<=<	Q 4.11	Output to Forward Solenoid

**Figure 16.23** The OR Gate: (a) logic symbol; (b) OR gate with inverted input; (c) lamp test added to *Figure 16.21(c)*

**Figure 16.25** Equivalent ladder and logic statements in Siemens notation

**Figure 16.26** OR gate equivalence in Siemens notation

Here :A denotes AND, :AN denotes AND-NOT and := sends the result to the output address Q4.11.

An OR operation is shown on *Figure 16.26*. The equivalent statement list is:

Instruction	Operation	Address number	Comment
00	:ON	I 2.7	Local Pump Running
01	:O	F 3.6	Remote Pump Running
02	:ON	Q 4.2	Local Pump Starter
03	: $\Rightarrow$	Q 4.4	Pump Healthy Lamp

where ON denotes OR-NOT and O denotes OR.

Where a set of statements can be anomalous, brackets can be used to define the operation precisely. This is similar to the use of brackets in conventional programming where the sequence  $3 + 5/2$  can be written as  $(3 + 5)/2 = 4$  or  $3 + (5/2) = 5.5$ .

Although the latter is the default assumed by a program, the brackets do make the operation clear to the reader.

*Figure 16.27* shows a typical operation, as usual in both logic and ladder diagram format. The equivalent statement list is:

Instruction	Operation	Address	Comments
00	:A (		Open First Set of Brackets
01	:O	F 3.3	Forward from desk 1
02	:O	F 3.4	Forward from desk 2
03	:)		Result of first set of brackets
04	:A (		AND Result with second set of brackets
05	:A	I 2.0	Motor 1 Selected
06	:A	I 2.1	Motor 2 Selected
07	:)		Now at point X
08	:A	I 4.1	Front Limit Switch Healthy
09	:AN	Q 5.5	Reverse Starter
10	: $\Rightarrow$	Q 5.6	Output to Forward Starter

Computer programmers will recognise this as being similar to the operation of a stack with the brackets pushing data down, or lifting data up, the stack.

**Figure 16.27** More complex statements in ladder and logic notations

The Mitsubishi PLC also uses statement lists, although the manual recommends the designer to construct a ladder diagram first then translate it into a statement list. The PLC system shown in *Figure 16.28* with Mitsubishi notation becomes the statement list:

Instruction	Operation	Address	Comments
0	LD	X401	LD starts rung or branch
1	AND	X402	Xnnn are inputs
2	ANI	X403	ANI is And-Not
3	LD	Y430	LD starts a new branch leg
4	AN	M100	Mnnn are internal storage
5	ORB		OR the two branch legs
6	AND	M101	
7	OUT	Y430	End of Rung

Figure 16.28 A rung in a Mitsubishi ladder program

### 16.3.6 Bit storage

As well as inputs and outputs, the PLC will need to hold internal signals for data such as 'Standby Pump Running', 'System Healthy', 'Lubrication Fault' and so on. It would be very wasteful to allocate real outputs to these signals, so all PLCs provide some form of internal bit storage. These are known variously as Auxiliary Relays, (Mitsubishi), Flags (Siemens), General Workspace (GEM-80) and Bit Storage (Allen Bradley). The notation used within the programs vary, of course, from manufacturer to manufacturer.

Mitsubishi use Mnnn with nnn representing numbers within the predefined area M100 to M377 octal. Like most small PLCs the memory layout is fixed and cannot be defined by the user. In the other, larger, PLCs we discuss, the user can define how many storage bits are needed.

The Siemens notation is F <Byte>. <Bit> (e.g. F27.06).

The GEM-80 has a variety of general work space. The commonest is called the G table, and appears in programs as G<Word>. <Bit> (e.g. G52.14). The G table is cleared when the PLC goes from a stopped state to a run state. Storage in the R table (e.g. R12.03) retains its state with the processor halted or with power removed.

Bit storage in the PLC-5 is denoted by B3/n where n denotes the signal (e.g. B3/192). The B denotes bit storage and the 3 is mandatory and arises out of the way the PLC-5 holds data in files. Bit storage is file 3; timers are file 4 (T4) and counters file 5 (C5) as we shall see later.

The ABB Master programming language does not really require internal storage bits, the function being provided by elements and connections within its database and the programming language.

Some form of memory circuit is needed in practically every PLC program. Typical examples are catching a fleeting alarm and the motor starter of the earlier Figure 16.20 where the rung remembers which button (start or stop) has been last pressed. These are known, for obvious reasons, as storage circuits.

The commonest form is shown in ladder and logic form in Figure 16.29(a). Here output C is energised when input A is energised, and stays energised until input B is de-energised.

The operation is summarised on Figure 16.29(b). As can be seen input B overrides input A, the action required of a start/stop circuit. In some circuits, however, the start is required to override the stop. We all have a typical example in our motor cars; the windscreen wipers run when we switch them on, but continue to run to the park position when we turn them off. The PLC equivalent is Figure 16.29(c), where A would be the run switch, B the park limit switch and C the wiper motor. B has again been shown energised to allow running. The operation is summarised on Figure 16.29(d).

Storage is provided in digital systems by a device called a flip flop shown on Figure 16.30(a). This has two inputs, S (for Set) and R (for Reset). The device remembers which input was last energised. If both inputs occur together, the

top (S) input wins. Such a circuit is called an SR flip flop. If the device is drawn with the R input at the top, as Figure 16.30(b), the reset input will override the set input if both are present together.

The flip flop is used in logic symbol PLC programming. A motor starter using a Siemens PLC is shown in Figure 16.31. Note that the RS version has been used to ensure the stop logic overrides the run logic, and the stop signal acts as a permit to run.

The ABB Master uses an almost identical symbol for the flip flop, with the addition that there are five versions. The first of these is the simple SR type shown earlier in Figure 16.30. The other versions are based on the fact that flip flops are invariably preceded by AND/OR combination of which Figure 16.31 is typical. The additional flip flops are one unit blocks consisting of a flip flop with built in AND/OR gates of user defined size. Figure 16.32 for example, is an ABB SRAO with an AND gate on the set input and an OR gate on the reset inputs. Other units are SRAA (AND/AND), SROA and SROO.

In Allen Bradley ladder diagrams, program clarity can be improved by the use of latch and unlatch outputs shown on Figure 16.33(a). These work on the same bit, setting the bit when the latch - (L) - is energised and resetting the bit when the - (U) - is energised. When both latch and unlatch are de-energised the bit holds its last state.

The Mitsubishi F2 uses a similar idea, but calls them S and R outputs as Figure 16.33(b). This would be coded into a statement list:

0	LD	X400	
1	OR	X401	
2	S	Y432	Set Output
3	LDI	X402	
4	ORI	X403	
5	R	Y432	Reset Output

With both the Allen Bradley latch/unlatch, and the Mitsubishi set/reset, the priority goes to which ever is last in the program because of the program scan. Both the examples of Figure 16.33 correctly give priority to the stop signals.

Power failure or halting of the PLC can cause a problem with storage. When the PLC restarts should a memory bit hold the state it was in before the PLC halted, or should the memory be cleared? This is always a question of safety and convenience. A water pump in a pump house by a river 5 km from the main site should probably be allowed to restart itself if it was running before the power fail, an automatic stamping machine should almost certainly not restart.

The PLC manufacturers therefore allow the designer to choose whether a storage bit holds its state after a power fail (called *retentive memory*) or is cleared when the PLC is first run (called *non retentive memory*).

In the Allen Bradley PLC-5, this is determined by the circuit; the simple coil of Figure 16.29 is non retentive, the latch/unlatch of Figure 16.33(a) is retentive.

Other PLCs use the bit address. On a Siemens 115, flag addresses F0.0-F127.7 can be made retentive. On the Mitsubishi PLC, auxiliary relays M100-277 are non retentive, and M300-M377 are retentive. In the GEM-80, the general bit storage G Table is non retentive, a similar R Table is retentive, so a circuit similar to Figure 16.29 constructed with R3.4 as the coil and retaining contact would hold its state after a power failure.

**Figure 16.29** Bit storage programs: (a) commonest storage program, stop B overrides start A; (b) operation of (a), (c) Program where start A overrides stop B; (d) operation of (c)

**Figure 16.30** The two types of flip flop storage: (a) the SR flip flop, Set overrides R; (b) the RS flip flop, reset overrides set

**Figure 16.31** Flip flop storage is commonly preceded by logic gates. Here either stop button will reset the flip flop. Note the circles on the stop button inputs denoting inverted inputs. These are necessary because the stop buttons give a signal in the not pressed state

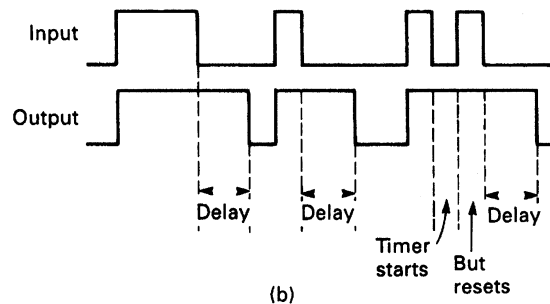

**Figure 16.32** An ABB master SRAO composite flip flop

**Figure 16.33** Other forms of storage: (a) the Allen Bradley latch/unlatch; (b) the Mitsubishi set/reset

The ABB Master uses a very structured PLC language, and forces a disciplined style on the programmer. The nature of sub elements such as memories and their behaviour when the PLC is first run is defined when the program elements are first declared.

Retentive storage can be very hazardous as plants can unexpectedly leap into life after a power fail. The designer should take care that the design does not accidentally introduce retentive features by an inadvertent selection of bit addresses.

**Figure 16.34** Different forms of timer: (a) the on-delay. This is the commonest timer and is often the only type available in many smaller PLCs; (b) the off-delay; (c) the fixed width pulse, often called a monostable

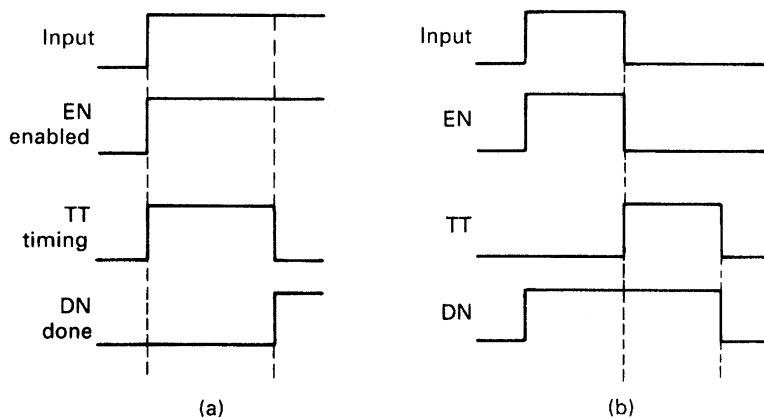

### 16.3.7 Timers

Time is nearly always a part of a control system. A typical example is: 'Lift Parking Brake, wait 0.5 seconds for brake to lift, drive to forward limit and stop drive, wait 1 second and apply parking brake'. A PLC system must therefore include timers as part of its programming language. There are many types of timer, some of which are shown on Figure 16.34

By far the commonest is the on-delay of Figure 16.34(a). All the other timer blocks can be built with this block and a bit of thought. A 0 to 1 transition is delayed for a preset time T, but a 1 to 0 transition is not delayed at all. An input signal shorter than T is ignored. The GEM-80 has only this type of timer, calling it a *delay*.

The off-delay of Figure 16.34(b) passes a 0 to 1 transition instantly but delays the 1 to 0 transition. A common use of the off-delay is to remove contact bounce or noise from an input signal. An off-delay can be obtained from an on-delay by using the inverse of the input signal and taking the inverse of the timer output signal (although the resulting program lacks some clarity).

Figure 16.34(c) is an edge triggered pulse timer, this gives a fixed width pulse for every 0-1 transition at the timer input. The PLC-5 has a Onescan pulse timer which produces a pulse lasting one (and only one) program scan. Pulses are useful for resetting counters or gating some information from one location to another.

**Figure 16.35** Allen Bradley timer notations: (a) EN, TT and DN for an on-delay (TON) timer; (b) EN, TT and DN for an off-delay (TOF) timer

A timer of whatever type has some values that need to be set by the user. The first of these is the basic unit of time (i.e. what units the time is measured in). Common units are 10 ms, 100 ms, 1 s, 10 s, and 100 s. The base unit does not affect the accuracy of the timer; normally the accuracy is similar to the program scan.

Next the timer duration (often called the *preset*) is defined. This is normally set in terms of the time base; a timer with a preset of 15 and a time base of 100 ms will last 1.5 s for example. In small PLCs this preset can only be set by the programmer, in the larger PLCs the duration can be changed from within the program itself. A delay off timer used to apply a parking brake, for example, could have different preset times dependent on whether the drive concerned is travelling at low speed or high speed.

When a timer is used there are several signals that may be available. Figure 16.35 shows the signals given for a PLC-5 delay on timer (called a TON) and a delay off timer (called a TOF).

EN (for enable) is a mimic of the timer input.

TT (for timer timing) is energised whilst the time is running.

DN (for done) says the timer has finished.

In larger PLCs the elapsed time (often called the *Accumulated Time*) may be accessed by the program for use elsewhere (a program may be required to record how long a certain operation takes).

PLC manufacturers differ on how a timer is programmed. Some, such as the GEM-80, treat the timer as a delay block similar to the earlier Figure 16.34(a) with the preset being stored in a VALUE block.

Siemens use a similar idea, but have different types of timer. The PLC-5, however, uses the timer as a terminator for a rung, with the timer signals being available as contacts for use elsewhere.

Figure 16.36 shows a typical application programmed for a PLC-5 and a GEM-80 in ladder logic and a Siemens 115-U using logic symbols. The program controls a motor starter which is started and stopped via push buttons. The motor starter has an auxiliary contact which makes when the starter is energised, effectively saying the motor is running. If the drive trips because of an overload, or because an emergency stop is pressed, or there is a supply fault, the auxiliary contact signal will be lost. The contact cannot, however, be checked until 0.5 s after the starter has been energised to allow time for the contact to pull in. The program in each case checks the auxiliary contact

and signals a drive fault if there is a problem. Note the difference in the way the timer is used and the fault signal is stored.

The accumulated time in the timers discussed so far goes back to zero each time the input goes to a zero. This is known as a *non retentive* timer. Most PLC timers are of this form. Occasionally it is useful to have a timer which holds its current value even though the input signal has gone. When the input occurs again the timer continues from where it stopped. This, not surprisingly, is known as a *retentive* timer. A separate signal must be used to reset the timer to zero. If a retentive timer is not available on a particular PLC, the same function can be provided with a counter, a topic discussed in the next section.

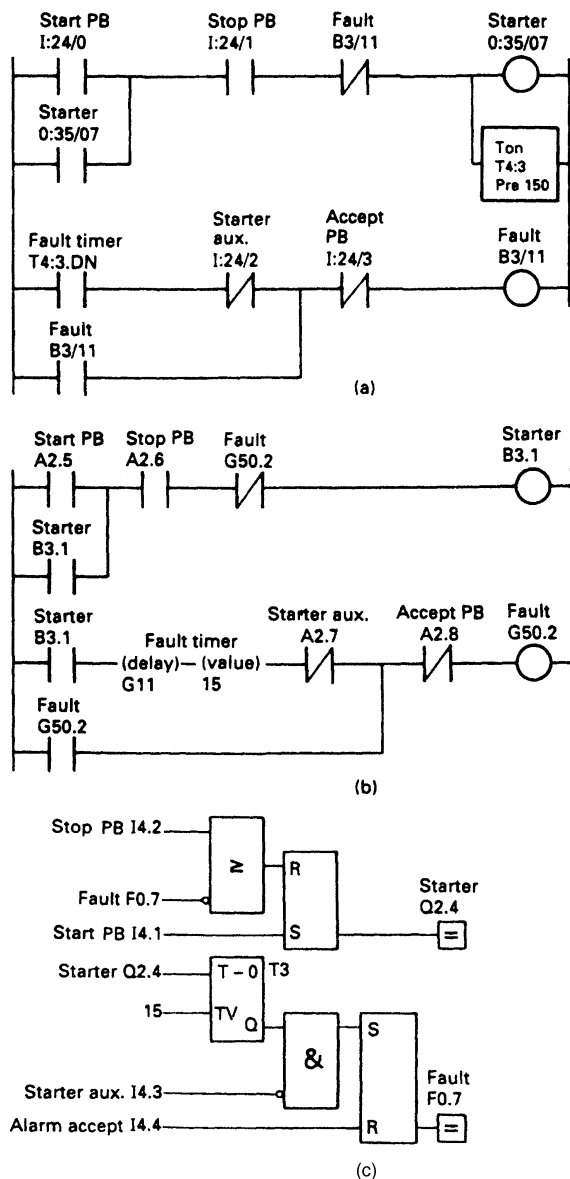

A typical timer can count up to 32 767 base time units (corresponding to 15 binary bits). Some older PLCs working in BCD can only count to 999. With a one second time base the maximum time will be just over 546 minutes or about 9 hours. Where longer times are needed, (or times with a resolution better than one second) timers and counters can be used together as described in the next section.

### 16.3.8 Counters

Counting is a fundamental part of many PLC programs. The PLC may be required to count the number of items in a batch, or record the number of times some event occurs. With large motors, for example, the number of starts have to be logged. Not surprisingly all PLCs include some form of counting element.

A counter can be represented by Figure 16.37(a), although not all PLCs will have all the facilities we will describe. There will be two numbers associated with the counter. The first is the count itself (often called the *accumulated value*) which will be incremented when a 0→1 transition is applied to the count up input, or decremented when a 0→1 transition is applied to the count down input. The accumulated value (i.e. the count) can be reset to zero by applying a 1 to the reset input. Like the elapsed time in a timer, the value of the count can be read and used by other parts of the program.

The second number is the *preset* which can be considered as the target for the counter. If the count value reaches the preset value, a *count complete* or *count done* signal is given. The preset can be changed by the program, a batching sequence, for example, may require the operator to change the number of items in a batch by a keypad or VDU entry.

**Figure 16.36** The same timer based application programmed on three different machines: (a) Allen Bradley PLC-5 TON Timer; (b) GEM-80 delay block; (c) Siemens S5 in logic notation

Similarly a signal *zero count* is sometimes available. The operation can be summarised as *Figure 16.37(b)*.

PLC manufacturers handle counters, like timers in slightly different ways. The PLC-5 and the Mitsubishi use count up (CTU) count down (CTD) and reset (RES) as rung terminators with the count done signal (e.g. C5 : 4 .DN) available for use as a contact.

The Siemens S5, ABB Master and the GEM-80 treat a counter as an intermediate block in a logic diagram or rung from which the required output signals can be used.

*Figure 16.38* shows a simple count application performed by a PLC-5, a Siemens S5 and a GEM-80. Items passing along a conveyor are detected by a photocell and counted. When a batch is complete, the conveyor is stopped and a

batch complete light is lit for the operator to remove the batch. When he does this, a restart button sets the sequence running again.

As we saw with timers, most PLCs allow a counter to count up to 32 767. Where larger counts are needed, counters can be cascaded with the complete (or *done*) signal from the first counter being used to step the second counter and reset the first. *Figure 16.39* is a variation on the same idea used to give a very long timer. It is shown for a PLC-5, but the same idea could be used on any PLC.

The first rung generates a free running one scan pulse with inter pulse period set by the timer period. (When the timer has not timed out, the DN signal is not present and the timer is running. When it reaches the preset, the DN signal occurs, resetting and restarting the timer.) The resulting one second pulse is counted by successive counters to give accumulated seconds/minutes/hours/days. As each counter reaches its preset it steps the next counter and resets itself.

Long duration timers built from counters are normally retentive (i.e. they hold their value when the controlling event is not present). They can be made non retentive by resetting the counters when the controlling event is not present, but this is rarely required.

### 16.3.9 Combinational logic

Any control system based on digital signals can be represented by *Figure 16.40(a)*, where a system has a set of outputs Z, Y, X, W, etc. whose state is determined by inputs A, B, C, D, etc. The control scheme can operate in a combination of two basic manners.

The simplest of these is *combinational logic* where the scheme can be broken down into smaller blocks as *Figure 16.40(b)* with one output per block, with each output state being determined solely by the corresponding input states. The loading valve for a hydraulic pump, for example, is to be energised when

The pump is running  
AND (Raise is selected AND top limit SW is not struck)  
OR (Lower is selected AND bottom limit SW is not struck)

The operation of this loading valve can be implemented with the simple ladder or logic program of *Figure 16.41*, but it is worth developing a standard way of producing a combinational logic program.

The first stage is to break the control system down into a series of small blocks, each with one output and several inputs. For each output we now draw up a so called *truth table* in which we record all the possible input states and the required output state. In *Figure 16.42(a)* we have an output Z controlled by four inputs A, B, C, D. There are sixteen possible input states, and Z is energised for four of these. This can be translated directly into the ladder diagram of *Figure 16.42(b)* or the logic circuit of *Figure 16.42(c)*, with each rung branch and or gate corresponding to one row in the truth table. The use of a truth table method for the design of combinational logic circuits leads directly to an AND/OR arrangement called, technically, a *Sum of Products* (S of P) circuit.

### 16.3.10 Event driven logic and SFCs

The states of outputs in combinational logic are determined solely by the input signals. In event driven logic (also known

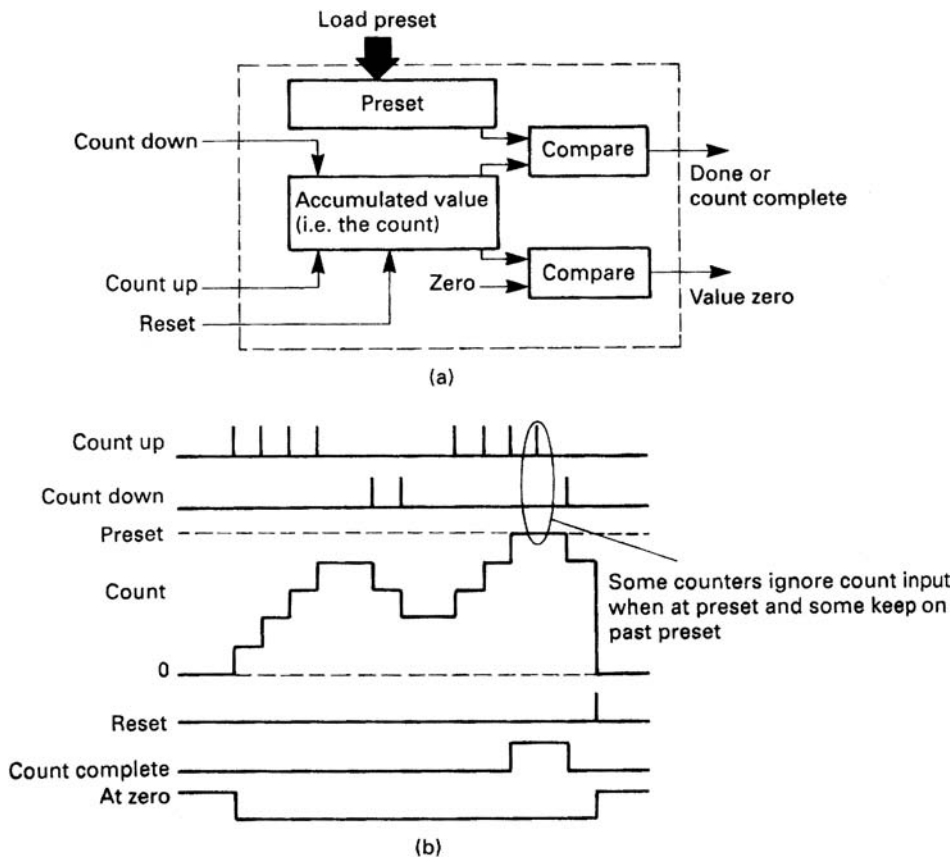

Figure 16.37 The up/down counter: (a) counter diagram; (b) counter operation

as a sequencer) the state of an output depends not only on the state of the inputs, but also on what was occurring previously. It is not therefore possible to draw a truth table from which the required logic can be deduced.

Consider, for example, the simple motor starter circuit of Figure 16.43(a). With neither button pressed, the motor could be running or stopped depending on what occurred last. The operation can be described by Figure 16.43(b) which is known as a *state transition diagram*, (often shortened to *state diagram*).

The square boxes are the states the system can be in; the motor can be running or stopped, and the arrows are the transitions that cause the system to change states. If the motor is running, pressing the stop button will cause the motor to stop. A bar above a signal (e.g. above stop PB OK) means signal not present; note the wiring of the stop PB and the signal sense. It is a useful convention to label states with numbers and transitions with letters.

State transition diagrams can be constructed from storage elements, with one less storage element than there are states, and the one default state being inferred by the absence of others. It therefore requires just one storage element (latch, SR flip flop or whatever) to implement the motor starter of Figure 16.43.

Figure 16.44 is a more complex example (based on a real silo). A preset weight of material is fed into a weigh hopper ready for the next discharge, which is initiated by a

Discharge pushbutton. A hood then lowers (to reduce dust emissions) and the material discharges. After the discharge, the hood retracts and the weighhopper re-fills. An abort pushbutton stops a discharge, and a feed permit switch stops the feed.

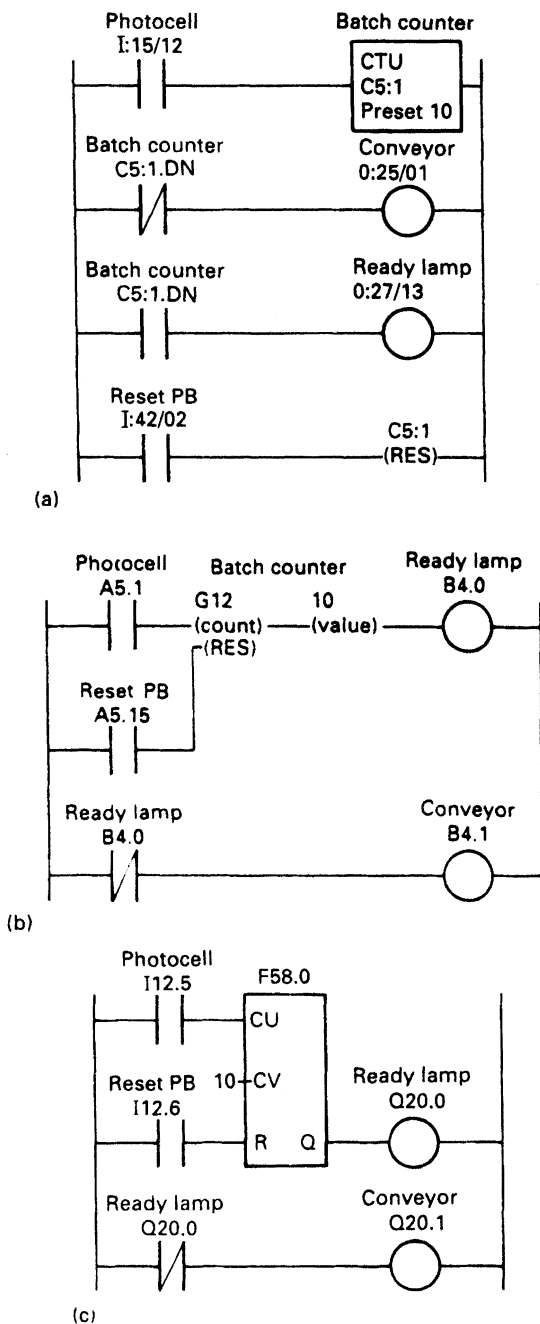

There are two fault conditions; failure to get the batch weight in a given time (probably caused by material jamming in the feeder) and failure to get zero weight from the discharge (again in a given time and again probably caused by a material jam). Both of these trip the system from automatic to manual operation to allow the cause of the fault to be determined.

We can now draw the state diagram of Figure 16.44(b). The default state is the state that the system will enter from manual, and care needs to be taken in its selection. Here feed is the sensible choice; if the hopper is already full the system will immediately pass to state 1 (ready), if not, the hopper will be filled. The choice of any other state as default could lead to a wasted cycle through all the states with no material in the weigh hopper.

We can now construct a table linking the outputs to the states. This is straightforward and is given on Figure 16.44(c).

The next stage is to translate this state diagram into a PLC program. The programming method relies very much on the idea of the program scan, described earlier in Section 16.2.4. By breaking down the program for our state diagram into four areas as Figure 16.45 we can control the

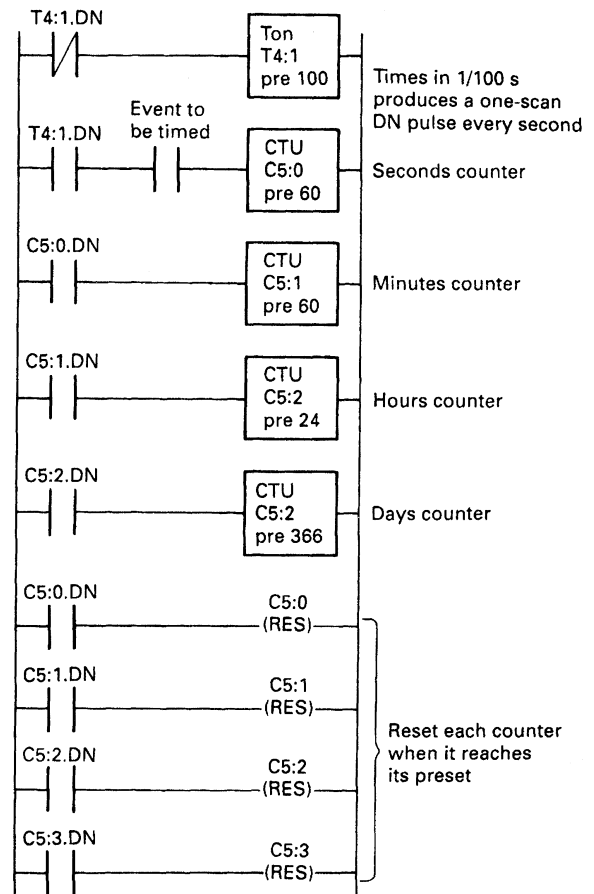

**Figure 16.38** A simple batch counter programmed on three different machines: (a) Allen Bradley PLC-5; (b) GEM-80; (c) Siemens S5 in logic notation

order in which each stage operates. The actual layout is not critical, but it is essential for transitions and states to be kept separate and not mixed.

Automatic/manual selection comes first, this is achieved with the simple rung of Figure 16.46. Automatic mode is only allowed if there are no faults and the hood is raised.

**Figure 16.39** Cascading counters to give a long delay. Allen Bradley PLC-5 notation has been used

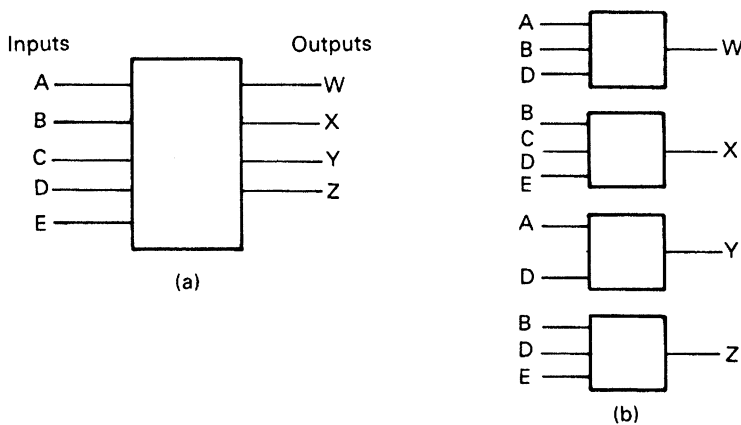

Next come the transitions, some of which are shown on Figure 16.47. These are straightforward and need little comment. Note that the first contact in each rung is a state, so inputs are only examined at the correct point in a sequence.

Some of the states themselves are given in Figure 16.48. With the exception of state 0, simple latches have been used throughout for the states and the auto/man selection so that after a power failure the system will resume in manual mode. Note that these are set and reset by the transitions.

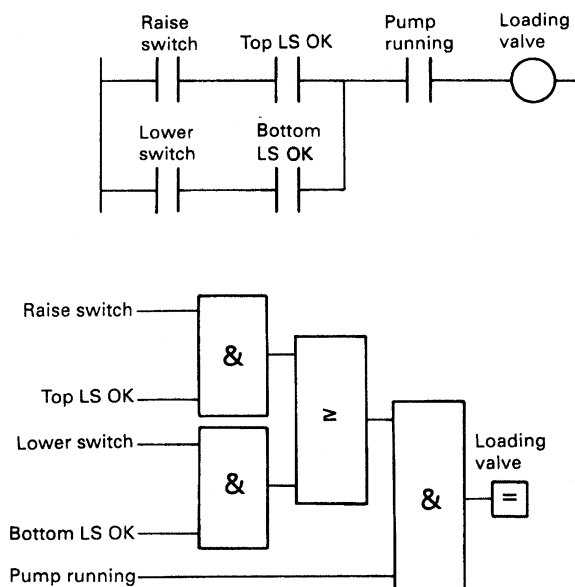

Finally we have the outputs themselves on Figure 16.49. An output is energised during the corresponding state(s) in automatic or from the manual maintenance push button in manual.

The state diagram technique is very powerful, but it can lead to confusion if the basic philosophy is not understood. The often quoted argument is it takes more rungs or logic elements than a direct approach programmed around the outputs.

This is true, but programming around the outputs can lead to very twisted and difficult to understand programs. Figure 16.50 is one rung roughly corresponding to state 2 of our state diagram. It mixes manual and automatic operation and its action is by no means clear (known colloquially as *Spaghetti programming*). Problems can arise where transitions go against the program scan as transition E on the earlier Figure 16.44(b). If care is not taken, a sequence based

**Figure 16.40** Combinational Logic: (a) top level view; (b) broken down into smaller blocks, each with one output, for programming

**Figure 16.41** Combinational logic in ladder and logic notations. Both perform the same function

purely on outputs can easily end up doing two things at once, or nothing at all because of the way the program scan operates. Modifications are also tricky with a direct approach, but simple with a state diagram.

State diagrams are being formalised by the International Electrotechnical Commission and the British Standards Institute, and already exist with the French Standard Grafset. These are basically identical to the approach outlined above, but introduce the idea of parallel routes which can be operated at the same time. Figure 16.51(a) is called a *divergence*, state 0 can lead to state 1 for condition *s* OR to state 2 for condition *t* with transitions *s* and *t* mutually exclusive. This is the form of the state diagrams described so far.

Figure 16.51(b) is a *simultaneous divergence*, where state 0 will lead to state 1 AND state 2 simultaneously for transition *u*. States 1 and 2 can now run further sequences in parallel.

Figure 16.51(c) again corresponds to the state diagrams described earlier, and is known as a *convergence*. The

sequence can go from state 5 to state 7 if transition *v* is true OR from state 6 to state 7 if transition *w* is true.

Figure 16.51(d) is called a *simultaneous convergence* (note again the double horizontal line) state 7 will be entered if the left-hand branch is in state 5 AND the right-hand branch is in state 6 AND transition *x* is true.

The state diagram is so powerful that most medium size PLCs include it in their programming language in one form or another. Telemecanique give it the name Grafset (with a 'c'), others use the name Sequential Function Chart (SFC) (Allen Bradley) or Function Block (Siemens). We will return to these in the next chapter.

Even the simple Mitsubishi F2 supports state diagrams with its STL (Stepladder) instruction. These have the prefix S and can range from S600 to S647. They have the characteristic that when one or more are set, any others energised are automatically reset. A RET instruction ends the sequence. The state diagram of Figure 16.52(a) thus becomes the ladder diagram of Figure 16.52(b).

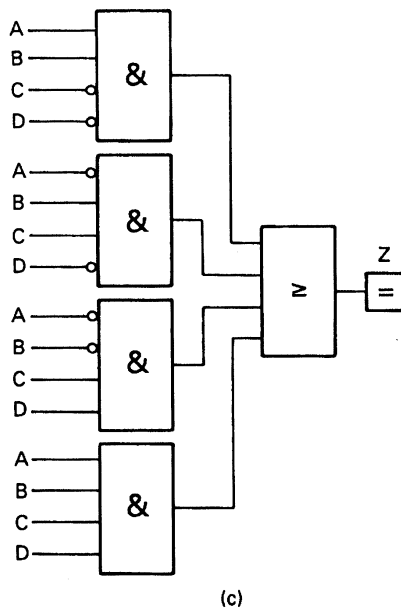

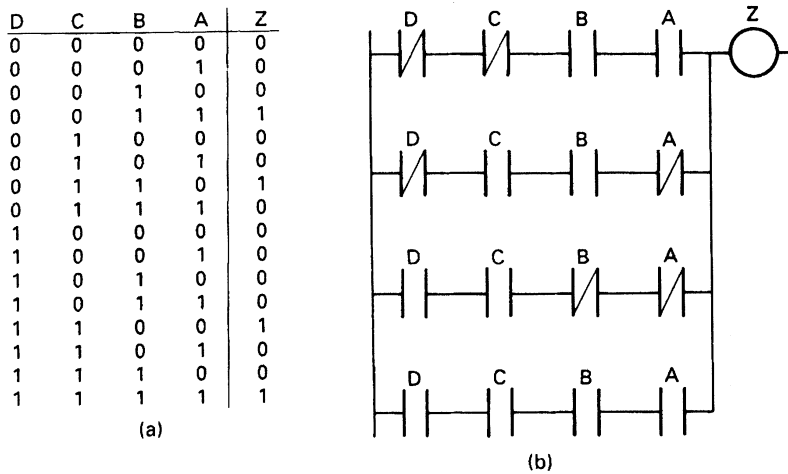

Where there are no branches and the sequence is a simple ring (operating rather like a uniselector) a sequence can be driven by a counter which selects the required step. The counter is stepped when the transitions for the current step are met. The GEM-80 has a SEQ (sequence) instruction which acts as a sixteen step uniselector.

### 16.3.11 IEC 1131

We have seen that PLCs can be programmed in several different ways. In recent years the International Electrotechnical Commission (IEC) have been working towards defining standard architectures and programming methods for PLCs. The result is IEC 1131, a standardised approach which will help at the specification stage and assist the final user who will not have to undergo a mind-shift when moving between different machines.

The earliest, and probably still the commonest, programming method described is the *Ladder Diagram* (or LD in IEC 1131).

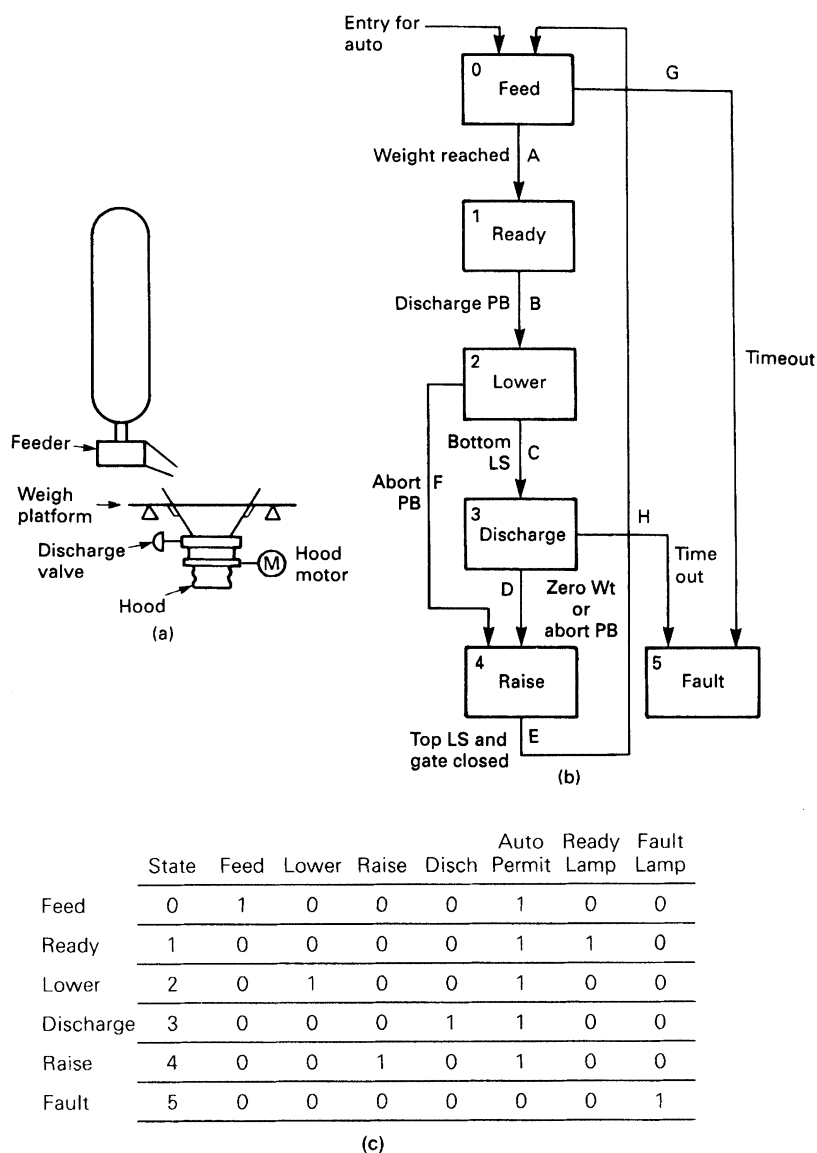

*Function Block Diagrams* (FBDs) use logic gates (AND/OR etc.) for digital signals and numeric function blocks (arithmetic, filters, controllers, etc.) for numeric signals. FBDs are similar to PLC programs for the ABB Master and Siemens SIMATIC families. There is a slight tendency for digital programming to be done in LD, and analog programming in FBD.

**Figure 16.42** Building combinational logic from a truth table: (a) truth table; (b) Direct conversion to a ladder program. Each row in the truth table which makes  $Z = 1$  is represented by one level on the branch; (c) Direct conversion to a logic diagram. Each row in the truth table which makes  $Z = 1$  is represented by an AND gate. The AND gate outputs are then OR'd together

**Figure 16.43** A simple state transition diagram; (a) A motor starter; (b) State transition diagram. Note that with no buttons pressed the system can be in either state

**Figure 16.44** A more complex state transition diagram for a real plant: (a) physical layout; (b) state transition diagram; (c) output table

Many control systems are built around state transition diagrams, and IEC 1131-3 calls these *Sequential Function Charts* (SFCs). The standard is based on the French Grafcet standard shown earlier on Figure 16.51.

Finally are text based languages. *Structured Text* (ST) is a structured high level language with similarities to Pascal and C. *Instruction List* (IL) contains simple mnemonics such as LD, AND, ADD etc. IL is very close to the programming method used on small PLCs where the user draws a program up in ladder form on paper, then enters it as a series of simple instructions.

Figure 16.53 illustrates all of these programming methods.

A given project does not have to stick with one method, they can be intermixed. A top level, for example, could be an SFC, with the states and transitions written in ladder rungs or function blocks as appropriate.

It will be interesting to see the effect of IEC 1131-3. Most attempts at standardisation fail for reasons of national and commercial pride. MAP, and latterly fieldbus, have all had problems in gaining wide acceptance. A standard will be useful at the design stage, and could be accepted by the end user if programming terminals presented a common face regardless of the connected machine.

## 16.4 Numerics

### 16.4.1 Numerical applications

So far we have been primarily discussing single bit operations. Numbers are also often part of a control scheme; a PLC might need to calculate a production rate in units per

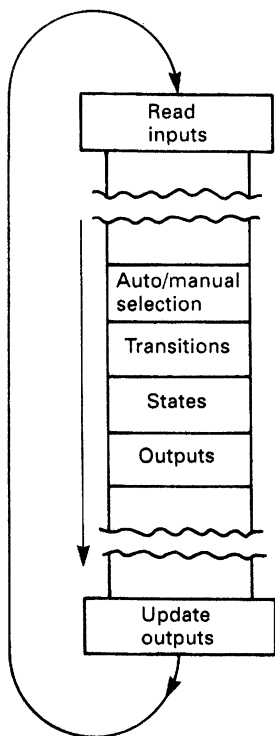

Figure 16.45 The program scan and the layout of a state transition diagram program

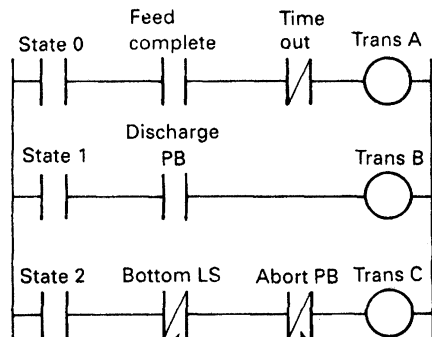

Figure 16.46 Auto/manual selection

Limit switch normally made, opens when struck

Included so that in unlikely case of Bottom LS and Abort arriving together, abort (Trans F) will win

Figure 16.47 The first three transitions

hour averaged over a day, or give the amount of liquid in a storage tank. Such operations require the ability to handle numeric data.

### 16.4.2 Numeric representations

Most PLCs work with a 16 bit word, allowing a positive number in the range 0 to +65 535 to be represented, or a signed (positive or negative) number in the range -32 768 to +32 767. In the latter case, known as *two's complement*, the most significant bit represents the sign, being 1 for negative numbers and 0 for positive numbers.

Numbers such as these are known as integers, and can only represent whole numbers in the above range. Where larger whole numbers are required, two sixteen words can be used allowing a range -2 147 483 648 to +2 147 483 647. This type of integer is available in the ABB Master (where it is known as a *long integer*) and the 135-U and 155-U in the Siemens family (where the term *double word integer* is used).

Where decimal fractions are needed (to deal with a temperature of 45.6°C for example) a number form similar to that found on a calculator may be used. These are known as *real* or *floating point* numbers, and generally consist of two sixteen bit words which contain the *mantissa* (the numerical portion) and the *exponent*. In base ten, for example, the number 74057 would have a mantissa of 7.4057 and an exponent of 4 representing  $10^4$ . PLCs, of course, work in binary and represent mantissa and exponent in two's complement form.

Real numbers are very useful but their limitations should be clearly understood. There are two common problems. The first occurs when large numbers and small numbers are used together. Suppose we had a system operating to base ten with four significant figures, and we wish to add 857 800 (stored as 8.578E5) and 96 (stored as 9.600E1). Because the smaller number is outside the range (four significant figures) of the larger, it will be ignored giving the result  $857\,800 + 96 = 857\,800$ .

The second problem occurs when tests for equality are made on real numbers. The conversion of decimal numbers to binary numbers can only be made to the resolution of the floating point format. If real numbers must be used for comparison, a simple equates ( $=$ ) is very risky. The comparatives  $>=$ , (greater than or equals), and  $<=$ , (less than or equals), are safer, but it is generally better practise to use integers for tests if at all possible.

The final representation, BCD for *Binary Coded Decimal*, is used for connection to outside world devices such as digital displays or thumbwheel switches. Such devices are arranged in a decimal format, with 4 binary bits per decade, for example

1 0 0 1 0 1 0 1

can be interpreted in BCD as 95.

This representation is wasteful, as six 'numbers' are not used per four bits (10 to 15 inclusive). It is, however, a convenient form to use with external wiring. Most PLCs therefore have instructions which convert BCD to the internal binary format of the PLC, and binary back to BCD.

The types of numbers available in each PLC range vary considerably according to the model (and obviously the price). The Mitsubishi F2, for example, purely allows movement, comparison and output of numerical data from counters or timers, making it essentially a bit operation machine.

In the Siemens range, the popular 115-U uses only 16 bit integer numbers but the next model in the range, the 135-U,

Figure 16.48 Three of the six states

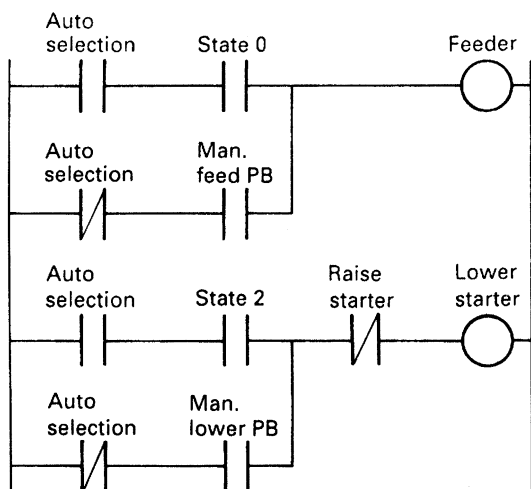

Figure 16.49 Two of the plant outputs

can handle 16 bit and 32 bit integers and floating point numbers. A similar spread of capabilities will be found amongst the Allen Bradley, GEM-80 and ABB families.

### 16.4.3 Data movement

Numbers are often moved from one location to another; a timer preset may be required to be changed according to plant conditions, a counter value may need to be sent to an output card for indication on a digital display or the result

of some calculations may be used in another part of a program.

The Allen Bradley PLC-5 uses one rung per move operation, and is possibly the simplest to explain first. Its simplicity of one rung per operation is continued in all the arithmetic functions we shall consider, but it can lead to more rungs being used for a given operation than in other machines.

Figure 16.54(a) shows the form of the rung. It starts with some binary conditions; if these are all made the output MOV (for MOVE) is obeyed, transferring data from the source to the destination. The source and destination can be any location where numerical data can occur, for example

Integer number (e.g. N7 : 26)

Floating point number (e.g. F8 : 33)

Counter or timer preset (e.g. C5 : 17 . PRE or T4 : 52 . PRE)

Counter or timer accumulated value (e.g. C5 : 22 . ACC or T4 : 6 . ACC)

I/O word data (e.g. I : 23 which is all 16 bits from inputs on card 3 in rack 2)

If data is transferred between integer and floating point forms, the conversion is performed automatically however care must be taken transferring floating point numbers to integers as an error can occur if the floating point number is outside the integer range. Finally, as a source only, a constant (such as 3, 17 or 4057) can be used.

The example of Figure 16.54(a) thus moves the number held in N7 : 34 to the preset of timer T4 : 6 when the rung conditions are met.

Siemens and GEC use a slightly different approach which leads to more compact programs. Both treat a data movement

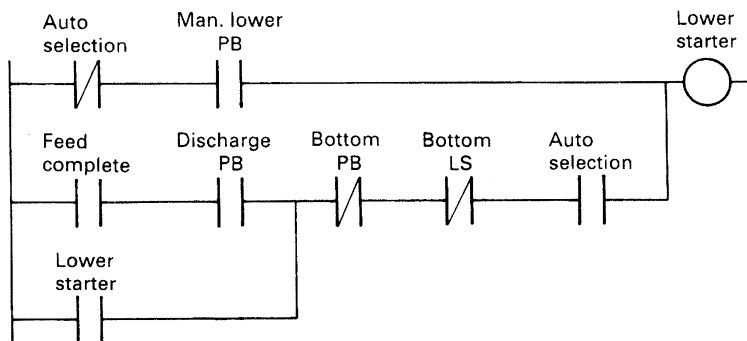

Figure 16.50 An example of spaghetti programming approximating to state 2

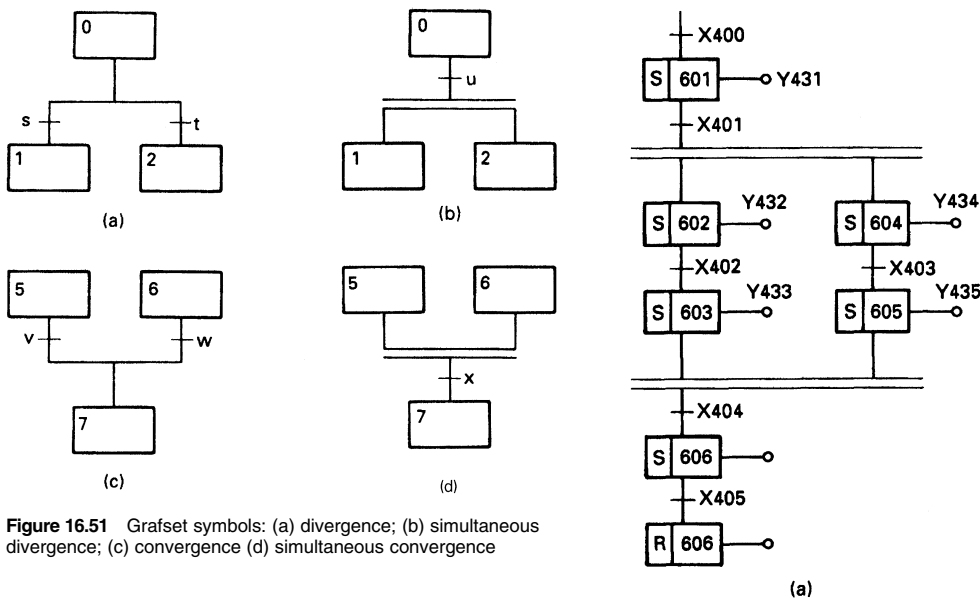

Figure 16.51 Grafset symbols: (a) divergence; (b) simultaneous divergence; (c) convergence (d) simultaneous convergence

as two separate instructions via a separate accumulator (a single word storage location). Siemens use the instructions load to move data from a source to the accumulator, and transfer to move data from the accumulator to the destination as Figure 16.54(b). The data can come from (or go to) any data storage area, some of which are

IW	a 16 bit input word
QW	a 16 bit output word
T	a timer word
C	a counter word
DW	a 16 bit data storage word

Figure 16.54(b) would thus be programmed as

```
:L T113 (timer value to accumulator)
:T DW45 (accumulator to data word 45)
```

The use of the accumulator is not obvious in the GEM-80. The-<AND>- instruction puts the binary number from the specified location (again internal storage or

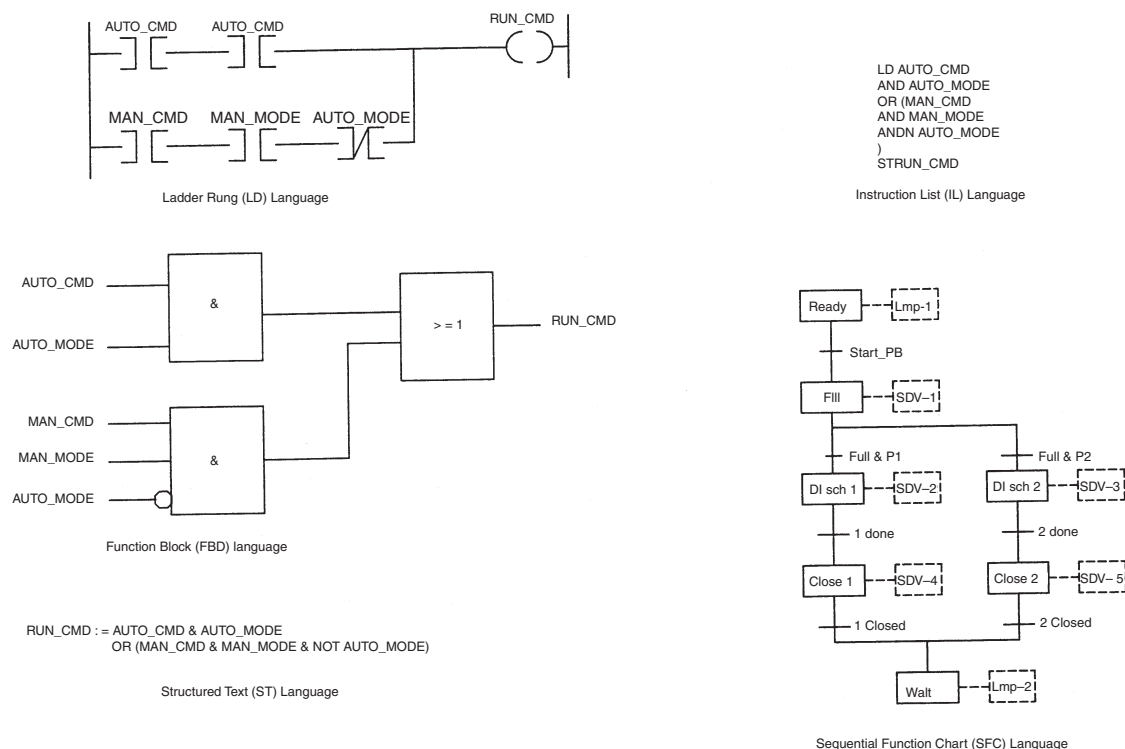

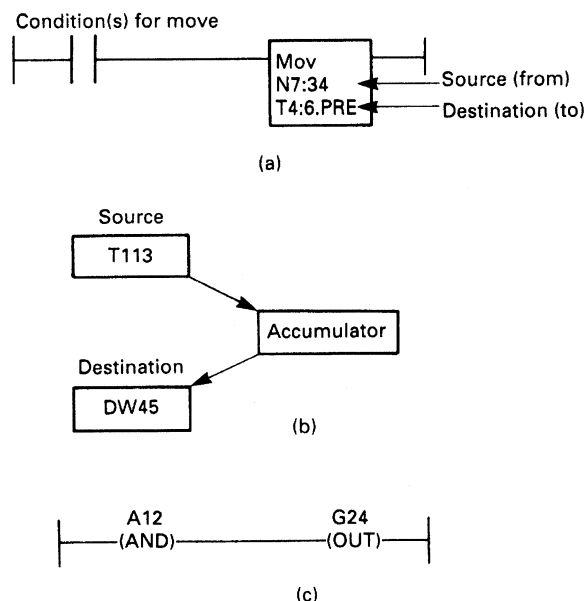

Figure 16.52 State diagrams on the Mitsubishi F2: (a) state diagram; (b) part of the ladder diagram corresponding to (a)

**Figure 16.53** The five programming methods defined in IEC 1131-3

**Figure 16.54** Data Movement: (a) Allen Bradley PLC-5; (b) Siemens S5; (c) GEM-80

I/O) into the rung, and the  $\text{--<OUT>--}$  instruction puts the value from the rung to the specified address. In *Figure 16.54(c)* the (binary) value from 16 bit input word A12 is placed into 16 bit storage word G24.

BCD/binary conversion is available with  $\text{--<BCDIN>--}$  and  $\text{--<BCDOUT>--}$  instructions, the direction of the conversion being obvious.

In the ABB Master, the points between which data is to be transferred are simply linked on the logic diagram.

#### 16.4.4 Data comparison

Numerical values often need to be compared in PLC programs; typical examples are a batch counter saying the required number of items have been delivered, or alarm circuits indicating, say, a temperature has gone above some safety level.

These comparisons are performed by elements which have the generalised form of *Figure 16.55*, with two numerical inputs corresponding to the values to be compared, and a binary (on/off) output which is true if the specified condition is met.

Many comparisons are possible; most PLCs provide

A Greater Than B	(A>B)
A Greater Than or Equal to B	(A>=B)
A Equals B	(A=B)
A Less Than or Equal to B	(A<=B)
A Less Than B	(A<B)

where A and B are numerical data. With real (floating point) numbers the equal test should be avoided for the reasons given in the previous section. There are many other possible comparisons; a PLC-5, for example has a limit instruction which tests for A lying between B and C and the GEM and Siemens have a not equal test.

Figure 16.55 Basic idea of data comparison

(a)

(b)

Figure 16.56 Use of data comparison for a high temperature alarm: (a) Allen Bradley PLC-5; (b) Siemens S5 in logic notation

Figure 16.56 shows the setting and resetting of an alarm flag B3/21 (for a PLC-5 ladder diagram) and F21/02 (for Siemens logic symbols). The alarm bit is set if temperature (read from an analog input card in format NN.N°C and held in N7:15 in the PLC-5 or DW42 in the Siemens 115-U) goes above 50.0°C. Once set, the alarm is stored until the temperature goes below 40.0°C.

### 16.4.5 Arithmetical operations

Numerical data implies the ability to do arithmetical operations, and all PLCs we are considering (apart from the simple F2) provide the ability to do at least four function maths (add, subtract, multiply and divide).

In Section 16.4.2 we discussed integer and floating point numbers. Care needs to be taken with integer operations. The range of a 16 bit two's complement number is -32 768 to +32 767. If an arithmetical operation goes outside this range, the number will overflow, for example

```
26732
+ 8647
-----
-30157          in 16 bit two's complement
```

which is not quite the expected result. The PLCs have an overflow flag which can be examined and used to flag an

alarm, or set the result to, say, zero with a move instruction. Similar precautions need to be taken with subtraction and multiplication (the latter being particularly vulnerable to giving an overflow; for example  $200 \times 200 = 40\,000$ , well over-range.)

Even greater care needs to be taken with division. A fault condition on external plant or a PLC input card or a programming error can lead to a divide by zero error. This will stop many PLCs dead in their tracks with a 'Program Fault'. It is therefore good practice to precede any vulnerable divide instruction with a limit check to ensure it will only be obeyed when a sensible result is obtained.

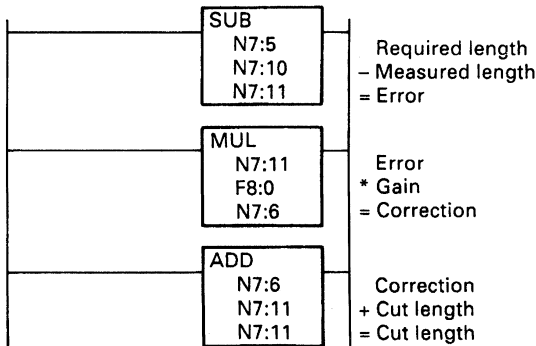

Each PLC manufacturer handles arithmetic in a slightly different way with varying degrees of ease and readability. None are as simple as a high level language such as BASIC or Pascal, and the facilities are generally limited to four function maths plus square root in all but the most expensive machines.

A PLC-5 uses maths blocks such as ADD, SUB, MULT, DIV, giving a simple, if somewhat lengthy, program. Figure 16.57 shows how a simple calculation could be performed for a self correcting length cutting program. More powerful PLC-5s (such as the 5-40) have a block compute instruction (CPT) which allows a mathematical expression to be evaluated in a single instruction.

The 115-U only evaluates arithmetic instruction in STL (statement list) format. It will be remembered from our discussion of the accumulator that the load, (L) and transfer (T) instructions use an internal accumulator. There are, in fact, two accumulators, and a load instruction moves the contents of accumulator 1 to accumulator 2 then moves the contents of the source to accumulator 1, shown in Figure 16.58(a). An arithmetic instruction (add, subtract, etc.) works on the contents of both accumulators. Figure 16.58(b), thus adds two numbers and transfers the result to storage.

The Siemens equivalent of Figure 16.57 would be

```
L DW30      (required length)
L DW31      (measured length)
SUB         (leaving error in Acc 1)
L DW32      (gain)
MULT        (leaving correction)
L DW40      (the old cut length)
ADD         (add change to give new length)
T DW40      (put back to store)
```

In high level language  
Cut length = Gain \* (required length - measured length) + cut length

Figure 16.57 Arithmetic in the PLC-5

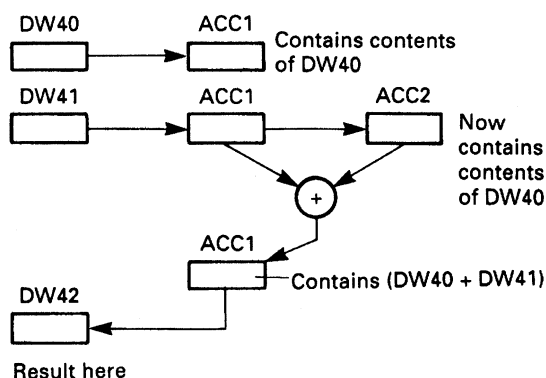

Figure 16.58 Arithmetic in a Siemens S5

The most understandable form of representation is possibly the GEM-80 ladder and the ABB Master formats shown in Figure 16.59(a) and (b) respectively.

All maths operations, particularly those involving floating point numbers, are time consuming, and it is good programming practice to only obey instructions when they are needed, and not waste time repetitively obeying them on every PLC scan.

#### 16.4.6 Analog signals

So far we have considered signals that are essentially digital (on/off) in nature plus simple numerical data from timers and counters. Often, though, a PLC will be required to measure,

or control, plant signals which can assume any value in some predetermined range. Typical signals of this type are temperatures, flows, pressure, speeds etc. These are known as analog signals. In a similar way a PLC may have to produce analog output signal to drive meters and proportional valves or provide a speed reference for a motor drive controller.

To meet these requirements a PLC needs analog input and output cards. These have somewhat different characteristics to the simple digital cards we have discussed so far. This section considers analog signals and the way they are handled.

An analog input card converts a continuously varying analog signal to a digital form that can be used inside a PLC program. The analog signal is generally represented initially, at least, as an integer number.

This analog to digital conversion (usually known by the initials ADC) is inherently accompanied by a loss of resolution which depends on the number of bits used. An 8 bit byte for example, can represent an integer in the range 0–255. If this was used to represent an analog signal measuring a flow with a span (range) from 0–1800 l/min, one bit will represent approximately 7 l/min (given by  $1800/255$ ). Any control strategy in the program based on finer resolution is meaningless (and particular care should be taken with comparisons, as some values can never be obtained; a flow of 138 l/min, for example, would never be given by our 8 bit system, it would jump from 134 l/min to 141 l/min. Comparisons should therefore always be based on (greater than or equal to) or (less than or equal to)).

A commoner resolution is 12 bits. This gives a representation as an integer from 0–4095. With our flow of 0–1800 l/min, one bit would represent just under 0.5 l/min ( $1800/4095 = 0.44$ ).

This 'coarseness' is not the problem it might at first appear. Although an analog transducer can give any value

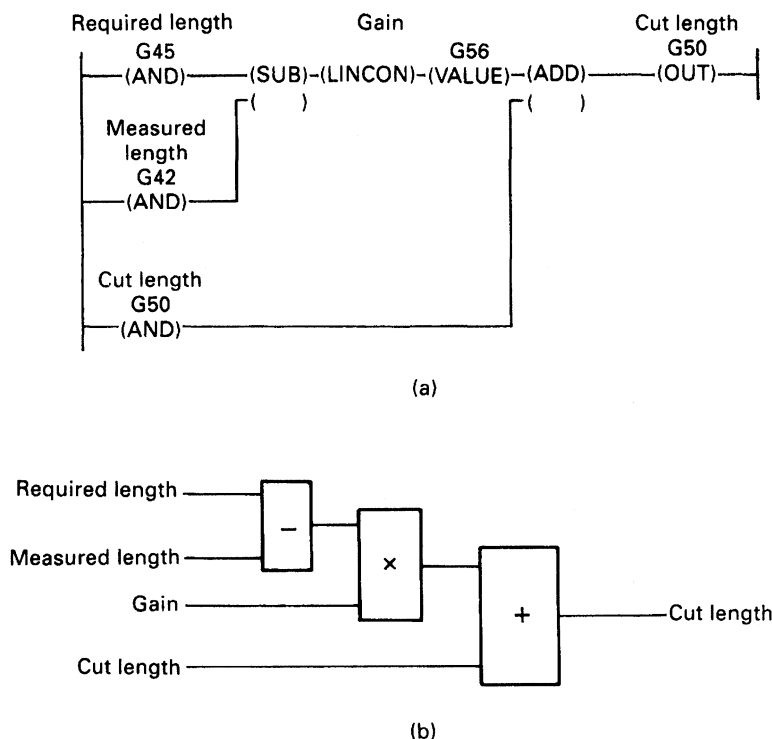

Figure 16.59 The same mathematical function in a GEM-80 and ABB Master: (a) GEM-80 program. LINCON is an arithmetic function used to avoid truncation errors with integer arithmetic; (b) ABB master program using function blocks. Variables are accessed by database names

**Figure 16.60** The effect of the sampling rate

in its span, it will have inherent errors. Many first line transducers are only 2% accurate. If our flow transducer had 2% accuracy, its measurement could be in error by 36 l/min. Alongside this error, the 7 l/min resolution from an eight bit card is probably quite reasonable.

It is therefore useful to think of the resolution in terms of an error which is to be added to the error from the transducer itself

No of bits	Range	Error
8	0-255	0.5%
10	0-1023	0.1%
12	0-4095	0.025%

Few industrial transducers have an accuracy better than 0.1%, and a 12 bit conversion will add little error in most applications.

The conversion from an analog signal to a digital representation is not instantaneous. Typically signals are read ten times per second. An analog input card thus takes regular 'snapshots' of each analog signal. In *Figure 16.60(a)* this causes no problems, in *Figure 16.60(b)* information is starting to be lost and in *Figure 16.60(c)* a totally false view of the signal is being given. This latter effect is known as 'aliasing'.

It is therefore very important to have a sufficiently fast conversion time. Every analog signal will have a maximum frequency at which it can change, and can be represented by a gain/frequency plot as *Figure 16.61* from which the bandwidth and the critical frequency  $f_c$  can be observed. To get a true series of 'snapshots' we must sample the signal at least twice the rate of  $f_c$ . If a certain analog signal has a maximum frequency of 2 Hz, we must at least sample it at 4 Hz, or once every 250 ms. This, somewhat simplified, is known as *Shannon's sampling theorem*. In real systems,  $f_c$  is rarely known precisely and a scan rate of  $4 f_c$  to  $10 f_c$  is normally chosen to give a reasonable safety margin. For our 2 Hz signal, an 8 Hz sampling rate or 12.5 ms conversion time, would be needed. It is good practice to pass the signal through a low pass filter before the ADC to ensure frequencies above  $f_c$  are removed. This is known as an *anti-aliasing filter*.

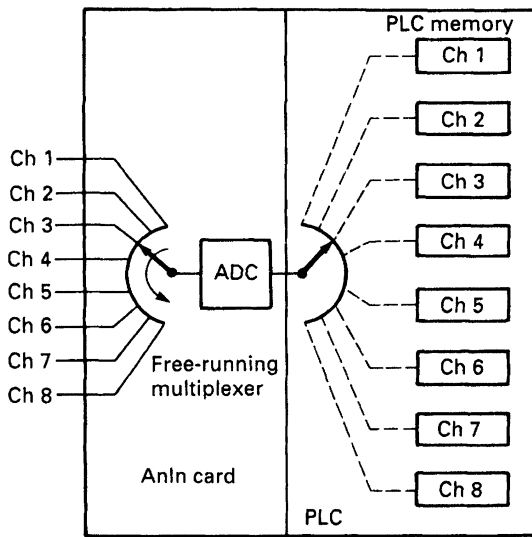

**Figure 16.61** Gain/frequency response for an industrial process

Surprisingly this rarely gives problems. Practical industrial systems, dealing with real plant signals concerned with materials with significant mass, rarely have bandwidths greater than 0.5 Hz, and any frequency higher than this can be considered to be extraneous noise and filtered out. Temperature loops, for example, can often be sampled as slowly as once every few minutes without introducing any errors.

A typical analog input card can read eight 12 bit signals, each ranging from 0-4095 in their 'raw' form. Generally these will need to be accessed via the PLC program and converted to engineering units such as °C, or psi, or l/min.

A common method of handling these signals, is shown in *Figure 16.62*. A block of storage locations in the PLC store is directly associated with the analog input card. The card 'free runs', writing digitised values into the store from where they can be read by the rest of the program. In Siemens PLCs with fixed slot addressing, for example, the store addresses are determined directly by the analog card position in the rack; a card in slot 2 of the first rack will write its values to a block of stores starting at location 192.

Conversion from a raw 12 bit signal to engineering units can have subtle traps for the unwary. In theory the conversion is simple. If  $N$  is the raw signal,  $H_R$  the high range

**Figure 16.62** Linking channels on an analog input card to a PLC's memory

signal (corresponding to 4095) and  $L_R$  the low range (corresponding to zero) then the measured value,  $M_V$  is simply

$$M_V = \frac{N \times (H_R - L_R)}{4095} + L_R \quad (16.1) \Leftarrow$$

If the calculation is done with real (floating point) numbers there should be no problem, and Equation 16.1 can be used directly.

If, however, integer numbers have to be used, great care must be taken. If the multiplication  $N \times (H_R - L_R)$  is performed first, arithmetic overflow is likely unless 32 bit results can be accommodated. If the division  $N/4095$  is performed first, the equation will not work as  $N$  is always less than 4095 giving an integer result of zero (and an  $M_V$  of  $L_R$ ). Wherever possible real numbers should be used if Equation 16.1 has to be performed.

To avoid this problem, the different manufacturers have devised methods to read analog input signals. In the ABB Master for example, the database for each signal defines  $H_R$ ,  $L_R$ , the sample rate and a name by which the signal will be referred to in the program. There are, obviously, detail differences, so by way of example we will look at the way analog signals are read by an Allen Bradley PLC-5.

The Allen Bradley PLC-5 reads analog signals with an analog input card (1771-IFE) which can in its simplest form, read 8 analog inputs. The PLC communicates with the card via instructions called block transfers which transfer data to (or from) a block of store locations. Data transfers from the PLC to a card are called block transfer writes (BTW) and, not surprisingly, transfers from a card to the store are block transfer reads (BTR). For each type of instruction, somewhat simplified, the programmer states:

- The direction of transfer (BTW or BTR).
- The card address (rack, slot and slot half, left or right).
- The store location start address where the data is to be received.
- The number of 16 bit words to be transferred.

The analog input card uses both BTW and BTR instructions, the BTW being used once, after power up, to configure

**Figure 16.63** The PLC-5 block transfer write (BTW) and block transfer read (BTR) instructions

the module and the BTRs subsequently to read the data as summarised in Figure 16.63.

The post power up BTW sets how the module is to behave; whether it gives data in binary or BCD and the minimum and maximum values for the input range ( $H_R$  and  $L_R$  in Equation 16.1) on each channel. The card uses these to return readings in engineering units (in 12 bit binary integer or two's complement format or 12 bit BCD).

Once set up, values can be read at the required time intervals with a BTR. This gives signal values in the specified store locations along with over-range and similar alarms. The values can then be used elsewhere in the program.

PLCs are often required to provide analog output signals. Like analog inputs, these signals have standard voltage ranges of 1–5 V or 0–10 V or the current range of 4–20 mA.

A typical analog output card, for example, is the Allen Bradley 1771-OFE which has four output channels, each turning a 12 bit (0–4095) digital signal into an analog output. Isolation amplifiers are used on the outputs to reduce the effects of noise and allow the signals to connect into external devices fed from different electrical supplies. The digital signals come from storage locations inside the PLC as shown on Figure 16.64. This conversion is known as *Digital to Analog conversion*, or DAC.

For best resolution the PLC should use the full 0–4095 range, but this is frequently impossible. If the PLC, for example, is setting the speed range of a motor from 0–1350 rpm, it will need to convert 0–1350 into the range 4–20 mA. Equation 16.1 can be re-arranged as

$$X = \frac{4095(N - L_R)}{H_R - L_R} \quad (16.2) \Leftarrow$$

where  $X$  is the value passed to the DAC (in the range 0–4095).  $N$  is the output number from the PLC in engineering units, and  $H_R/L_R$  are the high and low range values. As before, great care must be taken with Equation 16.2 to avoid overflow or loss of resolution.

The PLC-5 communicates with the 1771-OFE with the BTW instruction described previously. The programmer sets up a block of twelve words, the first four of which contain the values, and the balance the set up data such as  $H_R$  and  $L_R$ . The block of data is then written to the card with a BTW. Figure 16.65 shows a typical example where an analog speed reference can be raised or lowered by operator controlled pushbuttons. Note the use of greater than (GTR) and less than (LES) instructions to confine the counter value within the allowed range of 0–1350 rpm.

Ranging as above allows engineering units to be used inside the program, the counter in Figure 16.65, for example, holds the required speed directly in rpm, but this is accompanied by a loss of resolution as explained earlier. For the range 0–1350 rpm, we have a resolution of about 0.1%, compared with the theoretical 0.025% resolution available from the card.

Figure 16.64 Analog output signals

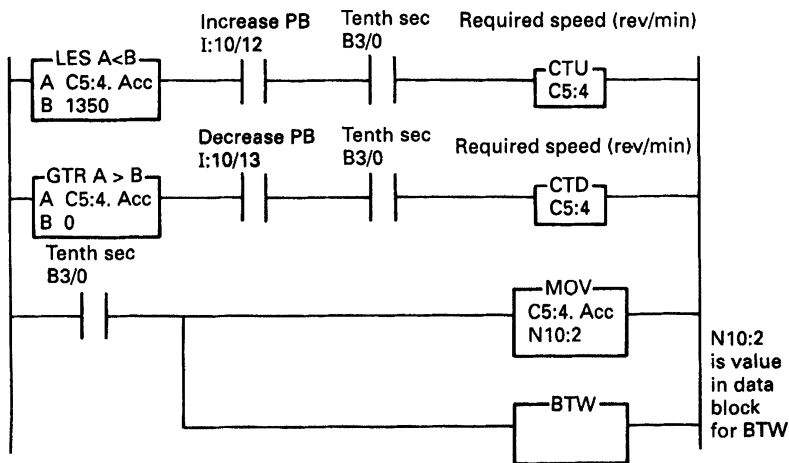

Figure 16.65 Setting the speed for a motor with a counter and an analog output card

There are other operations that can be performed on analog signals. A typical list, for the GEM-80, is

SQRT	Square root, mainly used with signals from orifice plates.
LINCON	Performs $X*(A/B) + C$ with limiting.
FGEN	Multipoint straight-line function generator used for linearisation as Figure 16.66(a).
LIMIT	Performs limiting of signals as shown on Figure 16.66(b).
RAMP	Rate limiting (with different rise and fall rates).
DEDBAND	Deadband functions as Figure 16.66(c). Useful for preventing 'dither' in closed loop control when PV and SP are close.
ANALAG	First Order lag. Used for filtering.

A simple first order filter can be produced by any PLC which supports floating point numbers using the procedure shown on Figure 16.67(a). This procedure uses just three rungs or three function blocks and is obeyed for one program scan at regular time intervals  $\Delta t$ .  $V_i$  is the raw input signal and  $V_f$  is the filtered output signal.  $V_{f(n-1)}$  is the filtered value obtained on the previous execution  $\Delta t$  seconds ago. The error between  $V_i$  and  $V_{f(n-1)}$  is calculated ( $V_e$ ) then multiplied

by a gain  $K$  to give a change  $V_c$ . This is added to  $V_{f(n-1)}$  to give the new filtered value  $V_f$ . Figure 16.67(b) shows the response for a step change in  $V_i$  with  $K$  set at 0.25. At each execution of the routine  $V_f$  moves 25% of the difference between  $V_i$  and  $V_{f(n-1)}$ . The gain,  $K$ , determines the apparent time constant and must be in the range  $0 < K < 1$ . The gain  $K$  should be set to  $\Delta t/T$  where  $T$  is the required time constant.

#### 16.4.7 Closed loop control

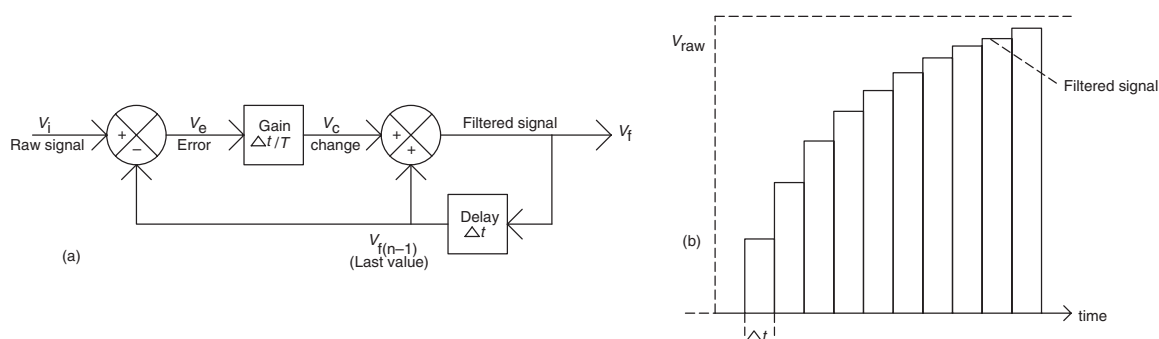

A closed loop system based on PLCs will be similar to Figure 16.68. The plant variable,  $P_v$ , is read by an analog input card, and the output  $O_p$  provided by analog output cards. The setpoint, SP, is provided by the operator or by some program sequence. The PID algorithm is then provided by the program. Chapter 13 gives more detail on the theory of closed loop control and an explanation of the PID algorithm.

It is possible to write PID algorithms with four function (+ - \*) mathematics, but it needs great care. The program scan time must be known for the integral and derivative routines, and protection against output actuator saturation must be built in to overcome an effect called integral wind-up.

PLCs, are becoming increasingly powerful, and most medium range PLCs now provide a three term PID function in

**Figure 16.66** GEM-80 special functions for use with analog signals: (a) FGEN with  $N$  points at equal intervals  $x$ ; (b) LIMIT, high and low limits can be different; (c) DEDBAND without and with offset

**Figure 16.67** Programming a first order filter: (a) schematic diagram; (b) response to step input

their instruction set. Figure 16.69 shows a ratio temperature control program written for an Allen Bradley PLC-5 processor.

These three rungs are controlling the temperature in a furnace, with the temperature PID block controlling the air valve. The air flow is measured, multiplied by the required ratio and used as the setpoint for the gas PID block.

The control blocks in each PID instruction hold the data and working areas for the PID function; things like auto/man status and the sum for the integral action. The setpoint is written directly into the third word of the control block. The process variable is the feedback signal from the variable being controlled, usually obtained from an analog input card. Settings for gain,  $T_i$  and  $T_d$  are also contained in the control block data.

A three term control algorithm can suffer from integral wind-up in saturation or manual operation. The tieback variable is used to give the current value corresponding to the driven actuator output (possibly after auto/manual changeover) and is used to prevent wind-up and to give bumpless transfer. The control variable is the signal from

the PID algorithm, usually sent to an analog output card via auto/manual changeover logic.

The three rungs of Figure 16.69 mask, to some extent, the work that must be done elsewhere in the program. Data from the outside world must be obtained with analog input cards, and the controller output(s) must be written to the actuators with analog output cards. The timing of these reads and writes must be regular and linked to the PID instructions.

Auto/manual changeover logic will also be required, linked into the PID instructions with the tieback variable and the auto/man status flag (which makes the integral term track the tieback in manual).

The operator will also require a link to the control, so pushbuttons, displays and alarms must be provided. All of this is in addition to the basic PID control.

#### 16.4.8 Intelligent modules

We have so far considered analog input and output modules, which are semi-intelligent (compared to 'dumb' digital

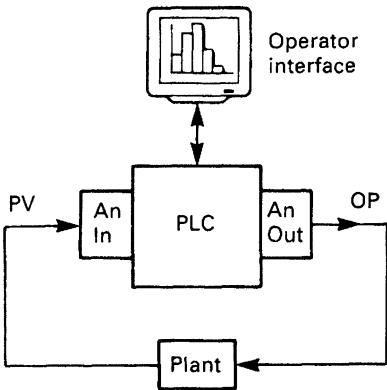

Figure 16.68 Closed loop control with a PLC

input and output cards). These are examples of a more general range of intelligent modules which most manufacturers offer to simplify the designers task.

A typical example is a high speed counter. We saw earlier in Section 16.2.4 that the scan time limits the maximum count rate of a PLC to about 10 Hz. High speed counter cards are available for use where higher count speeds are needed, or the program scan time introduces an unacceptable random error.

In these, the card contains a bi-directional counter which can be directly driven by a pulse encoder. The counter value can be loaded from the PLC, and read back when needed. The PLC can also download a preset value, allowing the counter card to directly drive outputs according to the relationship between the count and the preset.

Other common intelligent modules are bar code readers (for stock tracking), stepper motor controllers (for position control systems) and vision modules (for quality control applications).

Figure 16.69 PID control on an Allen Bradley PLC-5

## 16.5 Distributed systems and fieldbus

### 16.5.1 Introduction

For a true distributed control system we need a method where several PLCs or computers can be linked together to allow communication to freely take place between any member of the system.

To achieve this we need to establish a connection topology, some way of sharing the common network that prevents time wasting contention and an address system that allows messages to be sent from one member to another. Such systems are known as *Local Area Networks* (LAN) or *Wide Area Networks* (WAN) dependent on the size of the area and the number of stations.

### 16.5.2 Transmission lines

Any network will be based, to some extent, on cable, and at the high speeds used there are aspects of transmission line theory that need to be considered. Consider the simple circuit of *Figure 16.70(a)*. At the instance that the switch closes, the source voltage does not know the value of the load at the far end of the line. The initial current step,  $i$ , is therefore determined not by the load, but by the characteristics of the cable (dependent on the inductance and

capacitance per unit length). A line therefore has a *characteristic impedance*, typically  $75\ \Omega$  or  $50\ \Omega$  for coax, and  $120$  to  $150\ \Omega$  for biaxial or screened twisted pair. The initial current step will therefore be  $V/Z$  where  $Z$  is the characteristic impedance.

After a finite time, this current step reaches the load  $R$ , and produces a voltage step  $i \times R$ . If  $R$  is not the same as  $Z$ , this voltage step will not be the same as  $V$ , and a reflection will result. Typical results are shown on *Figure 16.70(b)*.

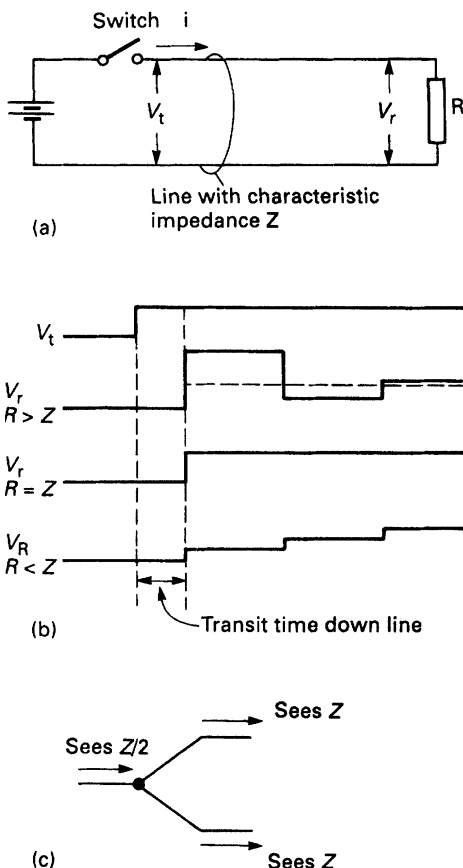

This effect occurs on all cables and is normally of no concern as the reflections only persist for a short time. If, however, the propagation delay down the line is similar to the maximum frequency rate of the signal, the reflections can cause problems. It follows that a transmission line should be terminated by a resistance equal to the characteristic impedance of the line. Normally, devices for connecting onto a transmission line have a high input impedance to allow them to tap in anywhere, with terminating resistors being used at the ends of the line.

A side effect of this is that T connections, or spurs, are not allowed (unless the length of the spur is short). In *Figure 16.70(c)* a T has been formed. To the signal, coming from the left, the two legs appear in parallel giving an apparent impedance of  $Z/2$  and a reflection.

### 16.5.3 Network topologies

From the previous section it should be apparent that any network can sensibly only be based on a ring (which needs no terminating resistors) or a line (with a terminating resistor at each end). *Figure 16.71* is a master/slave system where a common master wishes to receive or send data from/to slave devices, but the slaves never wish to talk to each other. All the slaves have addresses, which allows the master to issue commands such as 'Station 3; give me the value of analogue input 4' or 'Station 14; your setpoint is 751.2'. Such systems are often based on RS422 to provide improved noise immunity and allow longer lengths of line.

The Star network of *Figure 16.72* is again based on a master with a point to point link to individual stations. This arrangement is commonly used for high level computer

**Figure 16.70** Transmission lines and the characteristic impedance: (a) a transmission line; (b) the effect of the terminating resistor; (c) The effect of a 'T' in the line

**Figure 16.71** A Master/slave network

**Figure 16.72** A Star network

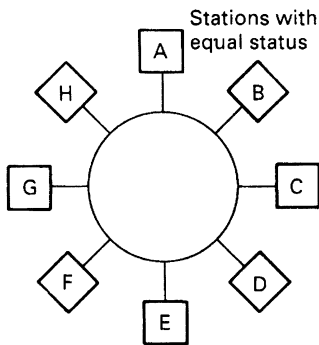

Figure 16.73 A masterless peer to peer or ring network

Figure 16.74 A peer to peer link arranged as a single line bus with terminating resistors

systems. Communication control is performed by the master station. Station to station communication is possible via, and with the co-operation of, the master.

In Figure 16.73 all the stations have been connected in a ring. There is no master, and all stations can talk to any other station and all have equal right of access. The term *peer to peer link* is often used for this arrangement. With Figures 16.71 and 16.72 control was firmly in the hands of the master. With the ring, some technique is needed to avoid clashes when two stations wish to use the line at the same time. We will discuss this in the following section.

Figure 16.74 is probably the commonest type of network used by PLCs. It is a single line with terminating resistors and, like the ring, is a peer to peer link where all stations have equal standing.

#### 16.5.4 Network sharing

A peer to peer link allows many stations to use the same network. Inevitably two stations will want to communicate at the same time. If no precautions are taken, the result will be chaos. Various methods are used to govern access to the network.

One idea is to allocate time slots into which each station can put its messages. This is known as *Time Division Multiplexing*, or TDM. Whilst it prevents clashes, it can be inefficient as a station will have to wait for its time slot even if no other station has a message to send. To some extent a mismatch between the frequency of messages from different stations can be overcome by giving more slots to hardworking stations. This is sometimes known as *Statistical TDM*.

The *empty time slot* of Figure 16.75 uses a packet which continuously circulates around the ring. When a station wishes to send a message it waits for the empty slot to come round, when it adds its message. In Figure 16.75, station A wishes to send a message to station D. It waits

Figure 16.75 Empty slot and token passing network

until the empty packet comes round. Then it puts its message onto the network along with the destination address D. Stations B and C pass the message but ignore it because it is not for their address. Station D matches the address, reads the contents (and appends that it has received the message). Stations E–H ignore it, but pass it on. Station A receives the message back again, sees the acknowledgement and removes its message leaving the empty packet circulating the ring again. A similar idea is a *token passing*, where a 'Permit to Send' token circulates round the network. A station can only transmit when it is in possession of the token, which is released when the acknowledgement that the message arrived is received.

Bus systems usually employ a method where a station wishing to send a message listens to the network to see if it is in use. If it is, the station waits. If the network is free, the station sends its message (thereby locking out any other station until the message ends). This is known as *Carrier Sense Multiple Access (CSMA)*.

Situations can still arise, however, where two stations simultaneously start to send a message, and a collision (and garbage) results. This situation can easily be detected, and both stations then stop and wait for a random time before trying again. A random time is used to stop the two stations clashing again. This is known as *Carrier Sense Multiple Access with Collision Detection* (or much more simply as CSMA/CD).

There is a fundamental difference between TDM, empty slot, and token passing as one group and CSMA. With the former there is a certain amount of time wasting, but every station is guaranteed access within a specified time. With CSMA there is little time wasting, but a station can, in theory, suffer repeated collisions and never get access at all.

A useful analogy is to consider motor car traffic control. TDM/token passing approximates to traffic lights, CSMA to roundabouts. In heavy traffic the best solution is traffic lights; everyone gets through and the waiting is shared evenly. Roundabouts can 'lock out' one road when the traffic flow is heavy and uneven from one direction. In light traffic, however, roundabouts keep the traffic flowing smoothly.

#### 16.5.5 A communication hierarchy

Early process control systems tended to be based on a single large computer or PLC. The advent of cheap PLCs with good

Figure 16.76 A simple communication hierarchy

communications has led to the development of a hierarchy of machines which split the tasks between them. Such an arrangement is called a *Distributed Control System* or DCS.

Such a system is generally arranged as Figure 16.76 with a hierarchy split into four levels.

*Level 0* is the actual plant, with devices linking to the next level by direct wiring or simple RS232/422 serial links.

*Level 1* is the level the majority of this chapter is concerned with, consisting of PLCs and small computers directly controlling the plant.

*Level 2* is supervisory computers for large areas of plants.

*Level 3* is the large company mainframe.

Usually the layout is not as clear cut as this implies. There are also differences between different companies, some number the layers from top to bottom and some ignore level 0.

There are many advantages to distributed systems. The resulting tree is conceptually simple, and as such is easy to design, commission, maintain and modify. A correctly designed system will be, for short periods, fault tolerant and can cope in a limited mode with the failure of individual stations. A distributed system can also bring about an increase in performance as lower level machines take the work off higher level machines.

### 16.5.6 Proprietary systems

In this section we will look at a typical proprietary system used to link PLCs from the same manufacturer. Typical examples are the GEM-80s Coronet and ESP, Siemen's Sinec and Modicon's Modbus. For reasons of space we shall consider how machine to machine links are achieved with Allen Bradley PLC-5s which communicate with each other on a peer to peer (no master) token passing highway based on twinaxial cable and operating at 57.6 Kbaud. Their trade name is Data Highway Plus. The PLC stations' addresses are set on switches in each PLC, and up to 64 stations can exist on one line with octal addresses 0–77.

Communication is established with a single message (MSG) instruction. This can be set up to read or write a block of data, the programmer specifying:

- (1) The start address at the local end;
- (2) The start address at the target end;
- (3) The length of the block to be transferred (in words); and
- (4) The station address at the remote end.

The MSG instruction appears in a program as Figure 16.77(a), the transfer being initiated every time the rung

goes true. The ENable bit goes true when the transfer is started, and the DoNe bit goes true when it has been successfully completed. The ERROR flag goes true when an error occurs. Common errors are a line fault, a non existent address at the far end or the PLC at the far end shutdown. The cause of the fault is given in flags set in the message control word. Link statistics (e.g. number of retries) are kept in the processor for diagnostic purposes.

The details of the MSG instruction are set up by the programmer via the screen of Figure 16.77(b). These are mostly self explanatory, with the possible exception of the remote link which is concerned with sending data via a gateway module to a different highway, possibly of a different type.

The data highway is also used by the programming terminal, so a programmer can connect anywhere onto the data highway and link into any machine on the network.

### 16.5.7 Ethernet

Ethernet is a very popular bus based LAN originated by DEC, Xerox and Intel and is commonly used to link the computers at level 2 in Figure 16.76. It uses 50  $\Omega$  coaxial cable, with a maximum cable length of 500 m (although this can be extended with repeaters). Up to 1024 stations can be accommodated, although in practical systems the number is far lower. Baseband (i.e. non modulated) signalling is used with CSMA/CD access control. The raw data rate is 10 Mbaud, giving very fast response at loading levels up to about 20–30% of the theoretical maximum. Beyond this, collisions start to occur.

Because Ethernet uses CSMA/CD the successful transmission of a message cannot be guaranteed. It is possible, (but unlikely) for a given message to continually suffer from crashes and never get access to the network. In the jargon ethernet is '*non deterministic*'. In practice, if the network loading is kept below 30% of its theoretical capacity this is not a problem. Many PLCs (such as the PLC-5/40E) now can provide direct connection to an Ethernet network.

### 16.5.8 Towards standardisation

We have already discussed the difficulties of linking different equipment. There is normally little problem linking PLC networks to higher level computers. PLC manufacturers publish their message format and protocols, and interfacing software (called 'drivers') has been written for all common computers and PLCs. The difficulty comes when you want to link two machines from different manufacturers at level 1 in Figure 16.76. In many cases, the only economical solution is to do it through the computers and the higher level link.

**Figure 16.77** The PLC-5 Message (MSG) Instruction: (a) as written in the ladder diagram; (b) as seen in detail on the programming terminal

General Motors (GM) in the USA were faced with this problem and attempted to specify a LAN for industrial control. This was called MAP (Manufacturing Automation Protocol). A similar office based LAN called TOP (Technical Office Protocol) was conceived at the same time. With GM's purchasing muscle, it involved several automation equipment manufacturers. A firm commitment to the OSI model was made, and the network based on broadband token bus as specified in IEEE 802.4 was chosen as it is deterministic.

MAP, however, has not been widely adopted. There appears to be several reasons for this distinct lack of enthusiasm. The first is a bureaucratic organisation and a changing specification. The second reason is cost; MAP links often cost more than the PLC to which they are connected. The third reason is speed; by using token passing MAP is slow by comparison with other standards. The final, and perhaps most crucial, fact is that MAP seems to have settled at a level where it is in direct competition with established LANs such as Ethernet rather than the proprietary systems at level 1 of Figure 16.76.

A standardised fieldbus system would allow PLCs, sensors and actuators to be connected and communicate with minimal cost. Unfortunately at the time of writing (early 2002) a standard seems as far away as ever with progress being slowed by commercial and national infighting.

Profibus is one the more common fieldbus contenders, largely because it has been adopted by Siemens and many

other German electrical companies. There are three versions of Profibus designed for three different application areas. All use token passing.

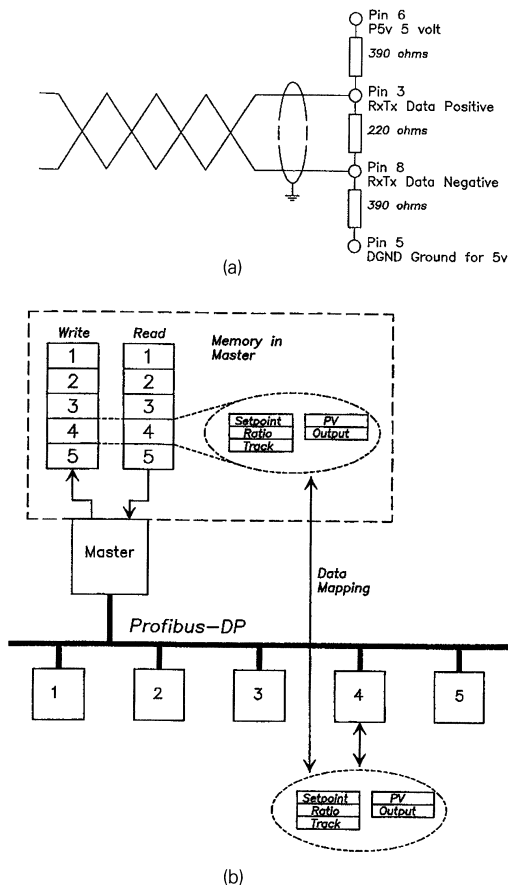

The first, called Profibus-DP, for decentralised periphery, is by far the commonest and is designed to link intelligent masters (e.g. a PLC), to slave devices such as sensors, drives or actuators. Profibus only uses levels 1 and 2 of the ISO/OSI model. Twisted pair RS485 or fibre optics are used for transmission.

The second, Profibus-FMS, for field message specification, is designed for the higher level with multiple masters and allowing peer to peer communication. Levels 1, 2 and 7 of the ISO/OSI model are used and RS485 or fibre optics for transmission.

Both DP and FMS share the same transmission standards and can consequently work together on the same network.

The final form, designed for process automation in hazardous areas, is Profibus-PA which permits the construction of an intrinsically safe network. Profibus-PA uses slightly different standards to DP and FMS, but can be linked by a segment coupler device.

All are a linear bus system, i.e. a straight line. Transmission speeds from 9.6 kbit/s (up to 1200 m) to 12 Mbit/s (up to 100 m) can be used. Screened twisted pair is used, with terminating resistors at each end of the bus. Up to 32 stations can be used in each segment, each with a unique station address. Segments can be coupled with segment repeaters, allowing a total of 127 stations to be

**Figure 16.78** Profibus-DP network: (a) connection at a Profibus device. Non terminating devices use only pins 3 and 8; (b) mapping between a Profibus device and memory in the network master

addressed. Addresses are assigned for global or group data reducing the number of messages and time lag problems when data for several devices are to be changed together.

Connections to masters or slaves are made via standard 9 pin D-type connectors, as shown on *Figure 16.78(a)*. Terminating resistors are either switched in internally at the end stations or connected inside the final plugs. Note that the terminating resistors require power, this normally comes from the end stations themselves.

The manufacturer of each device on the network, e.g. a VF drive, provides a disc file, called the GSD, which is a description of the data exchange the device can support (e.g. accepting speed reference and run command and providing load current and drive state etc.) plus operating parameters such as supported transmission speeds. Included in the GSD file is a unique identification number assigned by the Profibus User Organisation. The GSD files for all the devices on the network are used along with the station addresses to build a network description which is held in the master.

Because Profibus-DP only uses levels 1 and 2, the data exchange maps onto pre-determined areas in the master controller (usually a PLC) as shown on *Figure 16.78(b)*. To change the speed of the drive, the user simply writes the new speed into the mapped area, and the data is transferred with no further action. In a similar manner,

slave data and status is automatically read from the mapped area. A Profibus-DP network is thus totally transparent to the user.

A typical example of the problems that any attempts to specify a standardised fieldbus system may encounter is the continual introduction of new ideas. All the communications systems described so far are based on what is called the *source/destination model*. If station A has information for station B, a message is sent with the format:

Source A | Destination B | Data

If this information is to be sent to several stations, each will need their own message. In applications where multiple setpoints have to be sent to multiple controllers, the delay caused by the time shift between the messages can cause problems, although this can be overcome to some extent by the use of group or global addresses as used by Profibus.

In addition, if station A needs information from station B, (the state of an interlock for example), station A must perform a read on each occasion the data is required.

A recent development, called the *producer/consumer model*, uses a different approach. Here data is placed onto the network with no indication as to who it is for. The format is now simply:

Identifier | Data

All stations using this data accept it at the same time, eliminating the need for multiple messages. This significantly reduces the number of messages and hence increases the network speed.

The placement of data onto the network can be done in two ways. The first, and fastest, is 'notify on change'. Here a station only places information on the network when a new value is different than the old. Stations with an interest in this data assume that the status or value remains the same until notified otherwise. There are obvious dangers in this, and a regular pre-defined 'heartbeat' is included to say a station is active on the network. The second approach updates on a time basis, each data item having its own, or a global, update time.

At the time of writing, Foundation Fieldbus is the only producer/consumer fieldbus network, and Rockwell (Allen Bradley) have also adopted the method for their proprietary ControlNet. The latter is interesting as it combines the ideas of their remote I/O and Data Highway onto one system and allows PLC racks, (and their data), to be shared equally amongst several processors and not dedicated to one as before.

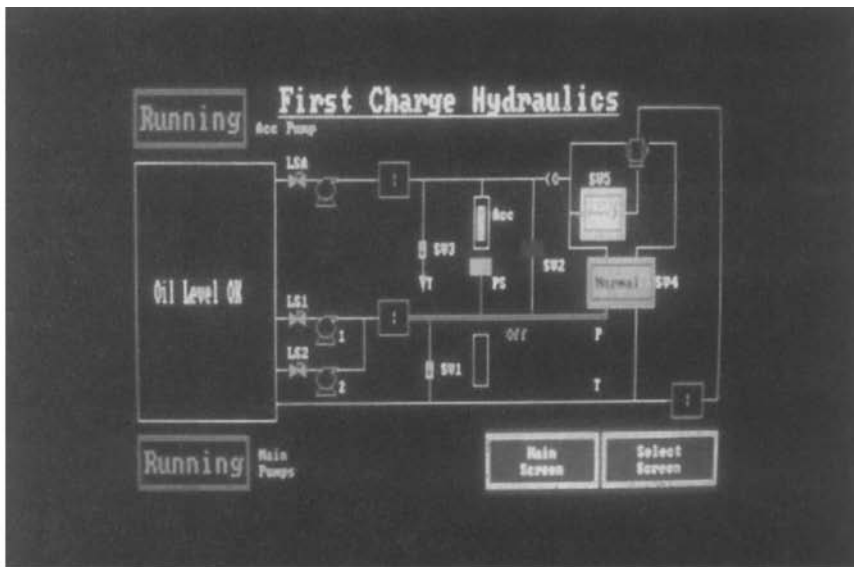

## 16.6 Graphics

Operator controls are being increasingly provided by computer graphic screens. These can be a display device designed specifically for a particular range of PLCs (for example the Allen Bradley Panelview and the CEGELEC Imagem) and general purpose graphic display devices (such as ABB/ASEA's excellent Tesselator) or graphics software running on conventional personal computers. *Figure 16.79* shows some typical examples.

The major advantages are simplicity of installation and flexibility. A graphics terminal has just two connections to the outside world, a serial link connection and a power supply. If it is used to replace a desk full of switches and indicators there are obvious cost savings.

The designer of desks or control stations often has to deal with changes and modifications. Constructing a desk is

(a)

(b)

**Figure 16.79** Various graphic displays: (a) Allen Bradley touchscreen Panelview using block graphics; (b) high resolution Scada system; (c) the ABB Tessellator. *Photos courtesy of Co-Steel Sheerness, Scomag and ABB*

always a fine balance of time, choosing between waiting until all the requirements are clear, and the minimum time needed to make it. Modifications at the commissioning stage rarely look neat. The displays on a graphical terminal can be modified relatively easily, and, more importantly, the modifications leave no scars. If the design of a normal desk can only start when the desk contents are 95% finalised (which is about right) a graphic screen can be started at 75% finalised. This flexibility is of great assistance as no job is ever right first time.

There are disadvantages, though. The most important of these is the limited amount of information that can be

displayed on a single screen. It is very easy to overcrowd a screen (giving a screen similar to a page full of text on a word processor) making it difficult for the operator to identify critical items. A useful rule of thumb is not to use more than 25–30% of the screen.

The effect of this is often a need to build up a hierarchy of screens; the top screen showing an overview, lower screens showing more and more detail. The problem with this is the time delay needed to shift through the screens. Direct screen to screen movement is possible by calling for a page number (which needs a good human operator memory, or a directory piece of paper, or wasted screen space) or by making all

(c)

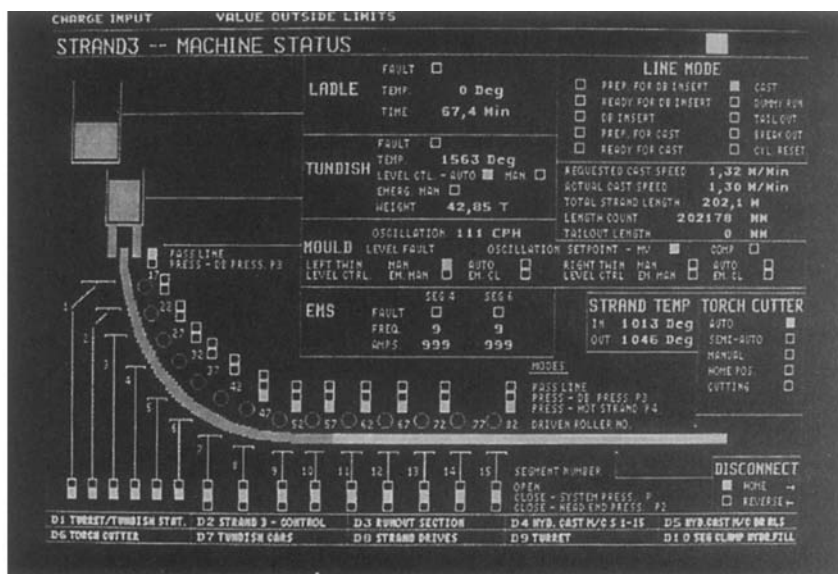

Figure 16.79 (continued)

screen changes via an intermediate directory page (with additional delay). These time delays are small (less than a second typically) but the cumulative annoyance is large.

The time taken to update screen data can also be problematical, particularly where a machine to machine link is involved. Again a response time of around one second is typical, but several seconds is by no means uncommon. The use of a graphic terminal for fault finding on a fast moving plant is not really feasible.

There are generally two types of graphic terminal. The simplest, known as block graphics, has one store location for each character position on the screen and approximates to the old CGA standard on a personal computer.

The second type of display deals not with individual characters, but with individual points on the screen called 'pixels'. A typical medium resolution screen will have 640 (horizontal) by 480 (vertical) pixels, a total of 307 200 points. Each of these can be accessed individually, allowing lines to be drawn at any angle, fill patterns of any type to be used and trend graphs of plant variables to be displayed. Each individual pixel can have its own colour (from over 256 possible colours in some displays) and intensity. The result is an almost photographic resolution. There are additional costs, the most obvious of which is a large store requirement. The system hardware and software is more complex (and hence more expensive) but, perhaps surprisingly, this is not apparent to the designer. Programming for these screens is surprisingly simple with instructions using keywords like

```
DRAW FROM <> to <>.
```

or pick and place functions similar to a good commercial graphics package.

*Supervisory Control and Data Acquisition (SCADA)* systems are based around graphical objects which are linked to variables in the control systems. The state of the objects on the screen (e.g. size, colour, rotation, etc.) can be changed according to the the values of the variables in the control systems giving a very visual image of the operation.

The environment around a display needs to be carefully considered. Most screens are mounted angled up, and are prone to annoying reflections from overhead lights and windows. Bright lighting (and above all direct sunlight) can make a display impossible to read. Displays are also adversely affected by magnetic fields. Close proximity to electric motors, transformers or high current cables will cause a picture to wobble and the colours to change. The effect can be overcome by screening the monitor with a mu-metal cage). Flat screen TFT or LCD displays do not suffer from this effect.

The size and weight of the monitors are often overlooked making them difficult to mount neatly, and even more difficult to change. Access should be made as easy as possible; trying to hold a 25 kg display in place with one hand whilst undoing interminably long mounting screws is not much fun.

Displays fail, and the implication of this needs to be considered in the design. If all the plant control is performed by screens, what will happen during the ten or so minutes it will take to locate a spare and change the faulty unit? Often dual displays are used to overcome this problem.

The operator will obviously need to input data and initiate actions. Keyboards are one approach, but many people are nervous of them and the cable connecting the keyboard always seems prone to damage. In dirty environments keys can become blocked with dirt and membrane keypads with tactile (feel) feedback should be used.

If the operator has to access points anywhere on the screen, a tracker ball is a useful device. Rather like an upside down mouse it controls the movement of a cursor on the screen. All normal actions can be performed with three buttons on the trackerball and a numerical keypad. Trackerballs work surprisingly well in dirty environments as they are open underneath and dirt seems to fall straight through. Mice perform a similar function but are vulnerable to damage and dirt and seem more suited to an office environment.

A final consideration is security. Most modern graphics systems are based on good quality personal computers. These have value outside of industry and are vulnerable to theft. Often it is not the PCs or screens which are stolen, but the

internal motherboards and memory cards. Suitable security methods should be used if a PC based system is to be left unattended for a period of time (e.g. during a Christmas shutdown). Needless to say backups should not be stored on the same PC as the original system.

## 16.7 Software engineering

Any project goes through six stages during its life. The first of these, *analysis*, is studying the application to understand what is required. This is by far the most difficult stage as the project requirements are usually unclear. Most projects that come unstuck do so because this first stage has been cut short or overlooked.

Next comes *specification*, which is documenting the analysis so everyone concerned can agree what is to be done and what the end result should be. If you can't produce a specification, how can you sensibly design it? Never say 'we'll sort that out later' because later becomes 3 a.m. as the plant starts up. The final testing procedures must also be defined at the specification stage; again if you don't know how you will test it, how will you know if it's working properly? Defining testing procedures in the cold light of day several months before the final frantic rush to meet a deadline also helps the poor commissioning engineer to resist the pleas for a premature start up.

The importance of these two first stages cannot be over-emphasised, too often the users do not know, or do not say, what they want, but once the project is complete they are sure it wasn't that. With these first two difficult stages over, the rest of the project becomes much easier!

The *design* stage can now start, (simple with a good specification) followed by *installation*. Next comes *commissioning*. These can also be difficult times, as in any project the control engineer ends up collecting everybody's delays and comes under pressure to 'get the plant away'. It is here that the advantage of the test schedule from the specification stage will be invaluable.

It is not generally understood that commissioning involves both *positive* and *negative* testing. Positive testing is obvious; it is ensuring that when the firkling button is pressed the plant firkles. Practically everyone sees the need for this. Negative testing is less obvious; it is ensuring that the control system deals correctly with all the unlikely circumstances and fault conditions. Negative testing takes far far longer, because there are many more fault modes than healthy modes. It is very common for people to say '*it works, let's go*' when only the positive testing has been done. Try to resist this pressure, at best it can lead to damaged plant a few years hence, at worse some safety features could be overlooked.

Finally the plant is handed over to the maintenance department. In commercial software it is generally thought that over 50% of the effort goes into *maintenance* as changes are made to meet new requirements or correct the inevitable bugs. For easy maintenance all the documentation must be complete and up to date.

## 16.8 Safety

Most industrial processes are hazardous, and the safety of all personnel must be of prime importance. This section is a personal view and can only give a simple discussion of safety considerations. The topic of safety is covered by both criminal and civil law. The designer and user of any

system must therefore consult the relevant legislation and codes of practice to ensure compliance.

Every single person has a safety responsibility. Employers have a '*duty of care*' for their employees and the public and must ensure the plant is kept in a safe condition, safe working procedures are devised for all conceivable activities, and training in these procedures provided for all relevant employees. Suppliers must ensure their equipment meets safety criteria, and draw the attention of purchasers to unavoidable hazards (protection and labelling of parts which are live during normal operation for example). Employees must follow safety procedures and not expose themselves (or others) to danger. These responsibilities are covered by the Health and Safety at Work Act 1974 (HASWA) which makes the universal responsibility for safety absolutely clear.

More recently in 1992 a block of EEC Health & Safety Regulations (commonly known as the '*six pack*') introduced the idea of *risk assessment*. This recognises the need to balance the cost and complexity of the safety system against both the likelihood and severity of injury. The procedures outlined use common terms with specific definitions:

<i>Hazard</i>	The potential to cause harm.
<i>Risk</i>	A function of the likelihood of the hazard occurring and the severity.
<i>Danger</i>	The risk of injury.

and outlines procedures to achieve acceptable safety standards. Risk assessment is a legal requirement under most modern legislation, and is covered in detail in standard prEN1050 '*Principles of Risk Assessment*'.

A Health & Safety Executive study of safety in control systems ('*Out of Control*' HSE books 1995 ISBN 0717608476) makes worrying reading. It suggests that more than 60% of safety related failures are introduced into a system before it is taken into service for the first time. Approximately 44% of safety incidents come from specification errors, 15% from design errors and 6% from poorly thought out changes during commissioning.

The inclusion of a programmable controller brings additional hazards (and solutions) which must be recognised. A PLC can introduce potentially dangerous situations in different ways. The first (and probably commonest) route is via logical errors in the program. These can be the result of oversight, or misunderstanding, on behalf of the original designer who did not appreciate that this set of actions could be dangerous, or by later modifications by people who deliberately (or accidentally) removed some protection to overcome a failure in the middle of the night. '*Midnight programming*' is particularly worrying as usually the only person who knows it has been done is the offending person, and the danger may not be apparent until a considerable time passes and the hazardous condition occurs.

The second possible cause is failure of the input and output modules; in particular the components connected directly to the plant which will be exposed to high voltage interference (and possibly direct connected high voltages in the not unlikely event of cable damage). Output modules can also suffer high currents in the (again not unlikely) event of a short circuit. Typical output devices are triacs, thyristors or transistors. The failure mode of these cannot be predicted; all can fail short circuit or open circuit. In these failure conditions the PLC would be unable to control the outputs. Similarly an input signal card can fail in either the 'on' or 'off' state, leaving the PLC misinterpreting a possibly important signal.

The next failure mode is the PLC itself. This can be further divided into hardware, software and environmental failures. A hardware failure is concerned with the machine itself; its power supply, its processor, the memory (which contains the 'personality' of the PLC, the user's program, and the data storage). Some of these failures will have predictable effects; a power supply failure will cause all outputs to de-energise, and the PLC supplier will have included memory checks in the design. Environmental effects arise from peculiarities in the installation such as dust, humidity, temperature (and rapid temperature changes) possible water ingress and vibration, and these can result in unexpected operation of output devices.

The final cause is electrical interference (usually called noise). Internally almost all PLCs work with 5 V signals, but are surrounded by high voltage high current devices. Noise can cause input signals to be misread by the PLC, and in extreme cases can corrupt the PLC's internal memory. PLCs generally have internal protection against memory corruption and noise on remote I/O serial lines, so the usual effect of noise is to cause a PLC to stop (and outputs to de-energise). This cannot, however, be relied upon.

Figure 16.80 shows a normal motor starter circuit built without a PLC. Safety precautions here are:

- Isolation switch at the MCC removes the supply for maintenance work.
- Normally closed contacts on the stop and emergency stop buttons. A broken wire will look like a stop button being pressed, as will loss of the control supply.
- If the emergency stop is pressed and released, the motor does not restart.
- Isolation and emergency stop have priority over start.

It is still possible to identify dangerous failure modes in this system. The button head of the emergency stop button could unscrew and fall off, or the contacts of the contactor could weld made, or a short could occur between the cores to the stop button but these failure modes are exceedingly rare, and Figure 16.80 would be generally accepted as safe for use in normal circumstances.

In Figure 16.81(a) the same functions have been provided by an *unsafe* PLC system. To save costs the MCC door isolator has been replaced by a simple switch which makes to say 'Isolate'. Similarly normally open contacts have been used for stop and emergency stop. This is controlled by the unsafe program of Figure 16.81(b).

It is important to realise that to the casual user, Figures 16.80 and 16.81 behave in an identical manner. The differences (and dangers) come in fault, or unusual, conditions. In particular:

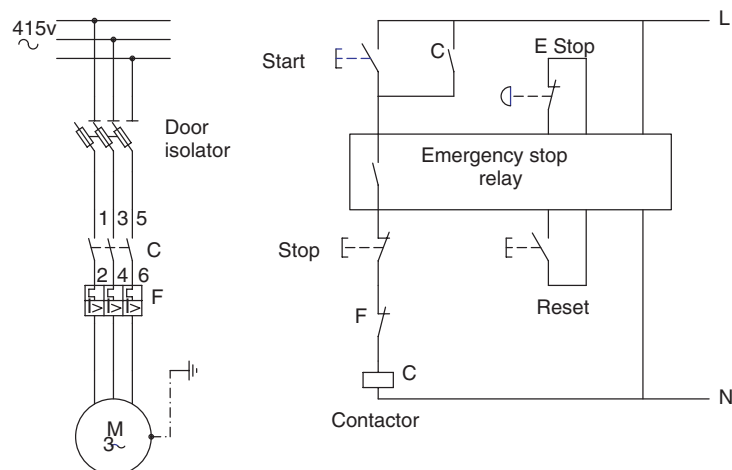

- A person using a programming terminal can force inputs or outputs and over-ride the isolation. Although it is unlikely that anyone would do this deliberately, it is easy to confuse similar addresses and swap digits by mistake (forcing 0:23/01 instead of 0:32/01 for example).
- A loss of the input control supply during running will mean the motor cannot be stopped by any means other than totally removing the supply to the system.
- The system is very vulnerable to input and output card faults.

None of these are apparent to the user until an emergency occurs.

A prime rule, therefore, for using PLCs is:

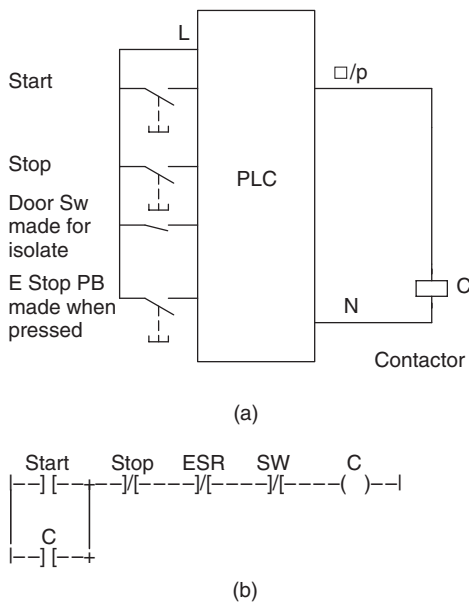

*'The system should be at least as safe as a conventional system'*

Figure 16.82(a) is a revised PLC version of Figure 16.80. The isolator has been re-instated with an auxiliary contact as PLC inputs, and normally closed contacts used for the stop and emergency stop buttons. An auxiliary contact has been added to the starter, and this is used to latch the PLC program of Figure 16.82(b). The emergency stop is hard-wired into the output and is independent of the PLC, and on release the motor will not restart (because the latching auxiliary contact in the program will have been lost). On loss of control supply the program will think the stop button has been pressed, and the motor will stop. Figure 16.82 thus behaves in failure as Figure 16.80.

**Figure 16.80** A standard hardwired motor starter for a low risk application. This would normally be considered to be safe. In higher risk applications there would probably be dual connections on the emergency stop button, dual contactors and the state of the contactors would be monitored by the emergency stop relay

**Figure 16.81** An unsafe PLC based system totally reliant on software. The dangers of this system only become apparent when failures occur

Although this example is simple, it illustrates the necessary analysis and considerations that must be applied in more complex systems.

Complex electronic systems can bring increased safety. Consider a thyristor drive controlling the speed of a large d.c. motor. In a typical arrangement there will be an upstream a.c. contactor to enable the drive. Hardwire connection of an emergency stop button into the a.c. contactor will obviously stop the drive, but the inertia of the motor and the load will keep it rotating for several seconds. A thyristor drive, however, can stop the load in less than one second by regeneratively braking the motor, but this requires the drive to be alive and functional. The operation of the emergency stop implies a dangerous condition in which the fastest possible stop is required. It is almost certain that at this time the drive controls are functional and there are no 'latent' faults.

Here the emergency stop can operate in two ways. First it initiates an electronic regenerative crash stop via the control

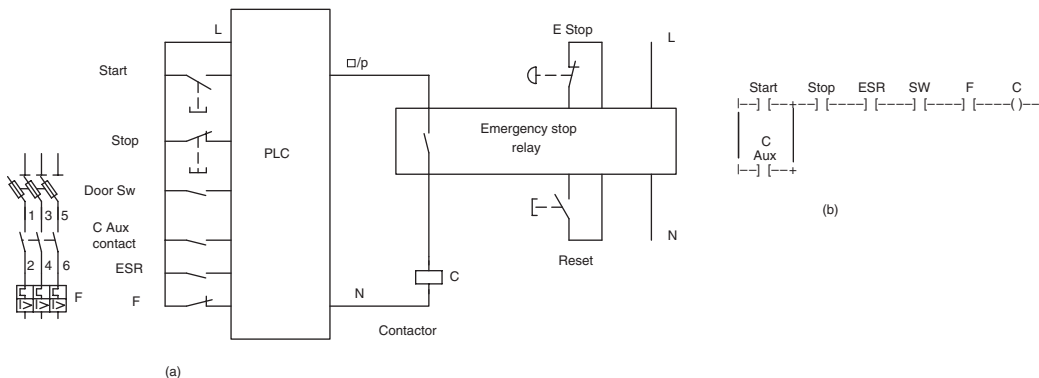

system which should stop the drive in less than one second. The emergency stop also releases a delay drop out hardwire relay set for 1.5 s which releases the a.c. contactor. This gives the safest possible reaction to the pressing of the emergency stop button. Safety considerations do not therefore, explicitly require relay based, non electronic hardware, but the designer must be prepared to justify the design decisions and the methods used.

Where complex control systems are to be used, a common method of improving safety is to duplicate sensors, control systems and actuators. This is known as *redundancy*. A typical application occurs in boilers where feed water is held in a drum. Deviations in water level are dangerous; too low and the boiler will overheat, possibly to the point of melting the boiler tubes; too high and water can be carried over to the downstream turbine with risk of catastrophic blade failure. High and low level sensors are therefore usually provided with each being duplicated. The safety system reacts to *any* fault signal, so two sensors have to fail for a dangerous condition to arise. If the probability of a sensor failure in time  $T$  is  $p$  (where  $0 < p < 1$ ) the probability of both failing is  $p^2$ . In a typical case,  $p$  will be of the order of  $10^{-4}$  failure per year giving  $p^2$  of  $10^{-8}$ .

There are two disadvantages. The first is that a sensor can fail into a permanently safe signal state, and this failure will be 'latent', i.e. hidden from the user with the plant running on one sensor. The second problem is that the plant reliability will go down, since the number of sensors goes up and any sensor failure can result in a shutdown. Both of these effects can be reduced by using 'majority voting' circuits, taking the vote of two out of three or three out of five signals.

Redundancy can be defeated by 'common mode' failures. These are failures which affect all the parallel paths simultaneously. Power supplies, electrical interference on cables following the same route and identical components from the same batch from the same supplier are all prone to common mode failure. For true protection, *diverse redundancy* must be used, with differences in components, routes and implementation to reduce the possibility of simultaneous failure.

To give true redundancy it is sensible to provide duplication in the control system as well to protect against hardware and software failures in the system itself. Duplicate control schemes, though, are vulnerable to a form of common mode failure called a 'systematic failure'. Suppose duplicated temperature sensors are compared, inside a PLC program, with an alarm temperature. Suppose both are identical devices, running the same program containing a bug which inadvertently (but rarely so it does not show up

**Figure 16.82** A safe PLC system for low risk applications. As for Figure 16.80 more features could be added if the risk was higher

during simple testing) changes the setting for the alarm temperature (from 60°C say, to 32.053°C). Such an effect could easily occur by a mistype in a MOVE instruction in a totally unrelated part of the program. This error will affect both control systems, and totally remove the redundancy.

If reliance is being made on redundant control systems, therefore, they should be totally different; different machines with different I/O and different programs written by different people with the machines installed running on different power supplies with different types of sensors connected by different cable routes.

The Health and Safety Executive (HSE) became concerned about the safety of direct plant control with computers, and produced an occasional paper OP2 'Microprocessors in Industry' in 1981. This was followed in 1987 by two booklets 'Programmable Electronics Systems in Safety Related Applications'. Book 1 (an Introductory Guide) is a general discussion of the topic, and Book 2 (General Technical Guidelines) goes through the necessary design stages. They suggest a five stage process:

- (i) Perform a hazard analysis of the plant or process;
- (ii) From this, identify which parts of the control system are concerned with safety and which are concerned purely with efficient production. The latter can be ignored for the rest of the analysis;
- (iii) Determine the required safety level (based on accepted attainable standards or published material);
- (iv) Design safety systems to meet or exceed these standards; and
- (v) Assess the achieved level (by using predicted probability of failure for individual parts of the design). Revise the design if the required level has not been achieved.

The books stress the importance of 'Quality' in the design; quality of components, quality of the suppliers and so on.

The IEC standard IEC 61508 *Functional Safety of Electrical/Electronic/Programmable electronic safety related systems* covers similar grounds to the HSE books. This is based on the ideas of *safety functionality* (what it is designed to protect against and how the protection is achieved

Figure 16.83 Safety critical input with the Siemens 115F PLC

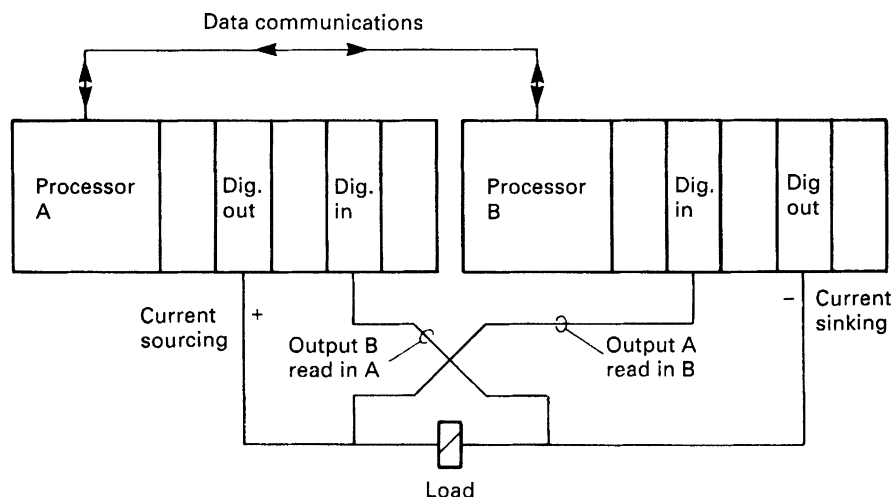

Figure 16.84 Safety critical output with the Siemens 115F PLC

e.g. 'open quench valve if temperature rises above 250°C') and the *Safety Integrity Level* (or SIL) which, somewhat simplified, is the probability,  $p$ , that the safety system will fail to operate on demand. The SIL covers the entire safety system including sensors, control system, and actuators. Four SILs are defined from a basic SIL-1 ( $10^{-1} > \rho > 10^{-2}$ ) to SIL-4 ( $10^{-4} > \rho > 10^{-5}$ ). The required SIL is determined from a risk assessment of the system. For continuous protection on a hazardous plant the normal requirement is SIL-3 or SIL-4. Guidelines for architectural constraints (such as keeping the safety system separate from the control system, and using redundancy) are also given. It is probable that IEC 61508 will become a European standard in the near future, and the two HSE books are being re-written to incorporate ideas from IEC 61508.

Surprisingly some fieldbus systems (e.g. specialist versions of Profibus and SafetyBus from Pilz) can achieve SIL-3 which makes a fieldbus safety system attractive in hazardous applications. Extreme care must, of course, be taken.

In America, the Instrument Society of America (ISA) standard S84 follows broadly similar lines to the HSE guidelines and IEC 61508.

Because the HSE books, IEC 61508 and S84 are standards they have the legal status of guidance notes and there is no formal requirement to follow them. In the event of an incident, however, the designers and users must be prepared to justify the actions they have taken and conformance with good practice is a legal defence.

Very high safety levels can be achieved with some PLCs. Siemens market the 115F PLC which has been approved by the German TUV Bayern (Technical Inspectorate of Bavaria) for use in safety critical applications such as transport systems, underground railways, road traffic control

and public elevators. The system is based on two 115 PLCs and is a model of diverse redundancy. The two machines run diverse system software and check each other's actions. There is still a responsibility on the user to ensure that no systematic faults exist in the application software.

Inputs are handled as *Figure 16.83*. Diverse (separate) sensors are fed from a pulsed output. A signal is dealt with only if the two processors agree. Obviously the choice of sense of the signal for safety is important. For an overtravel limit, for example, the sensors should be made for healthy and open for a fault.

Actuators use two outputs (of opposite sense) and two inputs to check the operation as *Figure 16.84*. Each sub-unit checks the operation of the other by brief pulsing of the outputs allowing the circuit to detect cable damage, faulty output modules and open circuit actuators. If, for example, output B fails on, both inputs A and B will go high in the Off state (but the actuator will safely de-energise.)

The operation of *Figures 16.83* and *16.84* is straightforward, but it should not be taken as an immediately acceptable way of providing a fail-safe PLC. The 115F is truly diverse redundant, even the internal integrated circuits are selected from different batches and different manufacturer, and it contains well tested diverse self checking internal software. A DIY system would not have these features, and could be prone to common mode or systematic failures.

A PLC system is an electrical system, and is subject to the same legislation as conventional electrical schemes. Apart from the Health and Safety at Work Act, the designer should also observe the Institute of Electrical Engineers Wiring Regulations, and the Electricity at Work Regulations 1990.

The development of power semiconductor devices began in the late 40s and 50s with the bipolar transistor and the power diode, this was followed a decade later by small thyristors and triacs. The thyristor has continued to develop over the years, growing in power and frequency rating, leading to high power press-pack fast switching thyristors and ultra high voltage thyristors in the 70s, and GTO Thyristors in the 80s. In turn these new devices have enabled the development of greater and greater efficiency in a wide range of power conversion systems. However the fundamental disadvantage of these devices was the complexity of the drive and control equipment they require. The first major breakthrough came with the advent of the Power MOSFET in the 70s and 80s. That enabled a major reduction in the complexity of the control systems, and pushed power conversion forward in frequency and efficiency, but the MOSFET would never challenge the thyristor in the high power arena. All this was changed however with the arrival in the 1990s of the high power insulated gate bipolar transistor (IGBT), essentially the single chip integration of a Power MOSFET and a highly efficient bipolar transistor.

The main types of power semiconductor switching device available today are shown in *Figure 17.1* illustrating the spectrum of power and switching frequency occupied by each type, and giving some of their main areas of application. Diodes are not shown on this picture as they encompass the whole range and essentially complement the switching devices. There are still on going developments of all these power switches, some of which will be covered in this chapter, and potentially new materials and new device structures will continue to re-write the story for power semiconductors.

Because of the generally superior performance that can be achieved, almost all power semiconductor devices are made today using monocrystalline silicon, and many of the highest power devices use extremely pure silicon crystals as their starting point. At the top end of the power range single-element silicon devices are available that are able to

withstand voltages in excess of 6000 V with average current ratings of 1000 A and voltages of 2000 V with average current ratings of 6000 A. Typically the largest devices (diodes) have a forward volt drop of 1.2 V at 5000 A and a reverse leakage current of less than 100 mA at 5000 V, the voltage that a semiconductor device is able to withstand with a low leakage current is referred to as its 'blocking voltage'. This demonstrates the very small power loss dissipated in the device compared to the power controlled or rectified and the high efficiency of this type of component. Typically, large power devices of this type are mounted in a package that can be double-side cooled such as that shown in *Figure 17.2(a)*. More recently the plastic power module has become a widely accepted alternative to the double-side cooled press pack, *Figure 17.2(b)*. This module is single-side cooled through an electrically isolated base-plate and has all the power terminals on one face. It has become the preferred outline for the high power IGBT and diode module (see Section 17.6.1). At the other end of the spectrum is the Power MOSFET at a few 10s of watts but able to switch at high speed in the range of 100 MHz.

Power semiconductor devices can be divided into two groups, roughly splitting the power spectrum in two, these are minority carrier devices (bipolar), and majority carrier devices (unipolar). The bipolar device relies on the injection of both minority and majority carriers into a high-resistivity region of the device. This reduces the device on-state voltage by modulating the resistivity of its high-resistivity region and reducing the voltage drop across this region. However, these conductivity-modulated devices such as the diffused p-n junction silicon diode and the thyristor or silicon controlled rectifier (SCR) suffer the disadvantage that the injected carriers or charge must be extracted before a blocking state can be sustained. The charge also cannot be injected or extracted instantaneously into or from the high-resistivity region of the device. This takes some time to occur and during this period, before the low on-state voltage is established or the high blocking voltage can be attained, substantially higher instantaneous power is dissipated in the

**Figure 17.1** Power device power-frequency range

**Figure 17.2** (a) Press pack device; (b) IGBT power module

device. Similarly during turn on, a substantial level of charge must be injected before the device attains its optimum low conductivity state. In the case of a switching device this can result in a high power requirement from the gate drive, and also high instantaneous power during turn on. These phenomena combine to limit the maximum permissible switching speed of these devices. This has also resulted in a number of different types of conductivity-modulated devices being developed. Some of them are specifically optimised for 50 or 60 Hz operation, which are sometimes referred to as 'converter-grade' or 'phase control' devices. Faster types of devices have also been designed for operation at higher frequencies and are often referred to as 'inverter-grade' or 'fast' devices. Generally, however, the fastest conductivity modulated devices are limited in practical applications to an operating frequency below 50 kHz.

The second group of devices is the majority-carrier or unipolar device that does not rely on conductivity modulation, for example metal oxide silicon field effect transistors (MOSFETs) and Schottky diodes. In a majority carrier device, current is carried only by the majority carriers. The on-state voltage is therefore dependent on the concentration of majority carriers in the conducting region of the device. Injection of minority charge and conductivity modulation does not occur so that there is no reverse-recovery charge to be extracted on turn-on and turn-off losses are, therefore, much lower, resulting in an optimum operation at higher switching frequencies, as high as 100 MHz in some cases. However, on-state losses will generally be higher since the number of current carriers is restricted although this will also be dependent on the voltage design of the device.

Thus the maximum useful voltage rating of the MOSFET is less than 1000 V, and more typically less than 600 V, however this is quite suitable for most domestic mains voltage equipment, and so unipolar devices are used in very high volumes in such consumer based applications.

A third group of hybrid devices includes most notably the insulated gate bipolar transistors (IGBT) that combine some aspects of conductivity-modulated and majority carrier devices and offers special advantages in many applications. Although more complicated in construction it is the IGBT that has revolutionised power electronics in the more recent years.

It can be seen that in general it is the minority carrier (bipolar) devices which dominate the low frequency high power area, the majority carrier (unipolar) types in the high frequency and low power arena, and the hybrid IGBT which is predominant in the mid range.

## 17.1 Junction diodes

### 17.1.1 The p-n junction

A p-n junction is made by increasing the concentration of electron or hole populations in certain regions of a

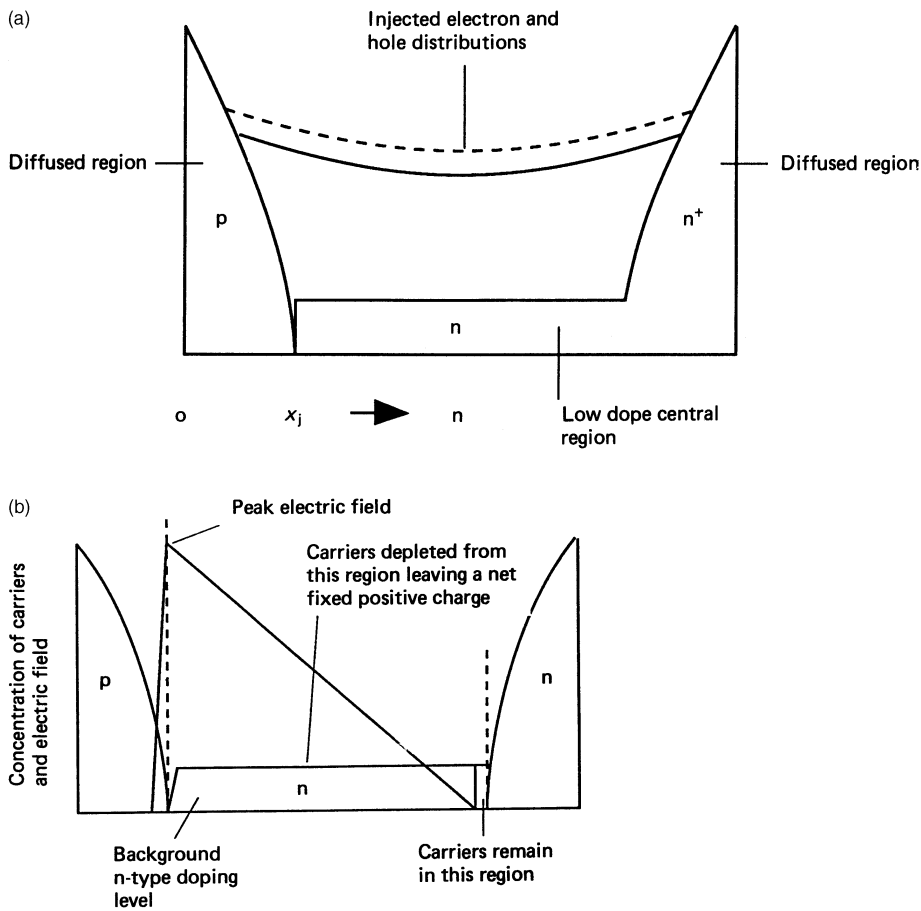

monocrystalline silicon disc or chip. This is done by introducing impurity atoms, such as phosphorus with five electrons in its valence band or boron with three electrons in its valence band, to create either electron-rich n-type or hole-rich p-type regions within the crystal lattice, respectively. The conductivity in these regions at normal device operating temperature is wholly determined by the concentration of the impurities introduced.

A depletion region (a region which is devoid of charge carriers and therefore very highly resistive) is established at the point in the crystal where the crystal ceases to become either electron or hole rich and reverts to the opposite type. This is caused by holes diffusing from the p region where they are present in a higher concentration into the n region and alternate electrons diffusing from the n to the p region. This forms an electrical potential barrier at the junction between the p and n regions. Under an externally applied forward bias with the p region held positive to the n region, carriers are injected across this potential barrier and a high current can flow through the diode with only a small voltage appearing across the device. When the p-n junction is biased with p region held negative with respect to the n region the depletion region widens to sustain the voltage and allows only a small reverse current to flow. This is called a reverse biased p-n junction. When the polarity is reversed it is called a forward biased p-n junction and current may flow freely across the junction with only a small resultant voltage drop. A more complete description of the physical behaviour of the p-n junction can be found in reference 1.

### 17.1.2 The p-n junction power diode

Construction of the power diffused p-n junction diode normally begins with a high-purity defect-free silicon wafer with a very uniform low doping concentration of n-type impurity such as phosphorus. The n-type silicon is preferred as the starting material because it offers a superior reverse-recovery characteristic as explained below. The silicon is then doped by the diffusion of a p-type impurity such as boron, aluminium or gallium at a temperature above 1000°C into one side of the wafer. The p-type diffusion takes place in a diffusion furnace under very carefully controlled conditions. This is followed by a similar high concentration n-type diffusion to the opposite side of the silicon disc to form the impurity concentration profile shown in *Figure 17.3*. The conductivity and final thickness of the central n-type region together with the final surface area of the silicon device ultimately determines the voltage capability and current rating of the device.

Under high forward bias conditions a high concentration of charge is injected in the central n region resulting in the injected carrier distribution (also shown in *Figure 17.3*). The injected electron and holes are present in the n region in equal quantities, which maintains charge balance locally

**Figure 17.3** (a) Impurity concentration in a p-n junction diffused diode and the injected carrier concentration under forward bias; (b) The electric field distribution across a p-n junction diode under reverse bias

throughout the n region. However, as can be seen from Figure 17.3, the concentration of carriers varies across the n region width. The reason for this is that, once injected into the n region, the excess carriers only have a finite lifetime before they recombine with another excess carrier of the opposite charge. Once injected across the p-n junction the injected carrier can on average only travel a certain distance before recombining, which results in the injected charge distribution shown in Figure 17.3. The rate of recombination is governed by the concentration of another type of impurity that provides a recombination centre through which the annihilation occurs. The time taken for the injected carriers to be annihilated is measured by a parameter that is commonly called the minority carrier lifetime. The aim in the construction of converter grade p-n junction diodes is normally to reduce the concentration of these recombination centres to the absolute minimum possible, which typically results in an average carrier lifetime of greater than 100  $\mu$ s. The conductivity of the n region is therefore increased by the presence of the injected carriers and the on-state voltage of the diode reduced. Thus the greater the minority carrier lifetime, and/or the greater the level of injected charge the lower the on-state voltage.

When the forward current is reduced to zero as the diode recovers its blocking state and reverse bias is applied to the p-n junction diode, it behaves initially like a short circuit until the charge in the central n region is removed. This

results in the typical reverse-recovery characteristic shown in Figure 17.4.

The length of time it takes for the diode to recover  $t_{rr} = t_A + t_B$  is affected by the carrier lifetime; a long lifetime results in a long recovery time. Also the recovered charge  $Q_{rr}$ , which is the charge extracted during the recovery time, increases with increased lifetime. As the reverse voltage is increasing across the diode during this recovery phase, there is an inherent energy loss, or recovery loss, determined by the product of volts and amps, during this phase. Thus there is a trade off between the recovery loss and the on-state voltage (loss) of the diode. This highlights one of the fundamental relationships of all bipolar devices: increasing on-state losses can be traded off against decreasing turn off losses by controlling the minority carrier lifetime, and/or the carrier injection levels in the p-n junction.

A p-n junction diode is normally designed so that when the maximum reverse-voltage rating is applied the whole of the depletion region is contained within the central n region of the device. Under these conditions an electric field is established across the depletion region as shown in Figure 17.3. The maximum peak electric field that can be sustained in silicon is between  $5 \times 10^4$  and  $8 \times 10^5$  V/cm. If the reverse voltage is increased above the maximum reverse voltage rating of the device the reverse-leakage current begins to increase rapidly as the peak electric field exceeds the point

Figure 17.4 Reverse recovery of a p-n junction diode

where avalanche multiplication of carriers occurs in the depleted region. The voltage at which carrier avalanche multiplication is initiated is called the 'avalanche voltage' of the diode. A typical characteristic for a silicon p-n junction diode is shown in Figure 17.5. As the temperature of the p-n junction diode is increased over its permitted operating range its characteristics also change, as illustrated in Figure 17.5. Note that as the junction temperature increases both reverse leakage current and the avalanche voltage increase, whereas the on-state voltage decreases at low current and increases at higher current.

The optimum design p-n junction diode with lowest on-state voltage and smallest reverse-recovery charge possible is obtained by manufacturing the device from a silicon crystal with the lowest resistivity and narrowest n-base consistent with the desired voltage rating of the device.

Figure 17.5 Characteristics of a 50 mm silicon p-n junction rectifier. Note the different scales in the different quadrants

As the design target maximum reverse voltage rating of the p-n junction diode is increased the resistivity of the n-type silicon has to be increased to ensure the design voltage is attained before the peak electric field reaches the point where avalanche breakdown occurs across the whole operating temperature range of the device. At the same time the thickness of the n-type region also has to be increased to accommodate the increased depleted region width. Because of the increased n-type-region thickness higher target voltage design p-n junction diodes have a higher on-state voltage at the same forward current and exhibit a larger reverse-recovery charge than lower target voltage design devices of the same surface area. This highlights a second basic relationship for bipolar devices, the device operating losses increase as the voltage rating of the device is increased. A more complete description of the p-n junction design principles is given in reference 1.

### 17.1.3 Fast-recovery p-n junction power diode

In order to reduce the reverse-recovery charge shown in Figure 17.4 extracted from a fast-recovery p-n junction diode and, thereby, to increase its maximum permissible operating frequency, the diode designer can apply two techniques. These are to reduce the level of charge injected into the diode, or to reduce the minority carrier lifetime in the central n region of the diode.

The lifetime is reduced by increasing the level of recombination centre impurities, as the concentration level of recombination centres is increased, the annihilation rate of the injected carriers increases with the result that the charge extracted during reverse-recovery decreases. However, the reduced reverse-recovery charge has to be traded off against increases in reverse leakage current and on-state voltage. The recombination centres or impurities that are generally used are gold, platinum and radiation damage. Each has its own individual characteristic that determines the shape of the reverse-recovery current after the peak of the reverse-recovery. Therefore, to optimise fully the performance of a fast-recovery p-n junction diode, not only do those parameters described above concerning central n-region resistivity and thickness have to be carefully controlled, but also the concentration and distribution of these recombination centres in the central n region of the device. Lower target voltage design fast-recovery p-n junction diodes constructed from thinner silicon not only have a lower on-state voltage but can also have very much lower reverse-recovery charge than higher target voltage design devices. This is because it is possible to introduce much greater concentrations of recombination centre impurities into lower voltage design fast-recovery diodes before impairing the reverse leakage and on-state voltage characteristics of the diode. However, in practice it is generally necessary to increase the concentration of recombination centre impurities to the point where their introduction has the effect of increasing reverse leakage current significantly. This reduces the maximum permitted operating temperature of fast-recovery p-n junction diodes compared to converter grade diodes, e.g. from 200°C or 175°C down to 150°C or 125°C. For example, a 600 V target voltage design fast-recovery p-n junction diode with an average current rating of 335 A has a maximum reverse-recovery charge of 4 μC. This can be compared to 25 μC for a 1400 V target voltage design fast-recovery p-n junction diode of the same size with an average current rating of 295 A.

One very important feature of fast-recovery diodes used with fast switching components such as IGBTs is called the

snappiness of the diode. During initial the recovery phase the charge is extracted by the formation of the depletion region in the n-base, when this charge is extracted very rapidly the device current can fall towards zero too fast, resulting in what is called snap off, and a consequential spike, or a series of oscillations in the recovery voltage waveform. Snappiness is quantified by the ratio between the two time periods of turn-off,  $t_A$  and  $t_B$ . A low snappiness factor, combined with a low recovered charge is the ideal situation: this is what is meant by a 'soft' fast-recovery diode. This can be a particular problem with p-i-n type diodes described later.

#### 17.1.4 Epitaxial fast-recovery p-n junction power diode

The central n region of a fast-recovery p-n junction diode designed for optimum performance with a target reverse voltage capability of 800 V or less is usually extremely thin and of the order of 70  $\mu\text{m}$  thickness or less. Unfortunately very thin silicon wafers are difficult to handle in manufacturing. One widely used manufacturing technique to manufacture this type of diode is with an epitaxial silicon deposition process. In this process a single-crystal high resistivity n-type silicon layer is grown from a vapour on top of a more highly doped  $n^+$  silicon single-crystal substrate. This is followed by a  $p^+$  type diffusion process to form the p-n junction of the diode. The substrate is of a low resistance and therefore provides a mechanical support for the active epitaxial diode structure without degrading the diode performance. This technique can be used to manufacture fast-recovery p-n junction diodes that have superior characteristics in certain respects compared to any other fast-recovery p-n junction diode designs. In most other respects the epitaxial fast-recovery p-n junction diode is very similar to the fast-recovery p-n diode. There are, however, a number of constraints imposed by the epitaxial process itself, including cost, which inherently limit the highest resistivity of the n-type layer which can be grown, the thickness of the layer and the degree of perfection to which the crystal can be grown over a large area. In practice, these parameters limit the upper voltage capability of this design to 1600 V with a maximum average current rating of approximately 100 A in a single silicon die.

#### 17.1.5 The p-i-n junction power diode

The p-i-n junction diode is another version of the fast-recovery p-n diode. As explained some of the transient forward and reverse-recovery characteristics of this device can generally be improved by reducing the thickness of the central region of the diode to the absolute minimum. However, the normal fast-recovery p-n junction diode is still designed to contain the whole of the maximum reverse-bias depletion region in its n region (see Figure 17.3). In the p-i-n junction diode the resistivity of the n region is chosen to be almost intrinsic; that is, the concentration of n-type impurities is very low and its resistivity very high. The thickness of that region is also chosen so that the depletion region of the device penetrates to the  $n^+$  region when the maximum design reverse voltage is applied as shown in Figure 17.6. It is possible in this way to design fast-recovery p-i-n junction diodes that have an n or i region that is as much as half the thickness of the n region of a conventional fast-recovery p-n junction. The resulting device, therefore, can have a much-reduced reverse-recovery charge because being thinner the base region has a lower effective resistance than that of the p-n diode when flooded with carriers. So it is possible to

Figure 17.6 Impurity concentration and electric field distribution under reverse bias of a p-i-n junction diffused diode

reduce significantly the base carrier concentration, by limited carrier injection or by lifetime reduction, without such an increase in the on-state voltage drop. For example, a 1400 V target voltage design p-i-n diode with an average current rating of 300 A has a maximum reverse-recovery charge of 8  $\mu\text{C}$ . This compares to 25  $\mu\text{C}$  for a 1400 V diode of the same size and an average current rating of 295 A.

One disadvantage of the p-i-n junction diode is that its reverse-recovery characteristic exhibits *snappy recovery* compared to the comparatively *soft recovery* of the fast-recovery p-n junction diode. This results from the fact that the depletion layer spread during recovery is very rapid in the low doped intrinsic base region. By careful design of the fast diode it is possible to minimise the snappy behaviour of the diode, this is of particular importance for IGBT applications as will be discussed in Section 17.6.

## 17.2 Bipolar power transistors and Darlington's

### 17.2.1 Bipolar n-p-n power transistors

The bipolar power transistor is a three terminal power device that relies on charge modulation to reduce device on-state voltage. Carriers are injected from the emitter region and transit across the base region to be collected at the collector and modulate the resistivity of the lightly doped collector. Almost all high power bipolar transistors produced today are based on the n-p-n type of construction, although the alternative p-n-p type of construction is also produced, mainly for use in complementary switching circuits. However, the same principles of operation apply for both types of device. High power bipolar n-p-n power transistors are available today in the type of package shown in Figure 17.7, made from a single silicon wafer with continuous current ratings of up to 1000 A and peak currents of up to 1200 A and collector emitter sustaining voltages of up to 1000 V. Construction of the device begins with the diffusion of an n-type impurity to form the  $n^+$  collector region and this is followed by further p-type and n-type diffusions

**Figure 17.7** Outline of a high power transistor package

This results in the typical bipolar n-p-n power transistor diffusion profile shown in *Figure 17.8*. An alternative manufacturing procedure replaces the initial n-type diffusion into lightly doped n-type silicon crystal with a high resistivity epitaxial silicon layer grown on a highly doped n-type silicon substrate. The surface structure of the high power bipolar transistor ensures an even distribution of base current over the active area of the device.

Generally, bipolar n-p-n transistors are operated either in a fully off state or in an on-state and driven between these two states as rapidly as possible to reduce instantaneous power losses. In the off state the base of the device is held at zero or negative bias to minimise collector leakage current. The electric field distribution that typically will exist inside the collector structure when the maximum permitted voltage is applied is shown in *Figure 17.9*. As can be seen from *Figure 17.6*, the electric field distribution in the

**Figure 17.8** Diffusion profile of a typical bipolar n-p-n power transistor and on-state injected carrier density

**Figure 17.9** Diffusion profile of a typical bipolar n-p-n transistor and off-state electric field distribution

reverse-biased collector region of the bipolar n-p-n power transistor is similar to the reverse bias p-i-n junction power diode. The objective of the two designs is the same, insofar as both aim to achieve as high a reverse blocking voltage capability as possible with the thinnest piece of n-type silicon that can be used.

Bipolar n-p-n power transistors are usually operated in one of two alternative on-states: saturation or quasi-saturation. However, it is sometimes necessary to operate these devices in the active region shown in *Figure 17.10* for certain applications, despite the fact that these devices are not designed and, therefore, not optimised for use in this region. Under these circumstances only a very reduced power-handling capability is possible. In the saturated on-state the collector emitter voltage  $V_{CE}$  is less than that for the forward bias voltage which appears across a simple silicon

**Figure 17.10** Output characteristics of the bipolar junction transistor in the common emitter configuration

p-n junction such as a p-n junction diode. This is because the collector base junction becomes forward biased at high collector current and this subtracts from the voltage across the base emitter junction resulting in typical  $V_{CE}$  voltages of 0.2–0.3 V. However, in this condition the whole of the base and collector regions of the bipolar n-p-n power transistor are saturated with injected carriers. When a device is switched off under these conditions a considerable amount of charge has to be extracted and this is associated with a long storage time,  $t_s$ . If the collector voltage is held above 1.5 V the device is said to be in quasi-saturation and the collector base junction is prevented from becoming forward biased.

To ensure safe switching of a bipolar n-p-n transistor between the off- and on-state a number of basic rules have to be observed. In addition, a large bipolar n-p-n power transistor has a number of important features that can best be understood by reference to *Figures 17.11 to 17.16*.

*Figure 17.11* shows the important waveforms involved in resistive load switching of a typical bipolar power transistor. Line A–C in *Figure 17.11(a)* shows a voltage-current excursion during both turn-on and turn-off. Turn-on and turn-off switching energy losses can be reduced by minimising the transition time from point A to point C. The delay time ( $t_d$ ) and rise time ( $t_r$ ) as defined in *Figure 17.11(b)* can be reduced by increasing the turn-on base current ( $I_{B1}$ ) defined in *Figure 17.13* and, thereby, the turn-on losses can be reduced. The fall time ( $t_f$ ) defined in *Figure 17.11(b)* of a saturated transistor can be reduced by optimising  $dI_{B2}/dt$ , the rate of application of  $I_{B2}$ . Optimisation ensures simultaneous cut-off of the emitter-base and collector-base junctions of the transistor. Once this has occurred the transistor enters the quasi-saturated region. Thereafter, a large value of  $I_{B2}$  may be safely applied and this ensures a minimum fall-time and, thereby, reduces the turn-off losses. A transistor already operating in the quasi-saturation region may have  $I_{B2}$  applied as rapidly as possible, without damage.

*Figure 17.12* shows the waveforms involved in switching an inductive load. The switch-on waveform shown in *Figure 17.12(a)* is indicated as that part of the switching locus  $A \rightarrow B \rightarrow C$  and the switch-off waveform  $C \rightarrow D \rightarrow A$ . The freewheel diode ( $D_f$ ) conducts load current ( $I_L$ ) when the transistor turns off. The diode is assumed to exhibit reverse-recovery characteristics and have an initial load current  $I_M$ . Consider first the turn-on sequence of the transistor. Assume  $D_f$  is initially in conduction when  $V_{CC}$  is applied across the transistor and stray lead inductance.  $D_f$  starts to recover but appears initially as a short circuit. When the diode recovers the voltage across the transistor ( $V_{CE}$ ) falls from  $V_{CC}$  to the on-state value and the transistor current increases to full load current value, as shown in *Figures 17.12(b), 17.12(c)* and *17.12(d)*. The rate of rise of this current is determined by the magnitude and rate of rise of  $I_{B1}$  and by transistor gain. High-gain transistors driven by large base currents exhibit the lowest turn-on losses. During turn-off the diode will remain non-conducting until  $V_{CE}$  reaches the supply voltage  $V_{CC}$ . Throughout the rise in  $V_{CE}$  all the load current flows through the transistor but, once  $V_{CE}$  reaches  $V_{CC}$ ,  $I_C$  drops to zero and  $D_f$  carries on conducting the load current. At this point  $V_{CE}$  can exceed  $V_{CC}$  by around 10–20 V due to the finite turn-on time of  $D_f$ . The total  $V_{CE}-I_C$  excursion during inductive switching is as shown in *Figure 17.12(a)*. By reducing the collector current switching time, energy losses can be reduced and the safe operating area extended. The safe operating area is that portion of  $V_{CE}-I_C$  switching boundary graph which a load line can traverse without damaging the transistor.

*Figure 17.13* shows the relevant base current waveforms.  $I_{B1}$  should initially be high during charging of the emitter-

base capacitance  $C_{BE}$ , that is usually 2–3 times the value required during the full turn-on phase. During free-wheel diode recovery, the transistor will carry the recovery current causing it temporarily to enter the linear region of the  $V_{CE}-I_C$  characteristic. During the conduction phase, sufficient base current must be applied to keep the transistor fully saturated or quasi-saturated. This current is about 1.5 times that for saturation of a minimum-gain transistor. Application of a negative base current  $I_{B2}$  will remove charge from the base-emitter junction.  $dI_{B2}/dt$  must be adjusted so that the emitter-base and collector-base junctions are cut off together. For inductive load switching, as with resistive loads, the quasi-saturated state does not suffer from this limitation.

High-frequency applications tend to favour the quasi-saturated mode of operation. Large  $I_{B2}$  values reduce storage and fall times but, once the ratio  $I_{B2}/I_{B1}$  exceeds 3, little further improvement is observed.

In order to improve the voltage hold-off capability and control any  $dv/dt$  effects, a reverse bias of at least 3 V needs to be maintained across the emitter-base junction. It is permissible to operate this junction in the avalanche region, provided that power levels are kept low.

Use of a 'Baker's' clamp as shown in *Figure 17.14* prevents transistor saturation, keeping the transistor in the quasi-saturated regions. Diode  $D_{as}$  conducts base current into the collector and prevents the collector voltage from going below a given value. Anti-saturation techniques such as this give shorter storage times and fast turn-off, since there are few excess carriers in the collector that need to recombine with the collector current.

The use of a low-value resistor  $R_{BE}$  of approximately 10–100  $\Omega$  between the emitter and base terminals increases the transistor blocking capability. Only a small current is diverted through this resistor and power loss is small. The effect of  $V_{CE} dv/dt$  can be controlled by applying a negative base-emitter voltage during the off state. Power losses in the  $R_{BE}$  resistor then become more significant during the off state than in the transistor on state. As  $R_{BE}$  is decreased storage time is also reduced which is due to a lower emitter-base junction capacitance time constant at turn-on.

Switching of transistors, especially with inductive loads, necessarily incurs the simultaneous application of supply voltage  $V_{CC}$  and full load current  $I_C$  as shown in *Figures 17.15* and *17.16*. Violation of the permitted safe operating area may occur under these conditions which can result in the transistor being driven into secondary breakdown and thermal destruction of the device. Restrictions must therefore be placed on the operating conditions of the transistor.

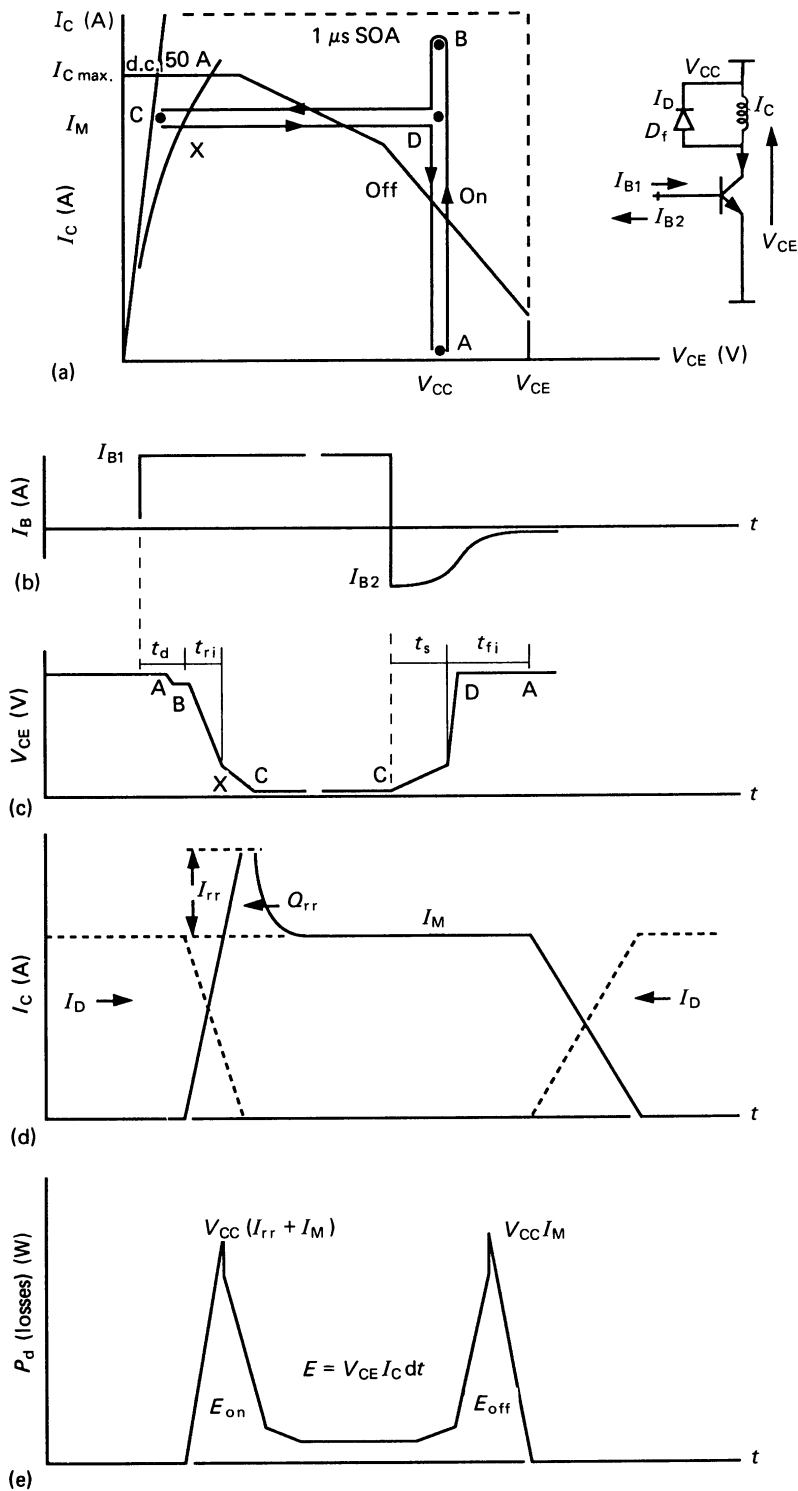

To avoid simultaneous application of high voltage and high current, the  $V_{CE}-I_C$  excursion needs to be modified such that its path across the safe operating region does not produce this situation. This also minimises losses and the full rating of the transistor can be obtained. The modification is effected by components that ensure that peak current and peak voltage do not occur together during turn-on and turn-off.

A turn-on aiding circuit is shown in *Figure 17.15*. The inductance holds off and controls the collector  $di/dt$  during turn-on. If the inductor used is non-saturable then  $di/dt = V_{CC}/L$ . The inductance  $L$  also controls the free-wheel diode recovery current.

If the inductance is saturable  $V_{CE}$  falls and the inductance initially holds off the supply voltage deficit without much current flow. The inductance then saturates to a low value and supports very little voltage. Losses in the inductance are low since the current required to magnetise it is small. In *Figure 17.15(c)* the saturable inductance supports the deficit

**Figure 17.11** Transistor switching with a resistive load. (a)  $I_C/V_{CC}$  trajectories; (b) base current  $I_B$  and collector voltage  $V_{CE}$  (in volts); (c) collector current; (d) instantaneous power loss

**Figure 17.12** Transistor switching with an inductive load. (a)  $I_C/V_{CE}$  trajectories; (b) base current; (c) collector voltage; (d) collector current; (e) instantaneous power losses

Figure 17.13 Transistor base current switching waveform

Figure 17.14 The Bakers clamp circuit

supply voltage until  $V_{CE}$  has fallen to zero. Once the inductor is saturated, the collector circuit non-load inductance becomes very low. The free-wheel diode reverse recovery  $di/dt$  is very large, possibly forcing the transistor into the linear region as shown in Figure 17.15(c) and the addition of a series non-saturable air core inductor may be required.

A resistance  $R_s$  in series with the diode speeds up the current decay. Similarly a diode/zener configuration will constrain the inductor voltage and also reduce the current decay time.

A turn-off aiding 'snubber' circuit and the waveform excursions developed are shown in Figure 17.16. At turn-off current is diverted from the transistor to the snubber capacitor  $C_s$  with the collector voltage clamped to the capacitor voltage. At turn-on  $D_s$  blocks and  $C_s$  discharges current through  $R_s$  and the transistor. The power losses in the resistor are given by  $P_c = \frac{1}{2} C_s V_{CC}^2 f$ .

If the collector voltage rise time  $t_{rv}$  is minimal compared to the  $I_C$  fall time ( $t_{fi}$ ), then maximum energy loss during switching in an unaided transistor is given by  $W_T = \frac{1}{2} I_C V_{CC} t_{fi}$ .

Losses are less for snubber-aided transistors because switching occurs at low  $V_{CE}$  voltages, allowing more efficient transistor operation. As  $C_s$  is increased, more energy is diverted from the transistor to the capacitor. The energy stored in  $C_s$  can become very large and must be dissipated as heat in  $R_s$  during the subsequent turn-on phase. At high voltages and switching frequencies the power rating of  $R_s$  will become large, making it more desirable to recover the energy in  $C_s$ .

The 'snubber' circuit maintains the transistor load inside the safe region of the curve RBSOA, increasing device efficiency, since most of the energy dissipated in the snubber would otherwise be dissipated by the transistor.

The size of the snubber capacitor determines the snubber effectiveness and its purpose is to yield a desired rate of rise of  $V_{CE}$  at a given peak  $I_C$ . The time interval ( $+t$ ) of interest for this calculation is that measured from the instant  $V_{CE}$  starts to rise at turn-off until  $I_C$  approaches zero. This time interval also is dependent on reverse-base current applied to the transistor.

$R_s$  is chosen to ensure that  $C_s$  will discharge completely during the conduction time of the transistor.

The power dissipated in a snubber resistor is given by

$$P_d = 1/2 V_{\max}^2 C_s \times f (\text{watts}) \leftarrow$$

where  $f$  is the frequency of operation. The snubber capacitor increases the fall time of the transistor by slowing the rate of rise of  $V_{CE}$ . The crossover point of voltage and current is lowered by the use of a snubber, indicating a reduction in peak power dissipation, as indicated in Figure 17.16. A more complete description of the bipolar n-p-n transistor is given in reference 1 and of the application of the device in reference 2.

### 17.2.2 Bipolar n-p-n power Darlington transistor

In spite of some disadvantages the monolithic, or one-chip, Darlington transistor continues to be extremely popular for power transistor switching applications. Its main advantage is its high gain with a minimum number of components. The gain of the Darlington is given by the following equation for an unstabilised Darlington

$$\beta_S = \frac{I_C}{I_{B1}} = \beta_1 + \beta_2 + \beta_1 \beta_2$$

where  $\beta_1$  is the gain of transistor  $T_1$  and  $\beta_2$  is the gain of transistor  $T_2$  in the simple Darlington configuration shown in Figure 17.17(a).

The addition of stabilising resistors  $R_1$  and  $R_2$  as shown in Figure 17.17(b), which are normally included in the silicon chip, improve storage time but reduce gain. The gain of the Darlington is then given by

$$\beta_S = \beta_1(\beta_2 + 1) + \beta_2 \left( 1 - \frac{V_{BE2}}{R_2 I_{B1}} \right)$$

when the effect of  $R_1$  is neglected.

To prevent the Darlington coming out of saturation under overload current conditions, it is necessary to over-drive the base as illustrated in Figures 17.18 and 17.19 and, although the device gain fails, the saturation voltage  $V_{CED}$  can be maintained at an acceptable level:

$$V_{CED} = V_{CE1} + V_{BE2}$$

At turnoff however the input transistor  $T_1$  displays a storage time  $t_{S1}$  after which  $I_{C1}$  drops resulting in a decrease in  $I_{B2}$ . The output from  $T_2$  is quasi-saturated with a storage time  $t_{S2}$ , and from Figure 17.20 it can be seen that

$$t_{SD} = t_{S1} + t_{S2}$$

As  $I_{B1}$  increases with  $I_C$  held constant, forced gain decreases and  $t_{SD}$  increases (Figure 17.21). Since the output transistor

**Figure 17.15** Transistor switch-on: (a) without a switch-aiding circuit; (b) with a switch-aiding circuit; (c) with a saturable reactor switch-aiding circuit

(c)  
Figure 17.15 (continued)

is in quasi-saturation, its storage time  $t_{S2}$  is independent of forced gain. Therefore, overdriving the Darlington (Figure 17.17) only influences the storage time of the driver transistor  $t_{S1}$ . This can be reduced if a negative base current is withdrawn from  $T_1$ . However, if the ratio of negative to the positive base current is increased, the effect on  $t_{SD}$  diminishes, as shown in Figure 17.22. Any further reduction in  $t_{SD}$  can only be brought about by reducing  $t_{S2}$  that can be achieved by fitting a speed-up diode  $D_1$ , as shown in Figure 17.23. When  $D_1$  is fitted the emitter-base junction of  $T_1$  is by-passed. A negative base current will then flow into  $T_2$  if a negative bias  $-V_{BB}$  is applied to  $R_1$ , which reduces  $T_{S2}$ , but only after the emitter-base diode of  $T_1$  begins to become reverse biased. Current flowing in  $D_1$  then reverse biases the emitter-base junction of  $T_1$ . However, the reverse-bias voltage may be insufficient to allow efficient turn-off of  $T_1$ . Therefore, several diodes may be connected in series to increase the reverse bias on  $T_1$ .

The Darlington turn-off sequence is complete after the fall time  $t_{FD}$ . This is dependent only on  $T_2$  ( $T_1$  having been previously turned off). The requirement for optimum turn-off of  $T_2$  is dependent on simultaneous cut-off of its emitter-base and collector-base junctions that can be achieved by carefully controlling the value of  $dI_{B2}/dt$ .

## 17.3 Thyristors

### 17.3.1 The basic thyristor

The basic thyristor structure is shown as a two transistor analogue model in Figure 17.24(a). As can be seen from this figure, the thyristor is a four-layer junction silicon device

that performs as a controllable rectifier. Functionally, it can be described in terms of two internally connected complementary transistors, with current gains,  $\alpha_{npn}$  and  $\alpha_{pnp}$  operative within a positive feedback loop. When the sum of their gains is raised to unity, the forward-biased thyristor switches from a high- to a low-impedance state. In normal operation, current injection through the third terminal or gate initiates this regenerative action. Two-terminal break-over also occurs, as shown in Figure 17.24(b) by carrier multiplication when the forward bias is increased to a critical value defined as the breakover voltage  $V_{BO}$ .

The vertical doping concentrations and the four semiconductor layers of the thyristor are shown in Figure 17.25. Forward- and reverse-blocking voltages are supported across the charge-depletion layers that develop around junctions  $J_2$  and  $J_3$  of the thyristor shown in Figure 17.25. The vertical layers of the p-n-p-n structure must be designed, therefore, in terms of widths and impurity concentrations to accommodate the depletion regions: this is achieved by the correct specification of the high-resistivity n-type starting material and of the detailed sequential diffusion and fabrication processes used to form the active structure. Under reverse bias, the anode is negative with respect to the cathode and both junctions  $J_1$  and  $J_3$  are reverse biased. Because the p and n regions at  $J_1$  are heavily doped this junction avalanches at a low voltage, and so the device behaves in essentially the same manner as a p-n junction diode, with a low leakage current being maintained up to a critical breakdown voltage.

Today, production thyristors are available with voltage ratings up to about 6000 V. Even higher voltages are feasible, but only at the expense of severe de-rating on other important parameters, including current rating and switching speed.

**Figure 17.16** Transistor switch-off: (a) without a switch-aiding circuit; (b) with a snubbing active-capacitor switch-aiding circuit

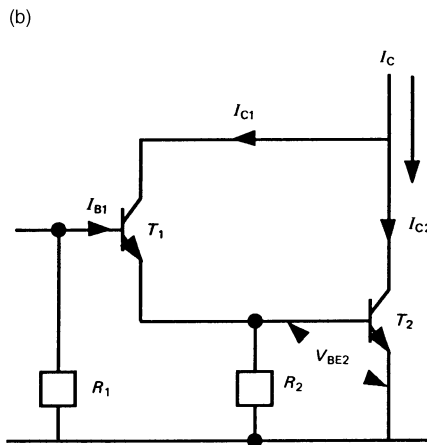

Figure 17.17 (a) Simple Darlington configuration; (b) stabilised

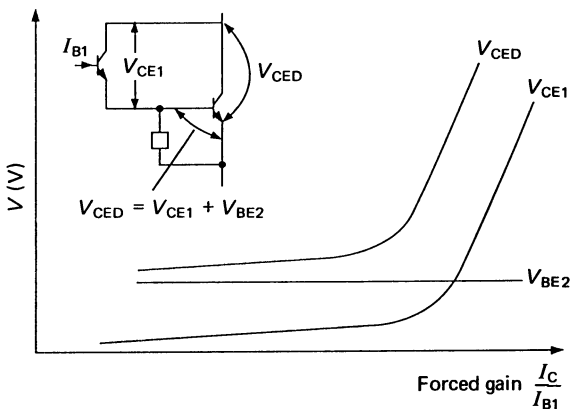

Figure 17.18 Effect of forced gain on Darlington collector emitter saturation voltage

The limit to reverse blocking is set by avalanche multiplication of carriers traversing the high electric field in the space charge region of  $J_3$  that occurs at a critical value of maximum field. A wide depletion layer is thus necessary to support a high blocking voltage, and this in turn implies the use of high resistivity, or lowly doped n-type starting

Figure 17.19 Effect of forced gain on  $V_{CE(sat.)}$

Figure 17.20 Darlington storage time as a function of forced gain

material. Although complicated to some extent by the loop-gain, similar considerations apply in setting the level of forward-blocking voltage.

This simple picture is true within the bulk of the thyristor structure, but neglects a factor of crucial importance: this is the termination of the p-n junctions at the silicon surface. Unless corrective steps are taken, electric-field enhancement can occur locally at the surface with a lowering of the breakdown voltage and destructive channelling of the avalanche current. The solution of this problem is by ensuring adequate field relief at the surface. Figure 17.26 shows one approach that can be used, that remains the basis for many of today's high-voltage 'alloyed' thyristors. The edge of the silicon pellet has a compound bevel, with a surface at angle  $\theta_1$  to the junction plane to control reverse blocking, and a surface at  $\theta_2$  to control forward blocking. These sections are frequently termed 'positive' and 'negative' bevels, respectively. The exact measure of the field relief afforded depends on both the diffused concentration gradients and the surface conditions, including the density of surface charge and the dielectric properties of the surrounding ambient. The positive bevel acts by spreading the equipotentials in the high-resistivity n-base region, and a four-fold reduction in peak field is obtained with a bevel angle of about  $20^\circ$ . Likewise, the negative bevel acts by equipotential spreading in the diffused p-region. Its effect is less pronounced and more dependent on the dopant concentration

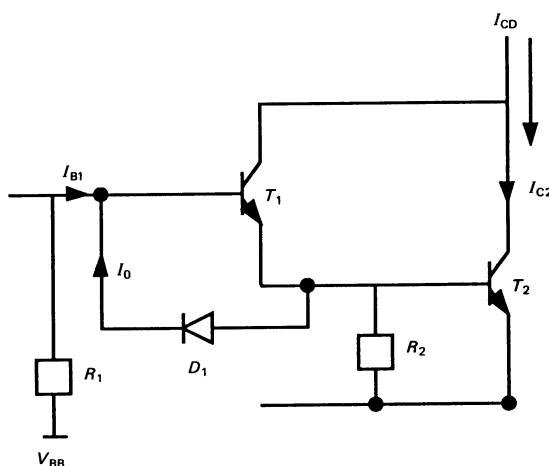

**Figure 17.21** The relationship between base current ( $I_{B1}$ ) the driver transistor collector current ( $I_{C1}$ ) and storage time ( $t_{S1}$ ), Darlingtong current ( $I_{CD}$ ) and the Darlingtong storage time ( $t_{SD}$ )

**Figure 17.22** The effect on  $t_{SD}$  of a negative bias applied to the driver transistor

gradient close to the junction. Low-angle bevels, typically  $2-4^\circ$ , are necessary.

Other types of edge termination are also used on higher power higher voltage thyristors: these include double negative bevels and double positive bevels. These techniques are generally applied to the so-called 'fully floating' thyristors. In the 'alloyed' device the anode contact is provided by a permanently 'alloyed' molybdenum disc, with the cathode contact using being a direct pressure contacted disc. In the

**Figure 17.23** The reduction of  $t_{S2}$  by means of an anti-parallel diode connected across the emitter-base junction of a driver transistor

free floating type both the anode and the cathode surfaces are contacted using a pressure plate. From the user perspective the alloyed type can offer a better transient thermal response, but it presents difficult manufacturing problems, particularly at high current ratings owing to the large diameter of the alloyed joint. In broad terms devices below 75mm silicon diameter are more usually alloyed, those of larger size more generally fully floating.

The thyristor conducting area is clearly one key factor in determining the on-state voltage, mean and surge current ratings of a thyristor. Also, when the thyristor is in the on-state, all three junctions are forward biased and the anode-to-cathode voltage drop approaches 1 V at low current densities. As the current is increased, additional non-linear voltage drops arise within the base regions, so that the on-state voltage drop becomes particularly dependent on their widths, and the injected carrier lifetime within them. (For a brief description of p-n junctions and carrier injection see Section 17.1.) Both high-voltage or wide-base, and fast-switching or low-lifetime design requirements imply an increase in on-state voltage drop, and hence reduction in current density rating.

The electrical performance of the thyristor is also dependent on the mechanical design and the thermal performance of the housing in which the silicon pellet is encapsulated. Typically high power thyristors are assembled in press pack housings such as that shown in Figure 17.2(a). But smaller devices use standard stud based or plastic packages. Moving outwards from the silicon pellet, low-resistance non-rectifying contacts must be made to the three electrode regions. As well as carrying the load current without a significant voltage drop, these contacts provide the path for heat flow away from its source within the silicon to an external heat sink or cooling system. This cooling is vital, since all the thyristor characteristics are to some degree temperature sensitive, and the maximum operating temperature of the silicon must be limited to about  $125^\circ\text{C}$ . Power ratings depend, therefore, on the thermal resistance between the silicon and the external heat sink, which is cooled by either natural convection or forced-fluid methods. Thermal resistance from junction to mounting base achieved by these techniques ranges from about  $3^\circ\text{C/W}$  for a low-power stud-mounted thyristor to below  $0.02^\circ\text{C/W}$  for a high-power double-side-cooled encapsulation.

**Figure 17.24** (a) Two transistor model of the thyristor; (b) Thyristor current-voltage characteristics

Long-term operational reliability is also a vital feature of all thyristor designs. The packages are hermetically sealed by techniques including electric resistance, projection welding, argon arc welding and cold pressure welding, after thorough vacuum out gassing of all components and filling with a dry nitrogen ambient. The materials used in the packaging are arranged so that the device can withstand many temperature excursions and as a result thyristors can be extremely reliable and survive under extreme conditions for several decades.

It is also possible to deposit a special passivation on the silicon surface, which allows highly reliable thyristor construction in moulded plastic packages similar in external appearance to those used for high power IGBTs (Figure 17.2(b)). An important application of these protected silicon pellets is in assemblies that provide most cost-effective arrangement for many medium and low-power control applications.

The switching behaviour of the thyristor is explained with reference to Figure 17.27 where it is defined in terms of the turn-on and turn-off times, together with the associated  $dI/dt$  and  $dV/dt$  ratings. The  $dI/dt$  rating is the maximum permissible rate of increase of load current, and the  $dV/dt$  rating is the maximum rate of rise of off-state voltage that will not initiate conduction.

The three phases of turn-on are shown in Figure 17.27. The delay time is associated with establishment of transistor, and hence regenerative, action in response to the gate current. Its duration is set by the level of gate drive and by the minority carrier transit times across the transistor bases. A high gate drive reduces the delay time, and wide base regions, or high blocking-voltage rating, increase it. Following the delay time the voltage across the thyristor collapses. Regeneration is well established during the rise time, with charge modulation of the base regions aiding carrier transport so that the rate of current build-up is more

Figure 17.25 Doping concentration across section of a thyristor. Junction positions  $J_1$ ,  $J_2$ ,  $J_3$  are shown

Figure 17.26 Section of a thyristor compound edge bevel. The depletion layer is shown around  $J_3$  under reverse bias on the left-hand side, and around  $J_2$  under forward bias on the right-hand side

Figure 17.27 The anode-to-cathode and voltage waveforms during thyristor turn-on and circuit-commutated turn-off

rapid. Again, longer rise times are to be expected in high-voltage thyristors with wide base regions, particularly when it is remembered that the collapse of the centre-junction depletion layer during turn-on widens the effective base widths. Finally, there is the spreading time. A fundamental feature of thyristor turn-on is its three-dimensional nature. Because of the finite transverse or sheet resistance of the p-base region, the initiating gate current influences only those regions of the cathode nearest to the gate contact. The gate contact is most usually in the centre of the thyristor. Regenerative switching action is restricted to the turned

on regions close to the gate thus formed a narrow conducting plasma. The establishment of the equilibrium current flow over the cathode area follows by outward spreading from this conducting plasma by field-aided diffusion. Plasma spreading is a relatively slow process, with a typical 'velocity' of  $0.1 \text{ mm}/\mu\text{s}$ . When the area of conduction is small the anode/cathode voltage is considerable, leading to high turn on power densities and excessive local heating may result if the current is allowed to increase too rapidly ( $di/dt$ ).

This turn on spreading phenomenon is affected not only by geometrical factors but also by base widths and such other factors as the recombination rate of carriers within them. The spreading velocity is decreased in both high-voltage and fast turn-off structures.

Where higher  $di/dt$  performance is required the amplifying gate structure shown in Figure 17.28(a) is employed. It may be viewed as the integration of two radially disposed thyristors with a common anode contact. The initiating gate pulse turns on the inner small area, or auxiliary thyristor, this draws current from the external load and provision is made to feed this current back into the silicon via an overlapping metal contact. This amplified current provides the gating current for the main power thyristor. Once the latter is switched, the auxiliary structure is extinguished due to lateral self-biasing voltages. In this way, the repetitive  $dI/dt$  rating can easily be increased to about  $500 \text{ A}/\mu\text{s}$  or greater and switching losses are reduced.

An extension to the amplifying-gate principle is to increase further the area of initial conduction by extending the edge length of the auxiliary thyristor coupling contact and ultimately incorporating an interdigitated gate structure on the silicon surface, as shown in Figure 17.28(b). The technique is applicable to the highest power large area thyristors. During the on-state all three junctions of the thyristor are forward biased, and both base regions contain excess minority and majority charge. In switching off the thyristor and reverting to the blocking state, charge must either be swept out by an electric field, or decay through regenerative processes within the silicon.

Practical circuits use anode commutation, or bias reversal, to turn off a thyristor, and this is represented by the waveforms as shown in Figure 17.27. When the reverse voltage

**Figure 17.28** (a) Amplifying gate thyristor; (b) interdigitated amplifying gate thyristor

is applied it forces the current to fall to zero at a rate defined as  $dI/dt$ . Once it reaches zero, current flow reverses since the minority carrier concentration at the junctions can support this current as they are extracted before depletion-layer build-up. The peak value of reverse current is reached when the excess hole concentration at the anode junction has fallen to zero. At this time the voltage across the thyristor reverses, with development of the anode depletion layer, and the current decays in a near-exponential manner as a result of charge recombination within the n-base region. It must fall to, at most, the holding current if the

thyristor is to block when forward voltage is reapplied. How long this takes is critically dependent on the mean lifetime of injected carriers in the n-base region, and on any extraction of stored charge (in the n-base region) into the load circuit or out from the gate connections.

Special steps are taken to reduce the n-base minority-carrier lifetime in thyristors designed for use in high-frequency applications. Gold, diffused through the structure, or radiation damage is used to provide a controlled concentration of impurity centres or traps through which the injected carriers recombine. Any method used to reduce minority-carrier

**Figure 17.29** The relationship between on-state voltage ( $V_T$ ) and circuit commutated turn-off time ( $t_q$ ) for fast switching and gold doped thyristors of different n-base width ( $W_n$ ) and hence different voltage rating

lifetime leads inevitably to some increase in the on-state voltage drop, principally through a reduction in conductivity modulation of the n-base region. As the recombination centre concentration is raised to reduce the turn-off time, this effect assumes increasing significance, particularly in the case of wide-base, high-voltage devices. The form of the relationship between on-state voltage and turn-off time is illustrated in Figure 17.29.

Under normal operation the forward-blocking voltage will be re-applied to the thyristor at a specified rate, or  $dV/dt$  as shown in Figure 17.27, and this gives rise to a uniform charge-displacement current as the depletion layer develops around the centre junction. Its magnitude is simply the product of the voltage-dependent junction capacitance, and the value of  $dV/dt$ . If no steps are taken to counteract this, the cathode junction will become forward biased by the flow of this displacement current, and this will lead to thyristor switching action.

The so-called 'shorted-emitter' technique shown in Figure 17.30 is effective in preventing this two-terminal switching up to high values of  $dV/dt$ . It is a method for controlling carrier injection by structural design via a regular array of small-area electrical short circuits in the n emitter to the underlying p region. These 'shorts' are usually in the form of an array of distributed dots over the cathode emitter. All high power thyristors use this technique. The displacement

**Figure 17.30** Distributed shorting of the thyristor-cathode junction to permit high rates of application of forward-blocking voltage or  $dV/dt$  rating

current flows laterally to these points and bypasses the emitter regions, this minimises the forward bias developed at the cathode junction. The limit on  $dV/dt$  is set by the ohmic voltage drop caused by transverse displacement-current flow in the p-base region. When any part of the cathode emitter is biased above about 0.6 V, it starts to inject and the thyristor may switch on. By correct selection of shorting dot diameters, spacing and array symmetry,  $dV/dt$  ratings exceeding 1000 V/ $\mu$ s can be realised without sacrificing much gate-triggering sensitivity. However, some loss in gate sensitivity is inevitable since a fraction of the gate signal will always flow to shorts near to the cathode edge and play no part in the turn-on process. With correct design this can be minimised and the threshold gate current to fire the device kept below a reasonable value of 100–150 mA. There will also be some degradation to the on-state voltage as the emitter shorts give an effective reduction in the cathode emitter efficiency.

From overall design considerations an array of closely spaced minimum area shorts is preferred for a given  $dV/dt$  rating. They then occupy the smallest fraction of the cathode area and have the least effect during on-state conduction, and provide the minimum impedance to conduction spreading during turn-on.

The turn-off performance of thyristors can also be improved through the use of increased n-emitter shorting. When the shorting density is in excess of that needed to meet the required  $dV/dt$  withstand, forward anode voltage can be re-applied earlier in the charge-decay period, and the residual charge extracted safely from the n base. This is because during turn off the emitter shorts give direct access to the base regions of the thyristor which assists charge extraction and reduces any emitter injection during the turn off period. In this way it is possible to realise high-power fast-switching thyristors for use at frequencies in excess of 10 kHz. A more complete description of thyristors is given in the references 1, 3 and 4 at the end of this chapter.

### 17.3.2 The converter thyristor

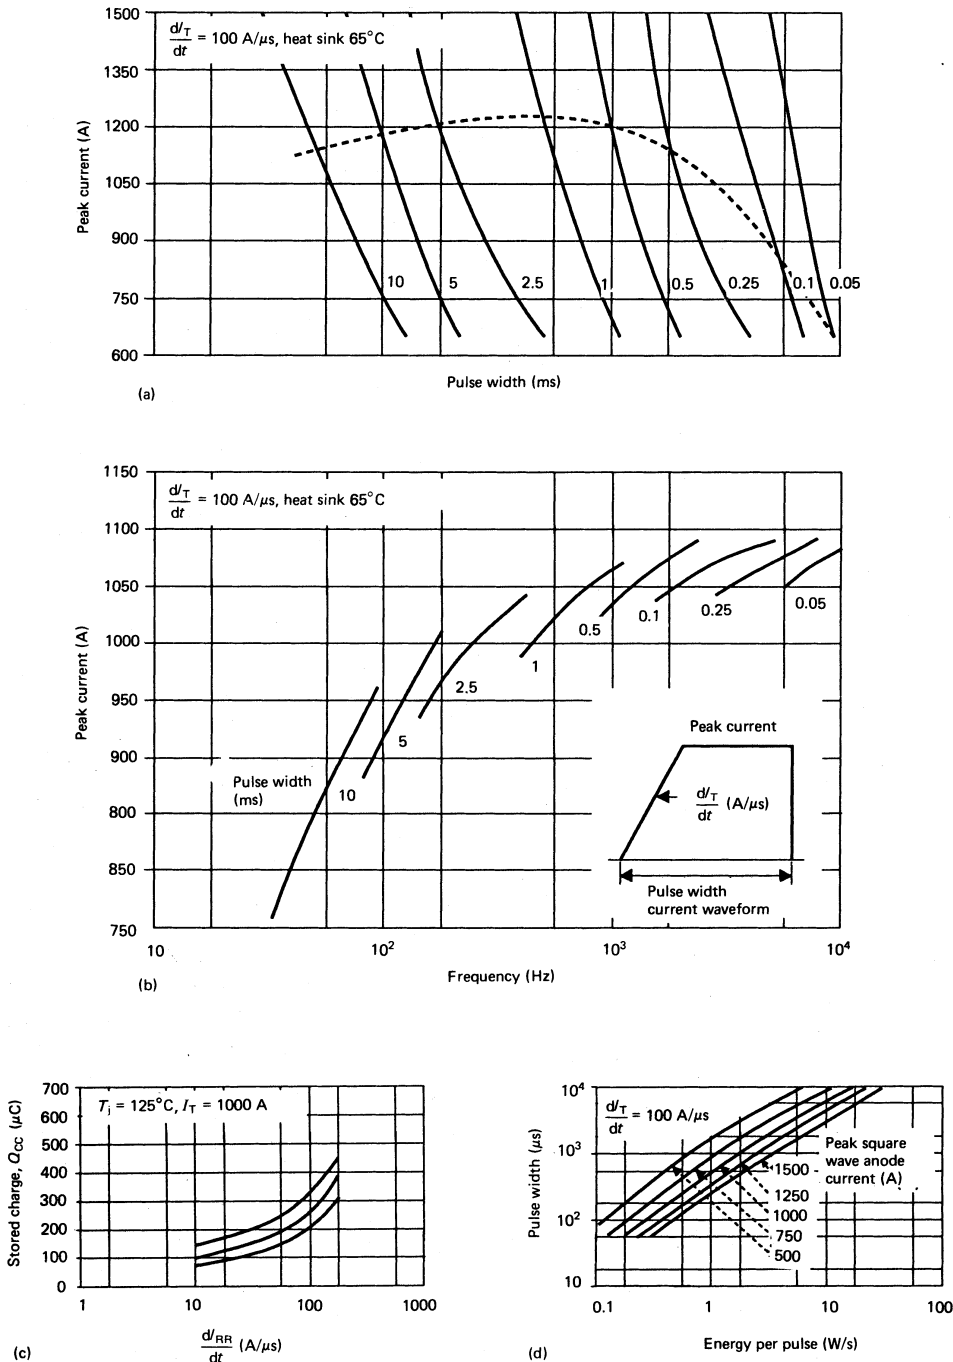

The converter thyristor is designed and optimised primarily for operation at 50 or 60 Hz (mains frequency) and is available up to 5000 V and 3500 A average current rating. The basic design of the converter thyristor is the same as the basic thyristor described above. The introduction of gold or electron irradiation recombination centres is not normally necessary in this type of device, where the main objective of the design is to achieve the lowest on-state voltage possible for the voltage rating required. However many high power applications interconnect several thyristors in series where both static and dynamic voltage sharing is essential between the thyristor levels. In this case it is necessary to achieve an accurate control of the recovered charge during turn off: this control is usually achieved by gold diffusion or radiation damage in a similar manner to that used for fast recovery diodes. As with the fast diode this results in a compromise between low on state voltage, recovered charge, and leakage current.

### 17.3.3 The fast thyristor

Fast thyristors are designed and optimised for operation frequencies above 400 Hz and up to above 20 kHz. The basic design principles of fast thyristors are the same as those for general thyristors as described above. Their maximum operating frequency is dependent on the switching

losses during turn on and turn off, and the turn-off time. The latter is influenced by the intensity of the cathode emitter shorting, the concentration of the recombination centres introduced in the same n-base region, i.e. the minority carrier lifetime, and also by the base width as shown in Figure 17.29. The turn on performance is improved by the

use of interdigitated amplifying gates (Figure 17.28), and the use of narrow high gain base regions. As these devices are used under high frequency conditions their safe operation is determined by the impact of switching losses, and the designer requires detailed rating data as shown in Figure 17.31. The frequency-rating curves ((a) and (b)) give the

**Figure 17.31** Examples of thyristor square-wave rating data. For ratings tests the gate-source impedance is  $10 \Omega$ , with a gate-pulse rise time to 1 A of  $0.5 \mu\text{s}$ . The thyristor is switched from 600 V and a resistive capacitive (RC) snubber network of  $10 \Omega$ ,  $0.25 \mu\text{F}$  is connected

limiting case for operation under a particular forward-conduction duty, to which must be added the reverse recovery losses derived from stored-charge curves (c). From this total average power loss, together with the steady-state thermal impedance, the maximum thyristor case temperature can be determined to retain the junction temperature within its defined rating. Data on the energy dissipation per pulse as a function of pulse base width are also needed to specify the allowable pulse width for a particular duty and an example of such curves is given in *Figure 17.31(d)*.

Fast thyristors are available with voltage ratings of 600–3000 V, average current ratings upto 2000 A, turn-off times down to 5  $\mu$ s and  $di/dt$  ratings over 1000 A/ $\mu$ s.

### 17.3.4 The asymmetric thyristor

The basic principle of the design of the p-i-n structure which is incorporated in the construction of asymmetric thyristors is similar to the p-i-n diode and is explained in Section 17.1.5. The other features of the basic thyristor structure are retained as shown in the section through an asymmetric thyristor shown in *Figure 17.32*. In this device, the n-base width is minimised for a particular forward-blocking voltage rating by making use of the limited base-width approach of p-i-n rectifiers and an additional heavily doped  $n^+$  layer is included within the n-base region of the device. As junction  $J_3$  is now a  $p^+n^+$  junction it cannot support a high reverse voltage. By sacrificing this reverse blocking capability which is not required in many applications a significant advantage can be obtained in an improved combination of forward blocking characteristic, on-state voltage and turn-off time. Asymmetric thyristors are available with voltage ratings up to 3000 V, or average current ratings over 500 A and turn-off times down to 2  $\mu$ s.

Asymmetric thyristors may be found in two types, fast turn on and fast turn off. The fast turn on asymmetric thyristor is used in power conversion applications, such as a resonant converter, where the device doesn't require forced commutation, or turn off. In this case the device can operate at high frequencies, in the 20 kHz and above

range, at high power, and most efficiently. A further useful application of such a device is as a pulse power component. The fast turn off device is an extension of the fast turn off thyristor described in the previous section, this type has the advantage of even faster turn off, at the expense of no reverse voltage, and increased manufacturing complexity and cost.

### 17.3.5 Triacs

The triac, or bidirectional thyristor, was evolved specifically for low to medium current a.c. load control as, for example, in lamp-dimming circuits. Its construction (shown in *Figure 17.33*) comprises two thyristors in inverse parallel within a five-layer n-p-n-p-n structure. A compound gate region is also included with balanced trigger sensitivities in both the so called first and third electrical quadrants with either a positive or a negative polarity gate bias. The main design problem with a triac is two fold; firstly the two thyristors interact and this will severely limit the turn off and  $dv/dt$  capability of the component, and secondly the gates are placed on the same surface, resulting in difficulties in triggering one of the two thyristors. Yet although the triac poses its own set of design compromises, it can be made by conventional all-diffused thyristor processes. In general, triac ratings were limited to about 50 A r.m.s., 800–1000 V and of only real use in main frequency applications due to their  $dv/dt$  and switching loss limitations but they provide the lowest-cost solution in some a.c. control circuits. For higher power applications, thermal and other considerations make an inverse pair of individual thyristors a more satisfactory proposition.

### 17.3.6 Light fired thyristors

Light fired or triggering of power thyristors offers the advantage of eliminating the normal gate-firing circuit and overcomes the problems of high-voltage isolation normally associated with gate-firing circuits. Light firing also offers advantages in applications in environments where electrical

**Figure 17.32** Doping concentration across a section of an asymmetric thyristor

**Figure 17.33** The bidirectional thyristor or triac for a.c. load control

noise is likely to cause problems by interfering with gate signals.

In the optical-triggering process, the light pulse generates electron and hole pairs. These pairs induce a current pulse that is amplified in turn via an amplifying gate region of the thyristor. This provides sufficient gate current to turn-on the thyristor.

Various light sources can be used such as the light emitting diode (LED) or laser. The light from these sources is pulsed at the appropriate moment into an optical fibre that delivers the light directly to the silicon surface to trigger the thyristor. One of the main problems is the reliability of the light source that is often not as good as the high-power thyristor. Special high-reliability LEDs have been developed for this application. However, although in principle this type of thyristor offers many advantages, it has not been widely used. This is partly because of the limited number of manufacturers who produce this type of device but also because the inclusion of the light-sensitive region on the thyristor adds to the cost and complexity of the device. A more complete explanation of light-fired thyristors is given in reference 3. The main application area for light triggered thyristors was for ultra high voltage electric utility equipment such as HVDC converter stations.

### 17.3.7 HVDC thyristors

The HVDC thyristor is a special type which although based on the standard converter thyristor structure has several demanding specification requirements. These include high fault current capability, high  $di/dt$ , very low on state voltage, a low turn off time, and accurately controlled stored charge. Because generally each HVDC system built is very large, each system design tends to have a specially tailored HVDC thyristor produced for it, using 75–150 mm diameter silicon. The special features that might be incorporated into this type of device are, for example, self-protection in voltage breakover, excess  $dV/dt$ , low voltage triggering and light firing. However these features and the highly demanding specification add significantly to the thyristor cost. Therefore such thyristors tend to be too expensive for general industrial applications but are used in other similar applications such as static valve active reactance (VAR) compensation. They are available with up to the highest voltages, e.g. 8000 V blocking voltage and 3000 A average current rating with carefully tailored characteristics.

### 17.3.8 The gate turn-off thyristor

The gate turn-off (GTO) thyristor has a unique advantage over the conventional thyristor in its ability to be turned off by the application of a negative gate current. Therefore,

in applying the GTO thyristor to thyristor inverter or chopper circuits, the forced commutation components are not needed. This offers the advantages of a simpler power-circuit configuration with an associated reduction in cost, volume and weight, less electrical and audible noise, and improved power-conversion efficiency. The GTO revolutionised high power AC motor drives when they became available and were the device of choice for this application prior to the advent of high power IGBT modules.

The GTO is a four-layer p–n–p–n semiconductor device similar in construction to a thyristor but with several design features which allow it to be turned on like a conventional thyristor and off by reversing the polarity of the gate signal. The turn-on action shown in *Figure 17.34* is similar to a conventional thyristor. Injection of hole current from the gate forward biases the cathode p-base junction causing electron injection from the cathode, these electrons flow to the anode and induce hole injection by the anode emitter. Injection of holes and electrons into the base regions continues until charge multiplication effects bring the GTO into conduction. As with a conventional thyristor only the area of cathode adjacent to the gate electrode is turned on initially, and the remaining area is brought into conduction by plasma spreading. However, unlike the thyristor, the GTO consists of many narrow cathode elements, such as the device shown in *Figure 17.35*. This shows the heavily interdigitated

**Figure 17.34** A GTO thyristor during turn-on. Turn-on is initially along the edge of the  $n^+$  emitter, the remainder of the emitter is brought into conduction by plasma spreading

**Figure 17.35** The emitter pattern of a GTO

**Figure 17.36** A GTO thyristor during turn-off. The gate is negatively biased and holes are extracted by the gate from the p base. The conducting region is squeezed to an area remote from the gate until sufficient charge is extracted to turn the device off

cathode and gate region. Therefore the initial turned on area is very large and the time that is required for plasma spreading is small. The GTO, therefore, is brought into conduction very rapidly and can withstand a high turn-on  $di/dt$ . This excellent turn on capability also makes the GTO attractive as a fast turn on thyristor for low frequency pulse duty applications.

In order to turn-off a GTO, the gate is reverse biased and holes are extracted from the p base, as shown in *Figure 17.36*. Hole extraction continues until the excess carrier concentration is low enough for carrier multiplication to cease and the device reverts to the forward-blocking condition. During turn-off the conducting area is squeezed down to an area remote from the gate electrode and an anode emitter short located in this area to assist turn-off. A lifetime control technique, such as gold or radiation damage is also used to reduce the device p-n-p current gain, thereby improving the turn-off power loss. The switching waveforms that can be observed in the GTO circuit shown in *Figure 17.37* are shown in *Figure 17.38*. Note, the active snubber network consisting of  $D_S$ ,  $C_S$  and  $R_S$  in *Figure 17.37* which restricts the  $dV_D/dt$  that appears across the GTO at switch-off. The meaning of the common terms in the switching waveform are also as shown in *Figure 17.38* ( $t_d$ ,  $t_r$ , etc.). The turn-on delay time ( $t_d$ ), the rise time ( $t_r$ ), and the turn-on energy ( $E_{ON}$ ) are all strong functions of the magnitude of the gate pulse ( $I_{FG}$ ) as shown in *Figure 17.39*. To minimise the turn-on times and energy losses the value of  $I_{FG}$  should be as large as possible, consistent with considerations of the drive power loss and cost.

**Figure 17.37** A typical GTO circuit

The turn-off of a GTO proceeds in three stages: storage time, fall time and tail time. During the storage time ( $t_{gs}$ ) the conducting area is reduced due to a squeezing action of the gate drive, and the negative gate current increases to a peak value  $I_{GQM}$ . The duration of the storage time depends on how rapidly the excess charge ( $Q_{GQ}$ ) is removed by the gate and is therefore a strong function of the rate of rise of reverse gate current  $dI_{GQ}/dt$ . At the end of storage time the anode current falls rapidly, and the reverse gate current begins to decay as the gate junction is forced into avalanche,  $V_{(RG)BR}$ . The avalanche condition is not damaging to the GTO thyristor and assists in the removal of stored charge from the device. During this period the blocking junction of the GTO recovers and the anode voltage rises. Unless a snubber circuit (as shown in *Figure 17.37*) is connected across the GTO the anode voltage could rise at a rate in excess of the device  $dV_D/dt$  capability and destroy the GTO.

After the fall time  $t_{gf}$ , the anode current has fallen to a low value  $I_{tail}$ , which decays away more slowly. This tail period is an important factor for the switching losses since the anode voltage is high at this time. In order to reduce these losses GTO thyristors use anode shorting and minority carrier lifetime control to give low values of  $I_{tail}$ .

The storage time, fall time, gate turn-off charge ( $Q_{GQ}$ ) and switch-off energy are all functions of the applied negative gate current as shown in *Figure 17.40*.

In the on state the GTO operates in a similar manner to the thyristor. If the anode current remains above the holding current level then positive gate drive may be reduced to zero and the GTO will remain in conduction. However, as a result of the turn-off ability of the GTO it does possess a higher holding current level than the normal thyristor and, in addition, the cathode of the GTO thyristor is subdivided into small finger elements to assist turn-off. Thus, if the GTO thyristor anode current transiently dips below the holding current level, localised regions of the device may turn off. Forcing a high anode current back into the GTO at a high rate of rise of anode current, after this partial turn-off, could be potentially destructive. Therefore it is usually recommended that the positive gate drive is not removed during conduction but is held at a value  $I_{G(on)}$  that is greater than the maximum critical trigger current ( $I_{GT}$ ) over the expected operating temperature range of the GTO thyristor.

Unlike the standard thyristor, the GTO thyristor does not include cathode emitter shorts to prevent non-gated turn-on effects due to  $dV/dt$  forward-biased leakage current. In the off-state of the GTO thyristor, therefore, steps should be taken to prevent such potentially dangerous triggering. This can be accomplished by either connecting the recommended value of resistance between gate and cathode ( $R_{GK}$ ) or by maintaining a small reverse bias on the gate contact. This will prevent the cathode emitter becoming forward biased and, therefore, sustain the GTO thyristor in the off-state.

Gate turn-off thyristors, or GTOs, are available with repetitive controllable current ratings up to 4000 A and 4500 V forward-blocking voltages. A more complete description of the GTO is given in references 1 and 3.

## 17.4 Schottky barrier diodes

A Schottky barrier diode, shown for example in *Figure 17.41*, is based on the formation of a potential barrier by the so called Schottky effect at the interface between a metal such as molybdenum, platinum, chromium or tungsten, and a semiconductor surface such as silicon that is in

Figure 17.38 GTO switching waveforms

Figure 17.39 The effect of turn-on gate drive  $I_{FG}$  on  $t_r$ ,  $t_d$  and  $E_{on}$

Figure 17.40 The effect of turn-off gate drive  $dI_{GO}/dt$  on  $E_{off}$ ,  $Q_{GQ}$ ,  $t_{gs}$  and  $t_{gf}$

**Figure 17.41** Reverse bias depleted region applied to a Schottky barrier diode

intimate contact with it. This phenomenon results in the non-linear current transport across the metal semiconductor interface. Forward conduction results from the electrons passing over the potential barrier from the n-type silicon into the metal, reverse conduction is impeded by the formation of a space charge layer. Therefore in conduction very little minority carrier charge is accumulated in the silicon and such conduction is predominantly by the majority carrier electron. The Schottky barrier diode is therefore a unipolar device that operates without the effect of injected carrier modulation. During reverse recovery it behaves almost like a perfect diode switching very rapidly from forward conduction to reverse blocking. This makes the Schottky diode an ideal device for use as a rectifying diode in very high frequency, and fast switching, applications.

In forward conduction the Schottky on-state voltage depends on the contact potential (barrier height) formed between the metal and the semiconductor and, in series with this, the resistance of the semiconducting layers (drift and substrate regions). Because there is no minority carrier injection the on-state voltage is much greater for thicker, and therefore higher reverse blocking, devices. Nevertheless for thin drift and substrate regions the on-state voltage is very low, (for example 0.3 to 0.5 V in silicon) and is therefore significantly better than the p-n diode.

The reverse off-state voltage of the Schottky diode is identical to that of an abrupt p-n junction diode, and is determined by the thickness and resistivity of the drift region. As the reverse voltage rating increases so does the silicon thickness needed to support the space charge region. Unfortunately, the reverse leakage current is also strongly dependent on the Schottky barrier height, and increases as the barrier decreases. This results in the type of characteristics shown in Figure 17.42.

Diffused guard ring structures are usually employed to improve reverse-blocking characteristics by reducing the electric field at the edge of the metal contact area. When combined with an optimised n-type epitaxial layer (Figure 17.41 but guard ring not shown) the best Schottky diode performance is achieved.

Schottky barrier diodes are commercially available with reverse voltages up to 150 V and forward currents of up to 300 A. Higher reverse voltages are prevented in silicon by the high leakage current and consequential operating temperature limitations.

Silicon is not the only semiconductor material that can be used for Schottky barrier diodes, although it is the only material in commercial use at the time of writing. However there is interest in the use of silicon carbide, owing to the

**Figure 17.42** Schottky barrier diode forward- and reverse-bias characteristics

high breakdown field and high Schottky barrier height of this type. With further development this will lead to the availability of much higher voltage and higher current Schottky barrier diodes in the future with the potential of higher temperature operation than silicon.

## 17.5 MOSFET

In the power Metal Oxide Silicon Field Effect Transistor (MOSFET) majority carriers move across an induced channel to carry forward an on-state current. This is better understood by reference to the basic MOS structure shown in Figure 17.43. In this structure the active MOS gate area of the device is on the silicon surface and the MOS gate is made up of three layers: the conductive layer (labelled *M* which could be a metal), the isolating layer (labelled *O* for oxide), and the semiconductor layer (labelled *S* for semiconductor). Layer *M* is the control electrode or gate. Layer *O* prevents any d.c. current flow from the gate electrode to the other two electrodes, but does allow the electric field imposed by the gate electrode to influence the surface of the semiconductor. This is how the term 'MOS' in MOSFET was originally derived. The MOS device switches on or off depending on the electric field imposed on the p-type semiconductor surface between the two n regions which act as the transistor source and drain regions. If the gate electrode is made positively biased it can induce an inversion layer on the p-zone surface and open a conductive n channel between the two n-type zones. In the on-state the residual resistance in the induced channel determines the level of on-state conduction in the device just below the silicon surface. In the off-state a depleting region is formed at one of the two p-n junctions when a bias is applied between them and the resistivity and width of the p region determines the device voltage rating. This type of structure is limited practically to a few amperes and 50–100 V although high voltage types are available for special applications. In more practicable high-power MOSFET

Figure 17.43 The enhanced n-channel in a basic MOS structure

Figure 17.44 Detail of a DMOS structure

structures the semiconductor is exploited both vertically as well as horizontally. One of the two n-doped regions (the drain region) shown in Figure 17.43 is extended to the bottom face of the semiconductor which in effect connects all the elementary structures together forming the drain of the device as shown in Figure 17.44. The p-n junction formed between the channel region and the drain also provides reverse-blocking performance with the depletion region penetrating predominantly into the lowly doped n region. At the same time, because this junction is positioned vertically, it also avoids the waste of horizontal space compared to the structure shown in Figure 17.43 and enables the conductive channel to become very short. To obtain the performance necessary in practicable power MOSFETs this channel is normally designed to be of the order of 1–2  $\mu\text{m}$ . The resulting power MOSFET device therefore consists of multiple-MOS basic cells, with all the  $\text{n}^+$  type source zones connected in parallel on the top side of the semiconductor chip, together with the gate cells as shown in Figure 17.48. As mentioned above, the substrate of the chip then forms the common drain for the entire multiple source cells on the other side of the chip.

This vertical double diffused DMOSFET silicon gate device described above has evolved to become the design that offers the best combination of characteristics and represents a culmination of the development of the power MOSFET. Because the power MOSFET has evolved and is continuing to develop through various stages of design, it is possible to find several different types in use, illustrated in Figure 17.46 and 17.47.

Figure 17.45 Horizontal layout and structure of a DMOSFET

Figure 17.46 (a) V-groove MOSFET; (b) Trench U-groove MOSFET

All these structures have a common feature in that the current flows through a vertical path like conventional high power bipolar devices and, as a consequence, all the devices have two electrodes on the top which are the gate and source, and one on the bottom which is connected to

**Figure 17.47** (a) Double-diffused MOS metal gate FET; (b) Double-diffused MOS silicon gate FET

the drain. Another common feature for all these n-channel devices is that the n-region largely supports the applied drain potential because its doping level is much lower than that of the p body region. However, it can be seen that the position of the p channel in the VMOSFET and the

UMOSFET differs from its position in the DMOSFET. Although the DMOSFET silicon gate structure needs a more sophisticated technology very similar to that needed to produce CMOS integrated circuits, it is generally possible to produce a far superior device using this process and, therefore, the other three power MOSFET structures are less widely utilised. This is because it can be manufactured using a self-aligned process that makes it far easier to produce. In this process the MOS channel regions are obtained by a difference in lateral diffusion of the two impurity distributions and the use of this double-diffusion technique achieves very short channel lengths of less than  $1.5\text{ }\mu\text{m}$ . This increases the potential source/gate packing density that directly reduces the cost and improves the performance of the device. At the same time the use of a polycrystalline gate also reduces the possibility of sodium ion contamination in the gate oxide, and results in a higher stable threshold voltage  $V_{GS(th)}$ .

However the UMOSFET structure has recently been given increased attention as fabrication techniques have improved to a degree that it could be practically realised. This type of MOSFET device is also referred to as a Trench MOSFET, and correspondingly the DMOSFET is called a planar MOSFET. The advantage of the Trench MOSFET is the capability to achieve far greater cell packing densities, but at the expense of increased manufacturing difficulty.

As mentioned previously, the n-MOSFET structure is switched on by applying a voltage between the drain and the source and positively biasing the gate with respect to the source. This bias creates an electric field in the channel region that reverses the polarity of the charge carriers in the body region to create a majority carrier path from the source to the drain. Electron current flows from the source metal to the source contact, laterally through the channel and then vertically through the  $n^-$  and  $n^+$  drain regions to the drain contact as shown in *Figure 17.44*. This structure also contains an internal parasitic diode, formed by the source short-p body contact, and a bipolar n-p-n transistor as shown in *Figure 17.48*.

**Figure 17.48** Schematic representation of a power MOS structure

The diode conducts when the drain is negatively biased with respect to the source and usually can conduct forward current at the same level as the MOSFET part of the device. Under these conditions charge is injected into the n-region and the parasitic diode behaves almost like the epitaxial fast-recovery p-n junction power. It does, however, suffer from the disadvantage that it cannot be made a very fast-recovery type, as normally required for high frequency MOSFET applications, without affecting the other characteristics of the MOSFET. Therefore, although it can be used in certain lower frequency applications as an internal inverse parallel diode, this is often avoided by inserting an external reverse blocking diode in series with the MOSFET and providing another inverse parallel to carry reverse current. Where the internal diode is used an allowance must be made for the additional power losses dissipated in the MOSFET structure and the parasitic diode's reverse recovery characteristics resulting in a reduced power rating and/or a lower permissible switching frequency. The advantage in using the internal diode is of course the elimination of the two external components. Where it is essential to use the external diodes they should be of the very fast-recovery type such as a Schottky barrier diode, or a fast switching p-n diode, to keep switching losses in the MOSFET to a minimum.

If the current flow in the diffused base resistance in the  $p^{+}$  region of the parasitic transistor shown in *Figure 17.48* (which may be very high under MOSFET current conditions) is sufficiently large, the  $p^{+}$ -n $^{+}$  emitter junction of the parasitic transistor will become forward biased. This injects current that will be conducted by the parasitic n-p-n transistor. Usually only a few of the MOSFET cells reach this condition first wherein a very high current is focused that destroys the device. This is one of the basic failure mechanisms of the MOSFET that is avoided by preventing the load current of the MOSFET exceeding a critical value. The critical value of current also decreases with increasing temperature but is usually well beyond the manufacturer's rating specification. However it is a mechanism which should be borne in mind together with the fact that a MOSFET does not have the capability of passing an unlimited amount of current for a very short time.

To minimise on-state power losses in a MOSFET the device on-resistance ( $R_{DS(on)}$ ) needs to be the minimum compatible with desired breakdown voltages. To achieve the maximum possible ( $R_{DS(on)}$ ) it is necessary to optimise the power MOS channel perimeters to achieve the highest packing density per unit area possible. As a result, planar DMOS low-voltage devices have a packing density of 1000–10 000 cells or more per square millimetre. This has resulted in the development of advanced 'Trench' MOSFET structures which can reach even higher cell densities up to 20 000 cells per square millimetre. For high-voltage devices the epitaxial layer resistance has a greater effect on the overall resistance and to optimise ( $R_{DS(on)}$ ) it is necessary to minimise the bulk resistance by choosing a lower packing density which increases the area of the epitaxial drift region. High-voltage devices therefore often have a packing density of about 500 cells per square millimetre. Many novel techniques have been considered for reducing the epitaxial drift region resistance, with such proprietary names as 'CoolMOS'.

The maximum breakdown voltage rating of the DMOSFET ( $BV_{DS}$ ) would be limited by junction edge breakdown effects below the bulk avalanche breakdown due to the curvature of the diffused junctions and surface electrical field crowding, unless an edge structure such as that shown in *Figure 17.49* is used. The field plate allows

higher breakdown voltages by spreading the field laterally along the surface of the device.

The gate threshold voltage ( $V_{GS(th)}$ ) is another important parameter. This is the voltage at which strong inversion begins to occur in the MOS gate and sets the minimum applied gate voltage for conduction in the channel. The threshold voltage is related to the thickness of the gate oxide and to  $N_A$ , the maximum peak impurity concentration in the region between the source and the drain. Channel punch-through can occur as the result of insufficient impurity charge in the channel, under strong reverse bias and to avoid punch-through a trade off between  $V_{GS(th)}$  and length must be made. Due to the negative temperature coefficient of  $V_{GS(th)}$  its value cannot be allowed to become too low otherwise the gate becomes too sensitive at high temperature. Also, if it becomes too high, the MOSFET cannot be directly driven by low-voltage logic circuits or requires too much gate power and, therefore, the value of  $V_{GS(th)}$  is normally designed to be in the range 2–4 V for power devices, although lower values of 1–2 V are found for logic-compatible devices.

Power MOSFETs require a certain amount of gate charge driven into their gates or extracted during the charging and the discharge phases of the input capacitance and behave quite differently from bipolar devices. In particular the switching performance of the device is influenced by the time it takes for the voltage to change across the device capacitance. *Figure 17.50* show a power MOSFET driven by a gate source with an internal resistance  $R_I$  and an open-circuit voltage  $V_I$  where  $R_L$  is the load in the main switching circuit.

The gate input capacitance  $C_{Gi} = C_{GS} + C_{GD}$  is non-linear during the switching cycle. The capacitance between the gate electrode and the drain  $C_{GD}$  is a function of the depleted drain layer thickness which in turn is dependent on  $V_{DS}$  (drain source voltage). As  $V_{DS}$  increases the depleted layer thickness increases and the static input capacitance  $C_{GD}$  decreases.

There is also a displacement charge which has to be supplied when  $V_{DS}$  decreases from  $V_{DD}$  to  $V_{DS(on)}$  and  $C_{GD}$  behaves as a higher equivalent capacitance than during the drain 'on' transitions.  $C_{GD}$  is called the Miller Capacitance and it causes the total input capacitance to exceed the sum of the static capacitance during the dynamic turn on phase.

During the turn on period the voltage across the gate increases until it reaches the threshold voltage ( $V_{GS(th)}$ ), at this point drain current begins to flow and  $C_{GS}$  becomes charged. When the gate source capacitance is fully charged, the drain voltage begins to fall while the drain current is almost constant charging the Miller Capacitance  $C_{GD}$ . During this phase the  $V_{GS}$  is also constant, as it cannot increase until the input capacitance is fully charged. This is the so-called Miller effect. Following this  $V_{GS}$  increases again until it reaches the gate supply voltage  $V_I$ .

The minimum charge that must be delivered by the gate drive to ensure turn-on is therefore given by the charge required to fully charge the input capacitance, however in practice gate drive design will require the use of greater capacity so that the gate voltage reaches the gate supply voltage, i.e. time  $t_4$  in *Figure 17.51*.

At turn-off, the behaviour of the input capacitance is exactly opposite, and the phenomena described above occur in reverse order.

Power MOSFETs are available with current ratings up to 200 A and voltage ratings to 1000 V and are capable of switching at frequencies up to 10 MHz. The high switching speed, wide SOA, high peak current capability and ease of

Figure 17.49 Power MOS edge structure

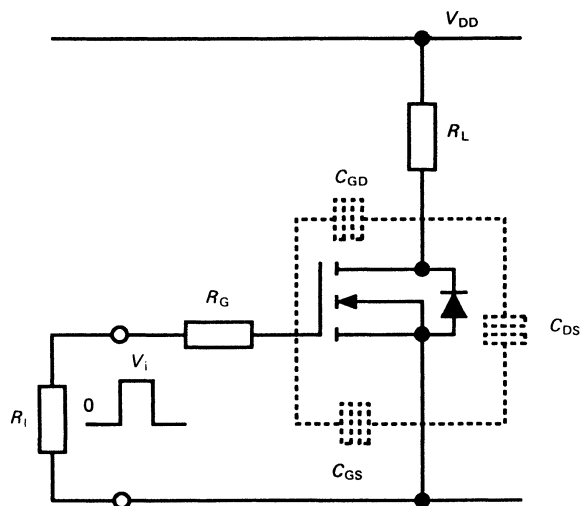

Figure 17.50 Power MOS equivalent circuit

Figure 17.51 MOSFET turn-on characteristics

control has made the power MOSFET the favoured device for the majority of power electronic applications. Unfortunately it is the unipolar operation of the device, that delivers the above benefits that also leads to highly temperature and blocking voltage dependent conduction

characteristics, and therefore restrict the useful application area to the lower power regime. A more complete description of the MOSFET is given in reference 2.

## 17.6 The insulated gate bipolar transistor (IGBT)

In searching for the ideal power device, designers have considered many potential design concepts that combine the voltage control of the MOSFET gate with the superior conduction characteristics of the bipolar device. Of the many candidates there is only one that has become widely commercially available, the insulated gate bipolar transistor (IGBT). There is much research and development work in hand to implement improved versions of the IGBT, for example incorporating Trench Gates and making use of accumulation layer emitter effects, however this falls outside the scope of this chapter where we will focus on the commercially available DMOS IGBT. The IGBT employs injected-charge modulation in the base region and, due to the need for this charge to be extracted or extinguished at turn-off, has higher switching losses compared to the MOSFET. But as it can be realised at much higher power ratings it has become the power device of choice for a wide range of medium to high power electronic applications. The main advantages of the IGBT are the simplicity with which it can be driven (which is comparable to a power MOSFET), its lower on-state conduction losses and the capability of switching high voltages. These characteristics, together with the ability of IGBT to survive a wide reverse bias safe operating area (RBSOA) make it superior to the power MOSFET in high-voltage applications. Typically, IGBTs are used for switching circuits requiring high voltage (up to 3300 V) and high current (up to 3000 A), with a switching frequency of the order of 1–40 kHz.

### 17.6.1 Device physics

Figure 17.52(a) shows a cross section through a single cell of the multi-cell structure of an IGBT and Figure 17.52(b) shows the power MOSFET for comparison. The drain region of the IGBT which contains a  $p^+$  doped layer represents the major difference in structure to that of power MOSFETs. The presence of the  $p^+$ - $n$  junction drastically reduces the on resistance of the IGBT during conduction because holes are injected from the p region, which results in the  $n^-$  region becoming conductivity modulated. In a

power MOSFET significant proportions of the conduction losses occur in the  $n^-$  region, for devices above 500 V this can amount to more than 70% of the total.

As is also shown in Figure 17.52 the Source of the MOSFET becomes the Emitter of the IGBT, and the MOSFET drain has become the Collector. This change in terminology correctly demonstrates that the IGBT is a bipolar device and that the effective 'Drain' of the MOSFET section is not directly connected to the external circuit.

A circuit model of the IGBT, shown in Figure 17.53(a), illustrates the internal arrangement. The MOS section provides a gate drive to the base of a p-n-p transistor (formed by the  $p^+$ - $n^-$ - $p^+$  layers in Figure 17.52(a)) where in this p-n-p transistor its emitter is directly connected to the IGBT collector and the p-n-p collector feeds into the base of a second n-p-n transistor (formed by the  $n^-$ - $p^+$ - $n^+$  layers). Thus it can be seen that the IGBT resembles a four layer n-p-n-p thyristor structure, see the two transistor analogue of the thyristor in Figure 17.24. In this thyristor analogy the gate drive to the thyristor derives from the MOSFET gate. As with the thyristor, should the sum of the n-p-n and p-n-p gains ( $\alpha_{npn} + \alpha_{pnp}$ ) exceed unity then the IGBT will latch on, as a thyristor, with consequential loss of gate control and potentially destruction of the device. In order to prevent latch up IGBTs are designed to achieve control over the gains  $\alpha_{npn}$  and  $\alpha_{pnp}$ . This gain control is usually achieved by three approaches. Firstly the resistance  $R_B$  is minimised (this is analogous to efficient cathode emitter shorting in the thyristor, see Section 17.3.1 and Figure 17.30). Secondly the injection efficiency of the  $p^+$  layer (at the collector) is reduced by various techniques, for example the structure in Figure 17.52(a) uses an  $n^+$  layer. Finally, the p-n-p gain may be reduced by minority lifetime control.

With the above mentioned techniques to de-sensitize the 'thyristor' action of the IGBT, the NPN transistor may be ignored and the equivalent model is simplified to that shown in Figure 17.53(b). In both models  $R_{mod}$  represents the effective resistance of the  $n^-$  region in the 'drain' region of the device (i.e. the MOSFET region drain). Referring to Figure 17.53(a) or (b) the drain region of the IGBT is the region in the centre below the gate, in this region the n-base region is surrounded by p-base regions. In the forward biased condition, and when the IGBT is conducting the

Figure 17.52 (a) IGBT structure; (b) Vertical DMOSFET structure

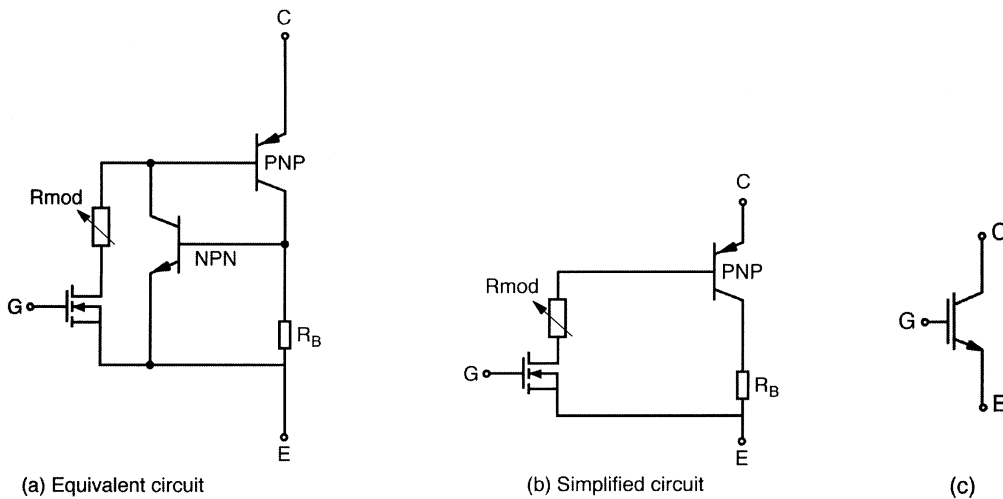

Figure 17.53 Equivalent circuits for IGBTs

Figure 17.54 Current flow in an IGBT during conduction

p-n junction between the p- and n-base is reverse biased. Thus this reverse biasing effect may increase the effective resistance  $R_{mod}$ . As a result many IGBT designs take particular care to maximise the conductance in this region of the device by increasing the n-type doping in this region for example. In some equivalent circuit models this is shown as a JFET (a Junction Field Effect Transistor) because the p<sup>+</sup> base regions surrounding this n<sup>-</sup> drain act as the junction of a JFET structure. For an explanation of the JFET see reference 5.

There are two major types of IGBT manufactured, either Punch-Through (PT) or Non-Punch-Through (NPT). The IGBT structure shown in Figure 17.52(a) is a PT IGBT and this has the similar structure to the Power MOSFET with the addition of the p<sup>+</sup> layer (Collector) to the drain side of the MOSFET. In this structure the off-state voltage is supported by the formation of a space charge region across the wide n-region, but this space charge region punches through to the n<sup>+</sup> buffer region before the junction breaks down. In this respect it is similar to the p-i-n junction (Section 17.1.5) in that it achieves a thinner device structure, and therefore minimum on-state voltage and improved dynamic characteristics, for the same blocking voltage.

In an NPT IGBT structure the n<sup>+</sup> buffer layer is omitted, and so the thickness and the doping levels in the n<sup>-</sup> region are chosen such that the junction breaks down before the space charge region reaches through to the p<sup>+</sup> collector region.

The choice between NPT and PT types is based on a number of factors surrounding the manufacturing process cost and yield and the IGBT characteristics. In the earlier IGBT types PT has been restricted to IGBTs at voltages less than 1200 V owing to the economics of growing the very thick epitaxial layers needed for higher voltages, but many manufacturers have developed both PT and NPT types across the full voltage range.

As with the Power MOSFET the IGBT is available in both DMOS and UMOS (or more usually 'Trench Gate') construction. The Trench gate is generally used in the high power IGBT to improve the effective conduction area of the IGBT and reduce the  $V_{CE(on)}$ , although it can also be used to increase the cell packing density to improve the switching speed for lower voltage designs. At the time of writing the trench IGBT was just becoming commercially available at

Figure 17.55 Turn-off of an IGBT showing three turn-off regions

1200 V levels with higher voltage designs in development, whereas the DMOS device is available up to 6500 V.

### 17.6.2 Packaging and thermal considerations

Although IGBT are available in discrete packages, i.e. packages that contain one IGBT die, the majority of IGBTs are supplied in module configurations. A module is a package that contains more than one IGBT die, and may more usually contain a combination of IGBT and fast recovery diode die. An example of a high power IGBT module, with one half of the lid cut away to illustrate the internal construction, is shown in Figure 17.56.

Typically the module has a conductive base plate of copper or alternatively a metal matrix material (such as AlSiC), the IGBT and diode die are soldered onto a DCB and one or more DCBs are soldered to the base plate. The DCB (Direct Copper Bonded substrate) consists of an insulating material, such as Aluminium Nitride or Alumina, with a copper layer bonded to both sides, and with the side to which the die are attached patterned to produce the necessary interconnections between the die. The DCBs may be further interconnected within the module and the main

Figure 17.56 IGBT module construction

terminal electrodes (cathode, anode and gate) are connected to the DCBs. Clearly the detailed design and construction of the module is extremely complex and requires consideration of the electrical, thermal (for high transfer) and mechanical requirements. Of prime importance is the reliability of the package, and manufacturers go to great lengths to optimise the life expectancy of the module.

The IGBT module will contain fast recovery diodes connected across the IGBTs, in anti-parallel. The inclusion of the diodes results in ease of assembly and low parasitic inductance to optimise the switching and operating area of the module. The diodes used in the modules are of the fast-recovery type but are specially designed to have soft-recovery. The use of soft-recovery diodes is essential in order to prevent the snappy recovery of the diode applying excess voltage stress on the IGBT at turn on.

In the assembly of equipment using IGBT modules the user usually connects to the power terminals by parallel busbar rails and the layout of the power terminals facilitates the use of extremely low inductance rails. The base of the module is connected directly to a heatsink surface and because the base plate is electrically isolated from the IGBT die several modules may be mounted side by side on the same heatsink. Thus the IGBT module lends itself to ease of assembly and extremely compact equipment designs.

### 17.6.3 On state characteristics and conduction losses

Current flow in the IGBT during conduction is shown in Figure 17.54. The total current  $I_{DS}$  is the sum of the two currents  $I_c(h)$  and  $I_b(h)$ , where  $I_c(h)$  is the current due to holes injected from the substrate  $p^+$  layer, which are collected on the surface of the source region, and  $I_b(h)$  is the current due to holes that combine with electron current flowing through the MOS channel in the base region of the  $p-n-p$  bipolar junction transistor. The IGBT, therefore, behaves like a bipolar junction transistor whose base current is provided by a MOSFET, and the drain current of the IGBT is thus the sum of the bipolar base and collector currents.

$$I_{DS} = I_{MOS}(1 + \beta_{npn}) \Leftarrow$$

From this it can be seen why the IGBT has a higher current carrying capability and lower  $R_{DS(on)}$  than a power MOSFET of equal chip size. However, the presence of the  $p^+-n$  junction in the drain produces an initial offset in the output characteristics of 0.6–0.8 V, and also limits the reverse breakdown voltage of the IGBT to 30–70 V. However for most applications (e.g. voltage source inverters) the lack of reverse blocking capability is not a problem.

### 17.6.4 Turn on and turn off

When the gate-source voltage ( $V_{GS}$ ) is greater than the threshold voltage ( $V_{TH}$ ), the MOSFET section of the structure turns on. The MOS drain current is then the base current of the parasitic  $p-n-p$  transistor and it turns on the  $p-n-p$  transistor in less than 100 ns. The IGBT turn-on time is therefore, a function of the impedance of the gate driver circuit and the voltage applied to the gate. During this turn-on time the falling voltage and rising current can result in high instantaneous power levels, leading to a total energy loss during this phase, called the turn-on switching loss.

Turn-off in the IGBT has typical features of both a power MOSFET and a bipolar junction transistor turn-off due to the use of conductivity modulation for increased current

density. Figure 17.55 shows how the turn-off can be divided into four regions, during the first phase (I) the gate voltage decreases to a point where the Miller effect begins and  $V_{DS}$  begins to rise. In the second phase (II) the gate voltage is

(a)

(b)

(c)

**Figure 17.57** (a) Variation in  $t_{fall}$  with  $V_{DS}$ ; (b) variation in  $t_{fall}$  with temperature; (c) variation in  $t_{fall}$  with the lifetime of the minority carriers in the  $n^{-}$  region

constant due to the Miller effect. During this period the gate capacitance decreases as  $V_{DS}$  increases. The gate voltage polarity is reversed with respect to the drain voltage, as  $V_{DS}$  rises above the gate potential and  $V_{DS}$  rises to its maximum value at a rate controlled by the driver circuit. These two phases (I and II) are dependent on the MOSFET behaviour as the base-collector junction of the p-n-p transistor becomes reverse biased. Regions III and IV define  $t_{fall}$ . In region III the turn-off process is MOS controlled which is very fast. In region IV the MOS channel is closed and the p-n-p transistor has an open base. During this period the current falls at a rate determined by recombination of excess carriers in the  $n^{-}$  region. The fall time can therefore be controlled by the gate drive-circuit, in region III, but in region IV is only dependent on the p-n-p transistor lifetime and gain. Figure 17.57(a) shows how  $t_{fall}$  varies with  $V_{DS}$ . It can be seen that, as  $V_{DS}$  increases, so the gain of the p-n-p transistor increases due to the reduction in the base thickness. This is caused by the depletion region increasing with increasing  $V_{DS}$ . The dependence of  $t_{fall}$  on temperature is shown in Figure 17.57(b) and confirms the correlation between  $t_{fall}$  and the p-n-p transistor gain. The lifetime of the minority carriers in the  $n^{-}$  region versus  $t_{fall}$  is shown in Figure 17.57(c).

### 17.6.5 Safe operating area

Protecting the IGBT against over-current or over-voltage effects that can be potentially destructive is a most important part of the design for the majority of applications. These can be specified by the ability of the device to withstand a short circuit load, the short circuit safe operating area (SCSOA) and to survive during switch off, the turn-off switching safe operating area (SOA).

The SOA is illustrated by considering the switching of an IGBT in a half bridge circuit shown in Figure 17.58. The switching waveforms are shown in Figure 17.59. The SOA curve is derived from the locus of maximum permissible current and voltage during the turn off phase,

**Figure 17.58** IGBT half bridge test circuit

**Figure 17.59** IGBT switching waveforms (a) turn-on; (b) turn-off

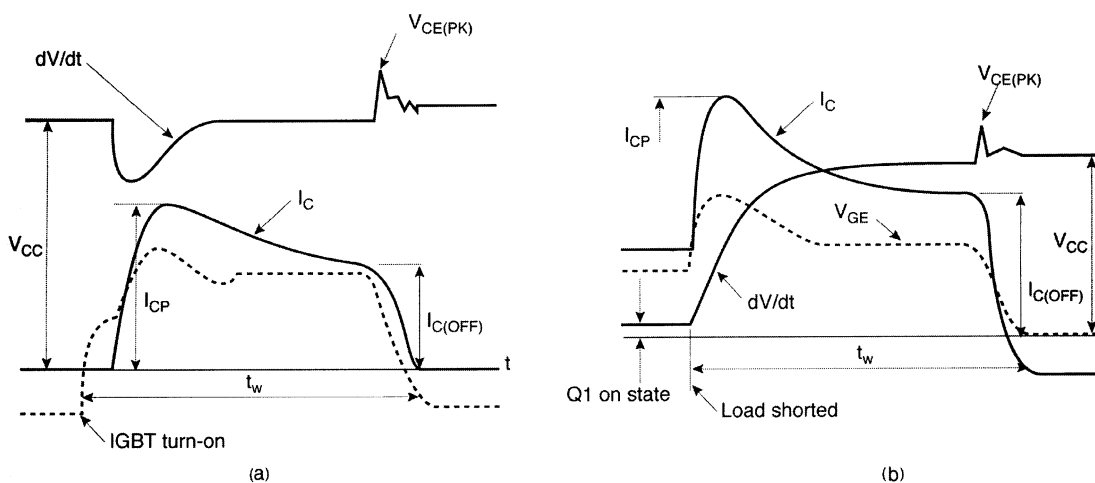

**Figure 17.60** Turnoff switching safe operating area for a 3300 V, 1200 A IGBT

for example *Figure 17.60*. The failure mechanism is typically due to the rapid extraction of charge from the bipolar section of the IGBT, this charge may flow laterally in the base regions and can lead to latch up of the equivalent thyristor section of the device.

In many applications it is important that the IGBT can withstand a short circuit event in the system, for example in the motor. There are two situations that may occur. Firstly where the IGBT is turned on into a short circuit *Figure 17.61(a)*. In this case the IGBT is initially off and supporting the supply voltage  $V_{CC}$ , the IGBT is turned on into a short circuit where the only load is the stray circuit inductance  $L_s$  and the IGBT voltage then drops due to the discharge of the stray inductance and then rises rapidly back to the supply level. This rapid  $dV/dt$  is picked up by the gate due to the internal capacitance of the IGBT, and this rise in gate voltage results in a further increase in the collector current. In this condition the IGBT must be turned off within a defined time of the order of  $10\mu\text{s}$ , and the peak over-current should be limited or the device will fail.

The second condition for SCSOA is where the device is already in conduction when the load is made short circuit. *Figure 17.61(b)*. The short circuit forces the IGBT into de-saturation, the collector voltage rises rapidly towards the supply voltage  $V_{CC}$ , as in the previous example this  $dV/dt$  forward biases the gate strongly leading to higher values of collector current. Again the peak

**Figure 17.61** IGBT switching waveforms under short circuit conditions: (a) IGBT turned on into a short circuit; (b) load short circuited while IGBT is conducting

collector current and the duration of the short circuit must be limited to avoid device failure. Most manufacturers will define the conditions to limit SCSSOA in their data sheets.

IGBTs are available covering a broader spectrum of power than almost any other power device, with the exception of the thyristor. IGBTs are available from a few amps and 300 V up to 3000 A and 6500 V. These devices are used over a broad frequency range from a few hundred Hz up to and exceeding 100 kHz. At the time of writing no suitable alternative has been released that might challenge the dominance of the IGBT, but there is no doubt that as this device technology becomes mature the device designers will turn their attention beyond the IGBT. For further reading a more complete description of IGBTs is given in reference 2.

Electronic processing of power provides the freedom to optimise the generation, conversion and use of electrical power. Most notably, it frees a system designer from the constraints of a fixed voltage supply (whether a 50/60 Hz a.c. public electricity supply or a d.c. source such as a battery). For example, wind turbines are more effective at capturing energy from the wind if freed from the constraint of rotating at synchronous speed, and pump flow rate is much more efficiently regulated through variable voltage/frequency control of the motor than through valves. But to realise the efficiency savings from varying the voltage or frequency of a power source we must ensure that the energy conversion process is itself efficient. Power electronics provides efficient means of energy conversion and has long since displaced electromechanical means.

Efficiency has been important in promoting the widespread adoption of power electronics, but the speed and degree of control that can be exercised over the power conversion process is at least as important. This control is essential in conditioning the power for an electrical machine in a machine tool or robotic manipulator. The speed of response that we can achieve from an electronic power converter depends on its implementation and, in turn, its power rating. In general, we can expect a response much faster than any electromechanical element of the system.

## 18.1 Electronic power conversion principles

The terms *power electronics* and *switch-mode electronics* are almost synonymous for the simple reason that semiconductor devices are energy efficient only when used as switches.

### 18.1.1 Switch-mode electronics

Voltage drop across a current carrying element is the indication of inefficiency. A transistor used in its active region (also known as the linear or amplifier region) dissipates power because it has voltage across it while carrying current. Figure 18.1 illustrates the active region of three common devices on graphs of their output characteristics (i.e. graphs of the current through the main terminals and the voltage across those terminals for a range of controlling voltages). The three devices, the Bipolar Junction Transistor (BJT), the Metal-Oxide-Semiconductor Field Effect Transistor (MOSFET) and the Insulated-Gate Bipolar Transistor (IGBT) were discussed in Chapter 17.

The effect this has on system efficiency is well illustrated by two alternative ways of regulating the voltage delivered to a load. Figure 18.2 shows a transistor used as a linear voltage regulator to reduce an input voltage,  $V_I$  down to a controlled output voltage,  $V_O$ .

As an example, consider a  $5\ \Omega$  load and a regulator set to produce a 5 V output from 15 V input. The load will draw a current,  $I_O$  of 1 A. Because the current drawn from the source of the transistor is matched by current drawn in through the drain, the input current  $I_L$  will be 1 A (assuming that the control circuitry draws negligible current). The power flow will be as follows:

$$P_{\text{out}} = V_O I_O = 5\text{ W}$$

$$P_{\text{in}} = V_I I_L = 15\text{ W}$$

$$P_{\text{lost}} = P_{\text{in}} - P_{\text{out}} = 10\text{ W}$$

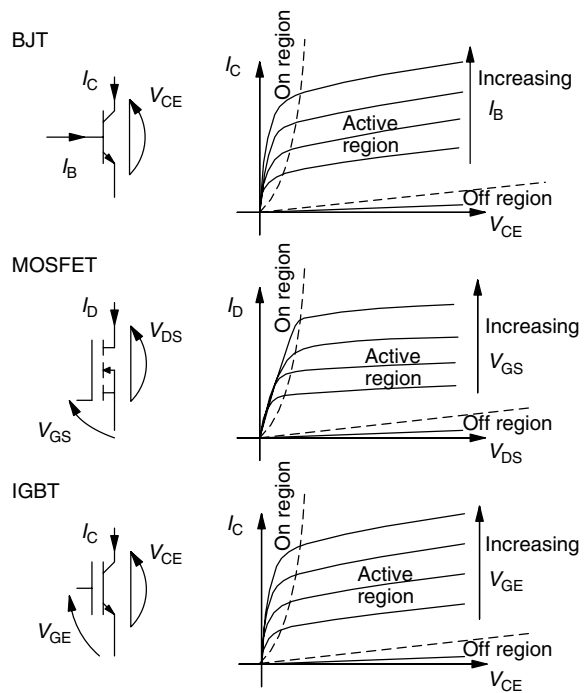

Figure 18.1 BJT, MOSFET and IGBT output characteristics and operating regions

Figure 18.2 A MOSFET based linear voltage regulator

This circuit shows an efficiency of only 33%. Efficiency is important in its own right because of the need to utilise primary sources of energy well, but there is a second important reason to aim for high efficiency. The energy lost in this circuit is lost as heat in the semiconductor material. Thermal management of the semiconductor is difficult because it can be difficult to remove heat from the silicon and so its temperature will rise far above ambient. Further, the semiconductor is a small mass and its temperature will rise quickly during short periods of high dissipation. Typical maximum temperatures of silicon devices are in the range  $125^\circ\text{--}150^\circ\text{C}$ .

The alternative way of regulating the voltage across a load using a transistor is to switch the input voltage into a series of pulses. The average voltage of the pulse train is necessarily less than the input voltage. By filtering the pulse train, the ripple component of the voltage can be removed to leave only the average, that is, d.c. component to be applied to the load. Figure 18.3 shows a transistor used to apply a pulse train to an LC filter.

Figure 18.3 A switch-mode voltage regulator

The ratio of the on-time to the off-time can be adjusted to control the voltage delivered to the load. The output voltage will be equal to the average value of the pulse train.

$$V_O = V_{\text{pulse}}^{\text{avg}} = V_1 \frac{t_{\text{on}}}{t_{\text{on}} + t_{\text{off}}} = V_1 \delta \quad (18.1)$$

The ratio of the on-time to the period,  $\delta$ , is known as the duty-cycle. If we wish to produce a 5 V output from a 15 V input, as we did with the linear regulator example, we would choose a duty-cycle of  $\frac{1}{3}$ .

Because the switch is either off (supporting voltage but not carrying current) or on (carrying current but without a voltage appearing across it) there is no coincidence of current flow and voltage drop. Therefore, there is no power dissipated in the transistor. We can also show this by considering the input and output powers. First we note that the inductor current,  $I_L$  will have the same magnitude as the output current (with no net current in the capacitor). When the switch is on, the inductor current flows as input current,  $I_1$ . When the transistor is off, the inductor current flows in the diode and no current is drawn from the input.

On state:

$$\begin{aligned} P_{\text{out}}^{\text{on}} &= V_O \cdot I_O = 5 \text{ W} \\ P_{\text{in}}^{\text{on}} &= V_1 \cdot I_1 = V_1 \cdot I_O = 15 \text{ W} \end{aligned}$$

Off state:

$$\begin{aligned} P_{\text{out}}^{\text{off}} &= V_O \cdot I_O = 5 \text{ W} \\ P_{\text{in}}^{\text{off}} &= V_1 \cdot I_1 = 0 \end{aligned}$$

On average:

$$\begin{aligned} P_{\text{out}} &= V_O \cdot I_O = 5 \text{ W} \\ P_{\text{in}} &= \frac{P_{\text{in}}^{\text{on}} \cdot t_{\text{on}} + P_{\text{in}}^{\text{off}} \cdot t_{\text{off}}}{t_{\text{on}} + t_{\text{off}}} = \frac{P_{\text{in}}^{\text{on}} \cdot t_{\text{on}}}{t_{\text{on}} + t_{\text{off}}} = P_{\text{in}}^{\text{on}} \cdot \delta = 5 \text{ W} \end{aligned}$$

The average input power matches the output power and therefore the circuit is ideally efficient.

### 18.1.2 Power loss in switch-mode circuits

In principle, a switch-mode circuit can be perfectly efficient whereas a linear-mode circuit cannot. In practice, of course, there are power losses in switch-mode circuits including power loss within the semiconductors. During the off-state, a semiconductor will leak current, and therefore there will be some power dissipation. The leakage

properties of semiconductors are very good and the off-state dissipation is negligible. During the on-state, a semiconductor will drop some voltage and there will be further power dissipation. The on-state power loss is normally significant. There is also power loss as the semiconductor passes through its active region as it is switched between its on- and off-states. The average power loss is found by dividing the energy loss per cycle by the period,  $T$ . The energy loss can be expressed as an integration of the product of the instantaneous voltage and current. We can partition the cycle of switch operation into four stages: the on-state, the off-state, the turn-on transition and the turn-off transition.

$$\begin{aligned} P_{\text{loss}} &= \frac{1}{T} \int_0^T v_T(t) \cdot i_T(t) \cdot dt \\ &= \frac{1}{T} \left[ \int_0^{t_{\text{on}}} v_{\text{on}}(t) \cdot i_T(t) \cdot dt + \int_{t_{\text{on}}}^{t_{\text{off}}} v_T(t) \cdot i_{\text{off}}(t) \cdot dt \right. \\ &\quad \left. + \int_{t_{\text{turn-on}}}^{t_{\text{turn-off}}} v_T(t) \cdot i_T(t) \cdot dt \right] \\ &= \frac{1}{T} \{ E_{\text{cond}} + E_{\text{leak}} + E_{\text{turn-on}} + E_{\text{turn-off}} \} \quad (18.2) \Leftarrow \end{aligned}$$

The on-state (conduction) energy loss is relatively straightforward to calculate. MOSFET devices are resistive in the on-state whereas most other devices have a near constant on-state voltage. Assuming a constant on-state voltage:

$$E_{\text{cond}} = V_{\text{on}} \cdot I_{\text{on}}^{\text{avg}} \cdot t_{\text{on}} \quad (18.3) \Leftarrow$$

Calculation of switching power loss requires detailed knowledge of the trajectory taken through the active region. This is dependent on the gate drive arrangement and the circuit topology.<sup>6</sup> Figure 18.4 illustrates a simple case where the load is inductive (and treated as a constant current element,  $I_L$ ) and is switched from a supply voltage of  $V_S$ . Diode recovery has been ignored and the transistor has been assumed to operate as a controlled current source while in its active region. The switching trajectory of MOSFETs and IGBTs and the reverse-recovery characteristics of diodes were discussed further in Chapter 17 (Sections 17.5, 15.6 and 17.1.2).

- (I) During the off-state, the load current flows in a loop involving the diode, and the transistor must support the full supply voltage (plus diode forward voltage drop).
- (II) At turn-on, the transistor begins to take current from the load and this current is assumed to rise linearly. The portion of load current not taken by the transistor continues to flow in the diode. Therefore, the diode is held in forward bias and the full supply voltage still appears across the transistor. Once the transistor current has risen to equal the load current, the diode ceases to conduct. (It is at this point that reverse-recovery will occur in a real diode as discussed in Section 17.2.1). The transistor voltage falls as the parasitic capacitances (of the diode and transistor) charge/discharge and the diode becomes reverse biased. The figure is drawn assuming the change of voltage is also linear.

**Figure 18.4** A MOSFET switching an inductive load, its trajectory through output characteristic and its drain current and drain-source voltage waveforms

- (III) During the on-state, the load current flows in the transistor.
- (IV) When turn-off of the transistor is initiated, the decrease of current flow through the transistor diverts current into the parasitic capacitances of the transistor and diode. The voltage across the transistor rises as a result of this. The voltage rises until it exceeds the supply voltage and the diode is forced into conduction. Once the diode is conducting, the transistor current can fall and the load current diverts into the diode.

With the assumptions of linear rise and fall of both voltage and current, the turn-on and turn-off energy loss can be found:

$$\begin{aligned} E_{\text{turn-on}} &= \frac{1}{2} V_S I_L (t_{ri} + t_{rv}) \\ E_{\text{turn-off}} &= \frac{1}{2} V_S I_L (t_{rv} + t_{fi}) \end{aligned} \quad (18.4) \Leftarrow$$

Some devices, notably MOSFETs, are specified in terms of the rise and fall times during switching (under standard

conditions). Others, notably IGBTs, that have more complex switching transients are specified in terms of the energy loss during switching (again, for standard conditions).

It is normal to express the loss in terms of power rather than energy and so we divide the energy loss per cycle by the period of the cycle.

$$\begin{aligned} P_{\text{loss}} &= \frac{1}{T} (E_{\text{cond}} + E_{\text{turn-on}} + E_{\text{turn-off}}) \Leftarrow \\ &= \delta \zeta V_{\text{on}} \cdot I_{\text{on(avg)}} + f \cdot (E_{\text{turn-on}} + E_{\text{turn-off}}) \Leftarrow \quad (18.5) \\ &= \text{Conduction loss} + \text{Switching loss} \end{aligned}$$

The power loss due to leakage in the off state has been neglected.

It is important to note that because the switching loss is an energy loss per operation, the power loss is proportional to switching frequency,  $f$ ; whereas the conduction loss is simply an average power loss as indicated by the duty cycle,  $\delta$ . The dependence of power loss on frequency acts against the desire to increase switching frequency that would otherwise bring benefits of faster response and the opportunity to use smaller passive components.

Proper thermal design of a power electronic system is essential to its success. There needs to be management of the power loss through operating mode or circuit design. Choice can be exercised over the package style for its heat transfer properties. The heat-sink to which the semiconductors are attached is often a bulky and expensive part of the system. Its type (natural convection, forced-air, liquid-cooled) and rating (temperature rise per unit power loss) must be carefully chosen.<sup>6</sup>

## 18.2 Switch-mode power supplies

There is a large variety of circuits available for converting power at one d.c. voltage to another. The linear regulator, introduced in Figure 18.2, offers only a step-down of voltage. Switch-mode power supplies, SMPS, can offer step-down, step-up and negation of the voltage through the three basic circuit topologies, viz., Buck, Boost and Flyback. Three further topologies, viz., Ćuk, SEPIC and Zeta, add extra passive components in order to improve secondary aspects such as current and voltage ripple. A family of circuits has been derived from the basic family that incorporate mutually coupled inductors to offer galvanic isolation between input and output. Another family of circuits, to be discussed in, Section 18.6 has been developed that incorporate a resonant element so that the switching trajectory of the transistor is modified to reduce power loss and enable higher frequency operation. The sections that follow cover a selection of the many circuits that are described in the literature. A fuller description and a wider selection of circuits are to be found.<sup>2,3,6</sup> Here, the description of the Buck SMPS is used to introduce several of the basic principles of analysis that apply to all SMPS circuits.

### 18.2.1 Buck SMPS

The Buck circuit has already been introduced in Figure 18.3 as the direct competitor to the linear regulator. Its operating principle is the storage and release of energy in the inductor during its two states as illustrated in Figure 18.5.

**Figure 18.5** Current paths in the on- and off-states of a Buck SMPS

The operation of the circuit can be summarised as:

On-state (*Figure 18.5(a)*):

- A voltage is imposed across the inductor of:

$$V_L = V_1 - V_{DS(on)} - V_O \\ \approx V_1 - V_O$$

- The current in the inductor increases according to:

$$\frac{di_L}{dt} = \frac{V_1 - V_O}{L}$$

- The energy stored in the inductor increases.
- Energy is also delivered to the output.

Off-state (*Figure 18.5(b)*):

- The current flow through the inductor is maintained by its stored energy.
- The diode is forced into conduction to provide path for the current.
- A voltage is imposed across the inductor of:

$$V_L = -V_{DS(on)} - V_O \\ \approx -V_O$$

- The current in the inductor decreases according to:

$$\frac{di_L}{dt} = \frac{-V_O}{L}$$

- The energy stored in the inductor decreases.
- Energy continues to be delivered to output.

This analysis shows that the inductor current ripples up and down. The circuit will settle into a periodic steady-state condition such that the inductor current at the end of the

cycle is the same value as at the beginning. The capacitor is chosen to be sufficiently large that the voltage across it changes very little during the cycle. It too will have ripple, and again the voltage at the end of the cycle will match that at the beginning.

There are two cases to examine. The first is known as continuous conduction and is the case where the decrease of current does not take it to zero. *Figure 18.6(a)* illustrates the principal voltage and current waveforms. The second case is known as discontinuous conduction and is where the decrease of current does take it to zero and the inductor has released all of its stored energy. The current will remain at zero until the switch is next turned on *Figure 18.6(b)*.

Applying Kirchhoff's current law to the node at the output, we can state that for every instance in time:

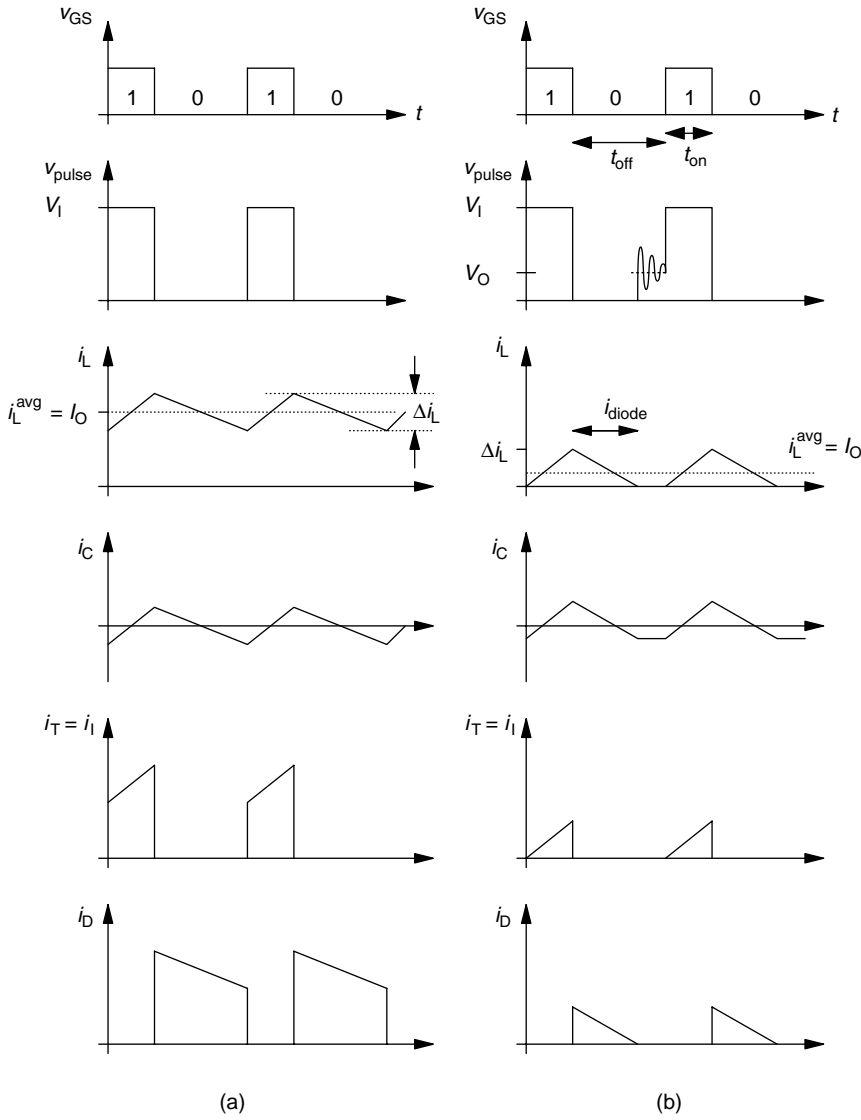

$$i_L = i_C + i_O$$

If we assume that the output current is constant (because the output voltage is very nearly so) we can write  $i_O = I_O$ . Then taking the average current:

$$i_L^{avg} = i_C^{avg} + I_O$$

In periodic steady-state there can be no average current flow through the capacitor. We can consider the inductor current to be composed of a constant component that flows through the load and a ripple component that diverts through the capacitor.

A relationship between the output voltage and the switching of the transistor follows from the statement that there is no net change in inductor current over a cycle. That is, the increase in current during the on-time of the transistor is matched by the decrease of current when the current flows in the diode. Here we make a distinction between the diode conduction time and the off-time because in the case of discontinuous conduction the diode does not conduct for all of the off-time.

**Figure 18.6** Voltage and current waveforms of the Buck SMPS in Figure 18.5 for (a) continuous and (b) discontinuous inductor current

$$\begin{aligned} \Delta i_{L(\text{on})} + \Delta i_{L(\text{diode})} &\approx 0 \\ \Delta i_{L(\text{on})} &\approx \frac{di_L}{dt} t_{\text{on}} = \frac{V_I - V_O}{L} t_{\text{on}} \\ \Delta i_{L(\text{diode})} &\approx \frac{di_L}{dt} t_{\text{diode}} = \frac{-V_O}{L} t_{\text{diode}} \end{aligned} \quad (18.6) \Leftarrow$$

$$\frac{V_O}{V_I} \approx \frac{t_{\text{on}}}{t_{\text{on}} + t_{\text{diode}}} \quad (18.7) \Leftarrow$$

For the continuous conduction case,  $t_{\text{diode}} = T_{\text{off}}$  and the output/input ratio is simply the duty-cycle of the switch,  $\delta$ .

$$\frac{V_O}{V_I} = \delta \quad (18.8) \Leftarrow \quad I_O = i_L^{\text{avg}} = \frac{1}{T} \int_0^T i_L \cdot dt = \frac{\frac{1}{2}(t_{\text{on}} + t_{\text{diode}}) \cdot \Delta i_L}{T} \quad (18.9) \Leftarrow$$

This is a very convenient relationship. It means that the output voltage is a linear function of the duty-cycle of the switch, as shown in Figure 18.7. This is something we can set easily and accurately. However, if the circuit operates in discontinuous mode the relationship is more complex. The conduction becomes discontinuous if the average inductor current (and therefore the output current) becomes small in comparison to the ripple. It is the magnitude of output current that dictates the proportion of the off-time for which the diode conducts. The output current in discontinuous mode is calculated by taking the average of the inductor current illustrated in Figure 18.6(b).

**Figure 18.7** Output voltage as a function of duty-cycle and output current

Substituting Equations 18.6 and 18.9 into Equation 18.7 and using the relation  $f = 1/T$  yields:

$$\frac{V_O}{V_1} = \frac{1}{1 + \frac{2I_O L f}{V_1 \delta^2}} \quad (18.10) \Leftarrow$$

Figure 18.7 also shows a typical graph of output voltage of a buck converter operated at constant duty-cycle as the output current is increased. There are two regions: discontinuous and continuous operation. The critical conduction point is when  $I_O = \frac{1}{2} \Delta i_L$ . At currents higher than this, the output voltage is constant, as predicted by Equation 18.8. In practice, the voltage will decrease slightly with current because of voltage drops across the semiconductors and the resistance of the inductor. Below the critical current, the voltage rises with decreasing current, according to Equation 18.10 until reaching the input voltage at zero output current.

The switching action of the transistor leads to voltage ripple on the output capacitor. This ripple may interfere with the operation of the circuit being supplied at the output. It is important to analyse this ripple and make design choices that reduce it. The capacitor current waveform was shown in Figure 18.6. The ripple voltage developed across the capacitor can be found by integrating this current.

$$v_C = \frac{1}{C} \int i_C \cdot dt \quad (18.11) \Leftarrow$$

Since the ripple must be centred on zero to have an average value of zero, we can find the ripple amplitude from the area under the positive excursion of the current (i.e. the charge delivered to the capacitor while the inductor current exceeds the load current). For continuous conduction the ripple is:

$$\Delta v_C = \frac{1}{8fC\Delta i_L} \quad (18.12) \Leftarrow$$

Using typical values of switching frequency and current ripple it becomes clear that capacitors of the order of 100  $\mu\text{F}$  are sufficient to keep the voltage ripple in the order of 10 mV. However, this is a misleading calculation because the parasitic components of the capacitor make a significant, in fact a dominant, contribution to the ripple voltage. Figure 18.8 shows the form (but not relative magnitude) of the ripple contributions. Another consideration is that much larger capacitors than indicated by Equation 18.12 are often used for providing some energy storage for supply-loss ride-through.

The magnitude of the voltage ripple due to the Effective Series Resistance, ESR is given by:

$$\Delta v_{\text{ESR}} = R_{\text{ESR}} \Delta i_L \quad (18.13) \Leftarrow$$

The magnitude of the voltage ripple due to the Effective Series Inductance, ESL, is given by:

$$\Delta v_{\text{ESL}} = L_{\text{ESL}} \Delta i_L \left( \frac{1}{t_{\text{on}}} + \frac{1}{t_{\text{off}}} \right) = L_{\text{ESL}} \Delta i_L f \frac{1}{\delta(1-\delta)} \quad (18.14) \Leftarrow$$

So, for a given current ripple, the voltage ripple due to the capacitance is inversely proportional to frequency and is normally insignificant. The voltage ripple due to the ESR is independent of frequency and is significant. The voltage ripple due to the ESL is proportional to frequency and is

**Figure 18.8** Contribution to ripple voltage from the effective series resistance (ESR) and inductance (ESL) of a capacitor

significant. In other words, the output capacitor is chosen for its ESR and ESL properties and its capacitance is normally satisfactory by default.

The output capacitance is not the only component for which parasitic effects are observed. *Figure 18.6(b)* illustrates a parasitic oscillation of  $V_{\text{pulse}}$ , the voltage across the diode, as the diode falls out of conduction when the inductor current reaches zero. In an ideal circuit we would expect  $V_{\text{pulse}}$  to rise to  $V_O$  so that no voltage appears across the inductor. In practice, this requires the junction capacitance of the diode to charge via the inductor as the diode enters reverse bias. Thus, a second order system is formed and a lightly damped oscillation of the voltage occurs.

### 18.2.1.1 Two and four quadrant chopper

The Buck SMPS is used at power ratings of less than 1 W to more than 1 MW. The larger versions are generally for control of d.c. machines in drive systems as discussed in Chapter 19 (Section 19.3.3.2, 'Step-down d.c.-d.c. converters'). The load is the armature circuit of the machine. The filtering action at the output is often inherent in the inductance of the armature winding and the inertia of the mechanical system (that keeps the speed and back-EMF constant over the short term). In some cases, extra inductance will be added to keep the current ripple low and prevent either excessive power loss in the armature resistance or torque ripple.

The simple chopper of *Figure 18.9(a)* is limited as a motor drive. The output voltage can only be varied between 0 and  $V_s$ . In particular, the voltage cannot be made negative and, therefore, reverse rotation cannot be supported. Further, there is no path for reverse armature current so it is not possible to develop reverse torque to decelerate the mechanical system (through regeneration). This circuit is known as a one-quadrant chopper because it can operate the drive only in the first quadrant of the torque-speed plane, *Figure 18.10*.

The circuit of *Figure 18.9(b)* allows controlled negative current. The switches are operated in anti-phase, i.e.  $T_1$  is on for period  $\delta T$  and  $T_2$  for period  $(1-\delta)T$ . This forces the voltage  $V_A$  to become a pulse train of amplitude  $V_s$  and duty-cycle  $\delta$  regardless of the direction of  $I_A$ . If the direction of  $I_A$  is such that it cannot flow in the switch that is on, then it will flow in the anti-parallel diode. The circuit is still constrained to positive voltage. It can therefore operate a drive in the first and fourth quadrants.

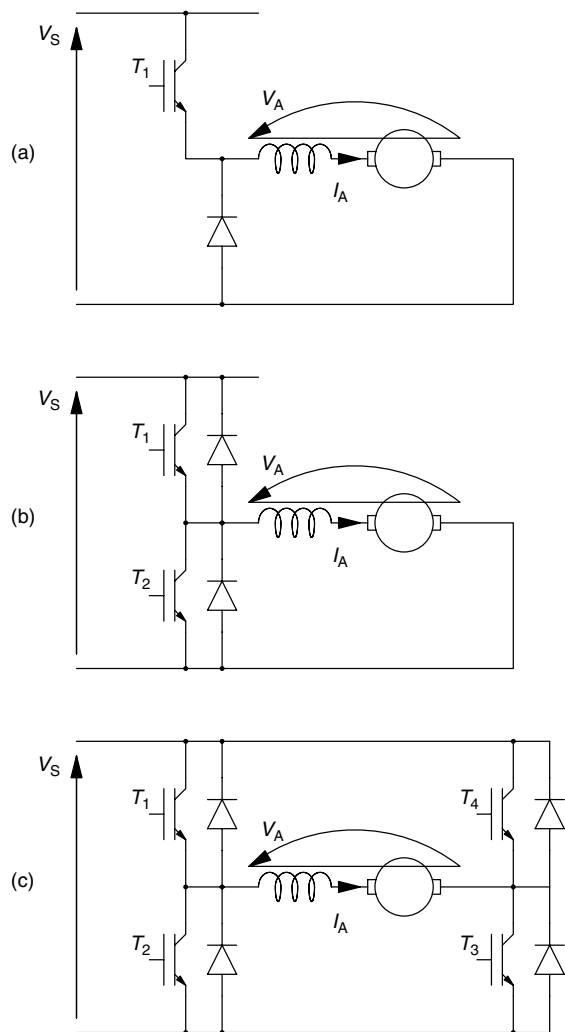

Figure 18.9 One, two and four quadrant choppers

Figure 18.10 Quadrants of the torque-speed plane

The circuit of *Figure 18.9(c)* is variously known as a four-quadrant chopper, a full bridge or an *H*-bridge. There are several ways to operate the circuit. The transistor pair  $T_1$  and  $T_2$  can be operated in anti-phase as in the two-quadrant chopper. Then  $T_3$  can be switched with  $T_1$  and  $T_4$  switched with  $T_2$ . Alternatively,  $T_3$  and  $T_4$  are not switched but simply used to select the polarity of the voltage. The circuit allows both directions of current flow and both polarities of output voltage. Therefore, the drive can be operated in all four quadrants.

### 18.2.2 Boost SMPS

The Boost circuit is a simple re-arrangement of the components of the Buck circuit, *Figure 18.11*.

As in the case of the Buck SMPS, energy storage in the inductor is the key to its operation. If the switch were left off for a long time, then the output capacitor would charge up via the inductor and diode to a voltage equal to the input voltage. The switching action then raises the output voltage above the input voltage hence the name Boost.

Operation of the circuit can be summarised as:

On-state (*Figure 18.12(a)*):

- The input voltage is imposed across the inductor:

$$V_L = V_1 - V_{DS(on)} \approx V_1$$

- The current in the inductor increases as:

$$\frac{di_L}{dt} = \frac{V_1}{L}$$

- The energy stored in the inductor increases.
- The diode is reverse biased and the load is supplied by the capacitor alone.

Off-state (*Figure 18.12(b)*):

- The current flow through the inductor is maintained by its stored energy.
- The diode is forced into conduction to provide a current path.
- A voltage is imposed across the inductor of:

$$V_L = V_1 - V_{D(on)} - V_O \approx V_1 - V_O$$

- The current in the inductor decreases because the output voltage is higher than the input voltage:

$$\frac{di_L}{dt} = \frac{V_1 - V_O}{L}$$

The energy stored in the inductor decreases as it is transferred to the capacitor and output.

The inductor current ripples up and down, and again there are two cases to examine. If the average current is large then the inductor will be in continuous conduction, *Figure 18.13(a)*. If the average current is small then the inductor will be in discontinuous conduction, *Figure 18.13(b)*.

Again following the principle that in steady-state the change in inductor current during the on-state must be matched by the change during the off-state, we can derive a relationship between input voltage, output voltage and the timing of the switch operation.

$$\Delta i_{L(on)} + \Delta i_{L(diode)} = 0$$

$$\Delta i_{L(on)} = \frac{di_L}{dt} t_{on} = \frac{V_1}{L} t_{on} \quad (18.15) \Leftarrow$$

$$\Delta i_{L(diode)} = \frac{di_L}{dt} t_{diode} = \frac{V_1 - V_O}{L} t_{diode}$$

$$\frac{V_O}{V_1} = \frac{t_{on} + t_{diode}}{t_{diode}} \quad (18.16) \Leftarrow$$

For the continuous conduction case where  $t_{diode} = t_{off}$  the output/input relationship is a simple, but non-linear, function of  $\delta$ .

$$\frac{V_O}{V_1} = \frac{1}{1 - \delta} \quad (18.17) \Leftarrow$$

For the discontinuous case, the relationship again becomes dependent on the circuit conditions. The relationship is found by expressing the average inductor current (equal to the input current) in terms of the diode conduction time.

$$\frac{V_O}{V_1} = \frac{1}{1 - \frac{V_1 \delta^2}{2fL}} \quad (18.18) \Leftarrow$$

It is important to note that the Boost circuit suffers a disadvantage in terms of the output voltage ripple. This is because the capacitor and output are supplied only when

**Figure 18.11** The Boost SMPS

**Figure 18.12** Current paths in on- and off-states of the Boost SMPS

the diode conducts, whereas in the Buck they are continually supplied via the inductor (provided that the inductor is in continuous conduction). The average component of the diode current flows onward to the load, and the ripple component flows in the capacitor. As can be seen from *Figure 18.13*, the ripple component of the diode current is larger than the ripple of the inductor current and is, in fact, at least as large as the output current.

On the other hand, the Boost SMPS draws an essentially smooth input current whereas the Buck SMPS draws a pulsed input current. This may be important if the interference generated in the input line is an issue.

### 18.2.3 Flyback SMPS

The Flyback SMPS is another rearrangement of the basic components as shown in *Figure 18.14*. This circuit is also known as the Buck-Boost SMPS. Some texts, such as,<sup>3</sup> reserve the name Flyback for the transformer isolated version of the circuit to be described in Section 18.2.5.

Operation of the circuit is as follows: the transistor is switched on to impose the input voltage across the inductor and store energy in that inductance. *Figure 18.15* shows the current paths in on- and off-states. It is clear that the release of the inductor energy by current flow through the diode charges the capacitor such that its lower plate becomes the more positive. In other words, the output voltage is negative.

The negation of the voltage is also apparent from the transfer characteristic which is derived from the assumption of steady-state in the normal way:

$$\begin{aligned} \Delta i_{L(on)} + \Delta i_{L(diode)} &= 0 \\ \Delta i_{L(on)} &= \frac{d i_L}{d t} t_{on} = \frac{V_1}{L} t_{on} \\ \Delta i_{L(diode)} &= \frac{d i_L}{d t} t_{diode} = \frac{V_O}{L} t_{diode} \end{aligned} \quad (18.19) \Leftarrow$$

$$\frac{V_O}{V_1} = - \frac{t_{on}}{t_{diode}} \quad (18.20) \Leftarrow$$

If the circuit is in continuous conduction, the transfer characteristic becomes:

$$\frac{V_O}{V_1} = - \frac{\delta \zeta}{1 - \delta \zeta} \quad (18.21) \Leftarrow$$

Thus, the circuit is capable of step-down (for  $\delta < 1/2$ ) or step-up (for  $\delta > 1/2$ ) but with a voltage negation as well.

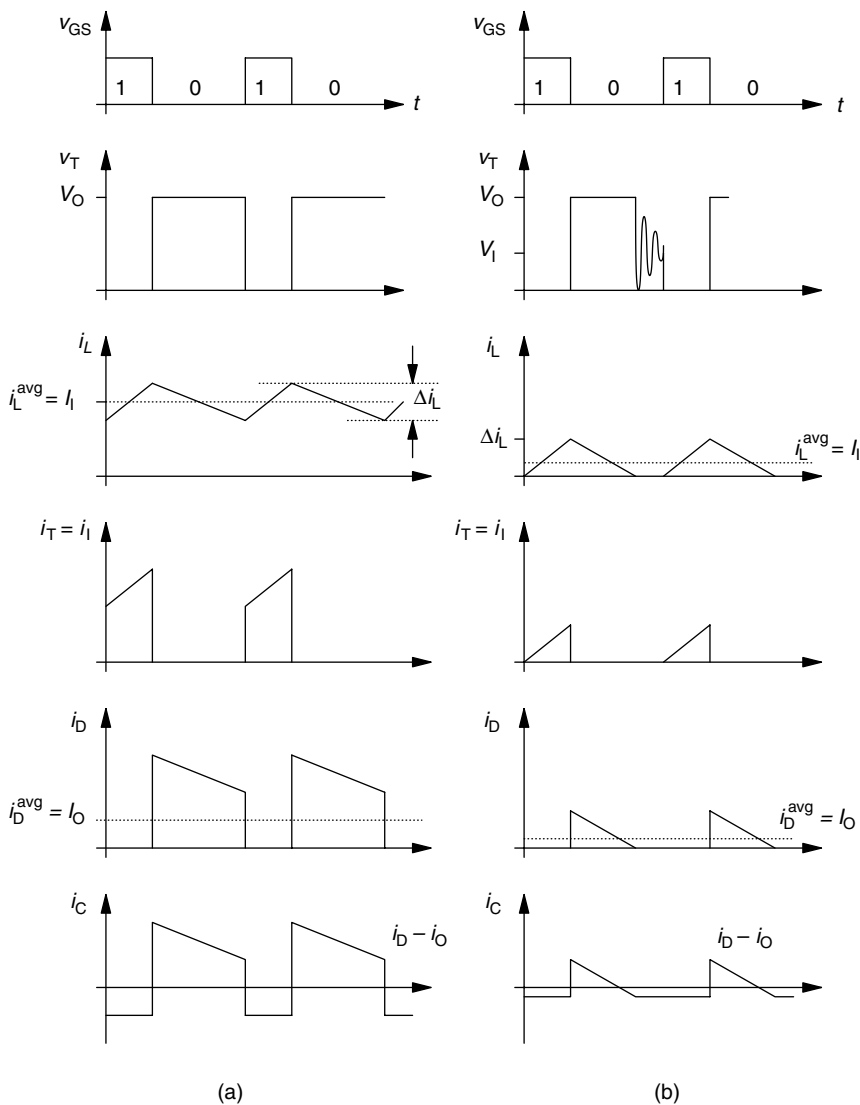

For discontinuous conduction the transfer characteristic is:

$$\frac{V_O}{V_1} = - \frac{V_O \delta^2}{2 I_{1(avg)} L f} \quad (18.22) \Leftarrow$$

The principal current and voltage waveforms in continuous and discontinuous conduction are shown in *Figure 18.16*. It can be seen that both the input current and the capacitor current are pulsed waveforms and, as a consequence, there can be large current ripple at both the input and output.

### 18.2.4 Capacitor coupled SMPS

A new family of SMPS can be formed by adding an extra capacitor and an extra inductor to the basic elements, *Figure 18.17*. The capacitor is part of the energy transfer process and is (partially) charged and discharged during the cycle of operation. They have voltage transfer relationships similar to that of the Flyback (with or without the negation) and are therefore capable of step-up or step-down depending on the duty-cycle. The Ćuk SMPS, *Figure 18.17(a)*, (named after its inventor) provides an identical transfer characteristic to the Flyback SMPS but has inductors in both the input connection and the charging path of the

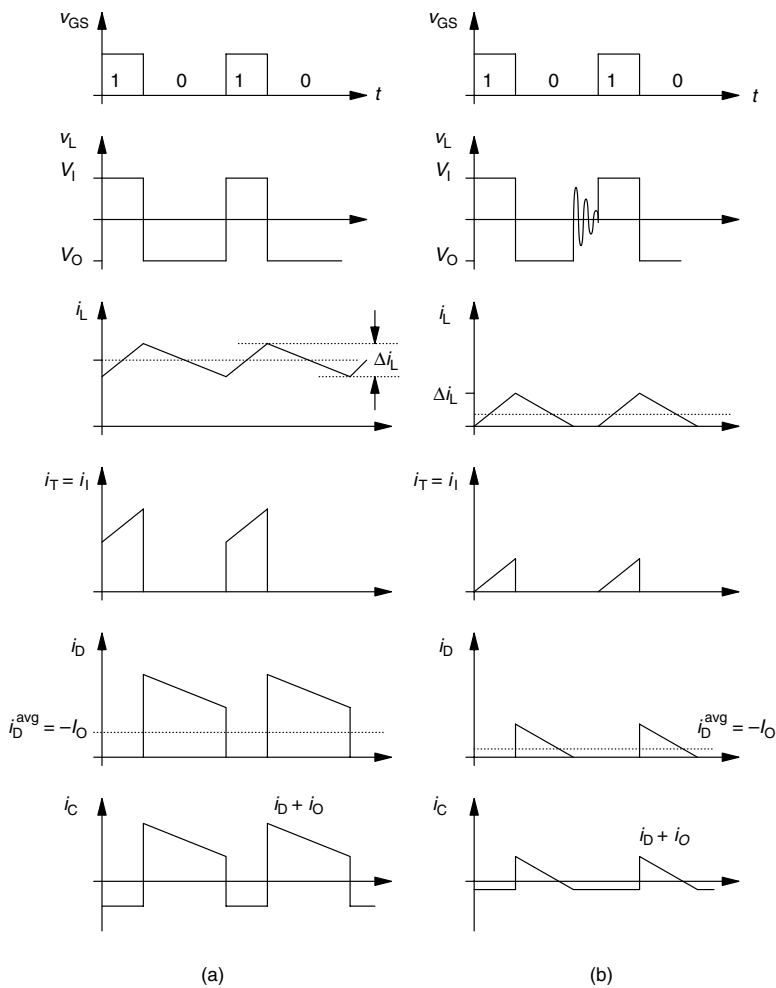

**Figure 18.13** Voltage and current waveforms of the Boost SMPS for (a) continuous and (b) discontinuous inductor current

**Figure 18.14** The Flyback SMPS

**Figure 18.15** Current paths in on- and off-states of the Flyback SMPS

**Figure 18.16** Voltage and current waveforms of the Flyback SMPS for (a) continuous and (b) discontinuous inductor current

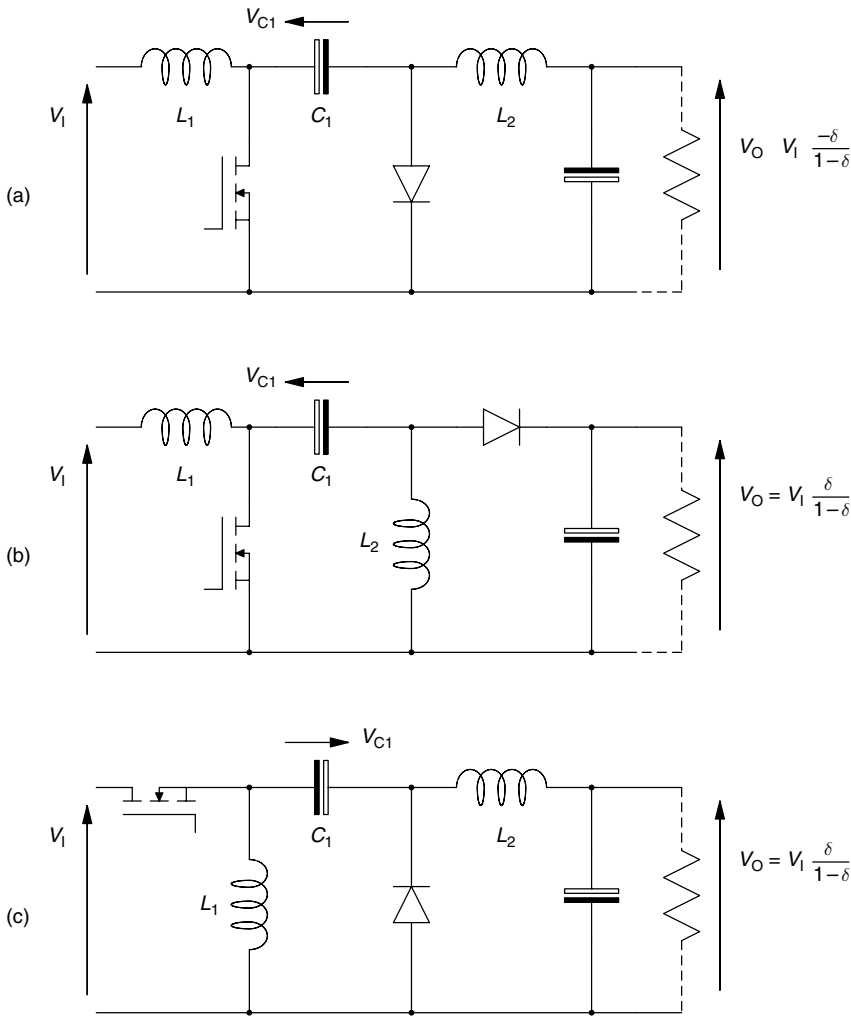

Figure 18.17 Čuk, SEPIC and Zeta SMPS

output capacitor. This provides low input current ripple and low output voltage ripple<sup>3</sup>. The SEPIC SMPS, Figure 18.17(b), (single-ended primary inductor converter) and Zeta SMPS, Figure 18.17(c), have a non-inverted output voltage and are capable of step-up or step-down. These two circuits differ in whether the input or output current is smoothed by an inductor.

### 18.2.5 Isolated flyback SMPS

Energy storage in the inductor is the key to SMPS operation. Energy can be built up by imposing one voltage and released into another. The energy is stored temporarily in the magnetic field of the inductor. If we use mutually coupled inductors then we can go one step further. We can build up stored energy in the magnetic field using one circuit and release the energy using an entirely separate circuit. Thus, we can achieve galvanic isolation between the input and output. This is useful for transferring energy from a ground-referenced supply to a non ground-referenced supply.

Figure 18.18 shows a Flyback SMPS incorporating a mutually coupled pair of inductors such that the input and output circuits do not have any direct electrical connection.

The current paths illustrated in Figure 18.19 are very similar to those of the non-isolated Flyback circuit, Figure 18.15.

In analysing the operation of the circuit, it is helpful to discuss the flux,  $\phi$  in the inductor core rather than the current. These two quantities are closely related, Equation 18.23 (which is written to include the possibility of more than two coupled inductors), but flux is the more useful quantity because it more directly relates to the stored energy in the magnetic field and is the quantity that must remain continuous from instant to instant (i.e. have a finite derivative).

$$\phi = \frac{N_1}{\mathcal{R}} i_1 + \frac{N_2}{\mathcal{R}} i_2 + \dots$$

or

$$\phi = \frac{L_1}{N_1} i_1 + \frac{L_2}{N_2} i_2 + \dots$$
(18.23)

**Figure 18.18** An isolated Flyback SMPS using a mutually coupled pair of inductors

where  $N$  is the number of turns of a winding,  $L$  is its inductance and  $\mathcal{R}$  is the reluctance of the magnetic path.

The voltage induced across any of the mutually coupled inductors is given by Faraday's Law and for the first inductor is expressed as:

$$E_1 = N_1 \frac{d\phi}{dt} = \frac{N_1^2}{\mathcal{R}} \frac{di_1}{dt} + \frac{N_1 N_2}{\mathcal{R}} \frac{di_2}{dt} + \dots \quad (18.24)$$

or

$$= L_1 \frac{di_1}{dt} + M_{12} \frac{di_2}{dt} + \dots$$

With these relations in mind, we can draw the principal voltage and current waveforms as shown in *Figure 18.19*. There are two cases: continuous conduction (defined as the flux in the core not reaching zero by the end of the cycle) and discontinuous conduction (defined as flux reaching and holding zero by the end of the cycle). The flux rises linearly

while the transistor is on because of the voltage imposed across the primary. When the transistor switches off, the primary current must stop and the diode is forced into conduction so that secondary current can flow to maintain the flux. The primary and secondary side currents are scaled versions of the flux according to the number of turns. When the diode is conducting, a voltage is imposed across the secondary and this is reflected on the primary according to the turns-ratio. Thus, the transistor must support  $V_1 + V_O N_1/N_2$  while it is off.

The transfer characteristic can be evaluated from rise and fall of flux in steady-state.

$$\begin{aligned} \Delta\phi_{(\text{on})} + \Delta\phi_{(\text{diode})} &= 0 \\ \Delta\phi_{(\text{on})} &= \frac{d\phi}{dt} t_{\text{on}} = \frac{V_1}{N_1} t_{\text{on}} \\ \Delta\phi_{(\text{diode})} &= \frac{d\phi}{dt} t_{\text{diode}} = \frac{V_O}{N_2} t_{\text{diode}} \\ \frac{V_O}{V_1} &= -\frac{N_2}{N_1} \frac{t_{\text{on}}}{t_{\text{diode}}} \end{aligned} \quad (18.25)$$

**Figure 18.19** Current paths in on- and off-states of the isolated Flyback SMPS

Because the output is isolated, we can choose to take the output voltage in either sense and it is more normal to see the circuit drawn as in *Figure 18.21*. In this circuit the primary has also been rearranged to give a ground referenced MOSFET connection. The transfer characteristic for continuous conduction is:

$$\frac{V_O}{V_1} = \frac{N_2}{N_1} \frac{\delta \zeta}{1 - \zeta} \quad (18.26) \Leftarrow$$

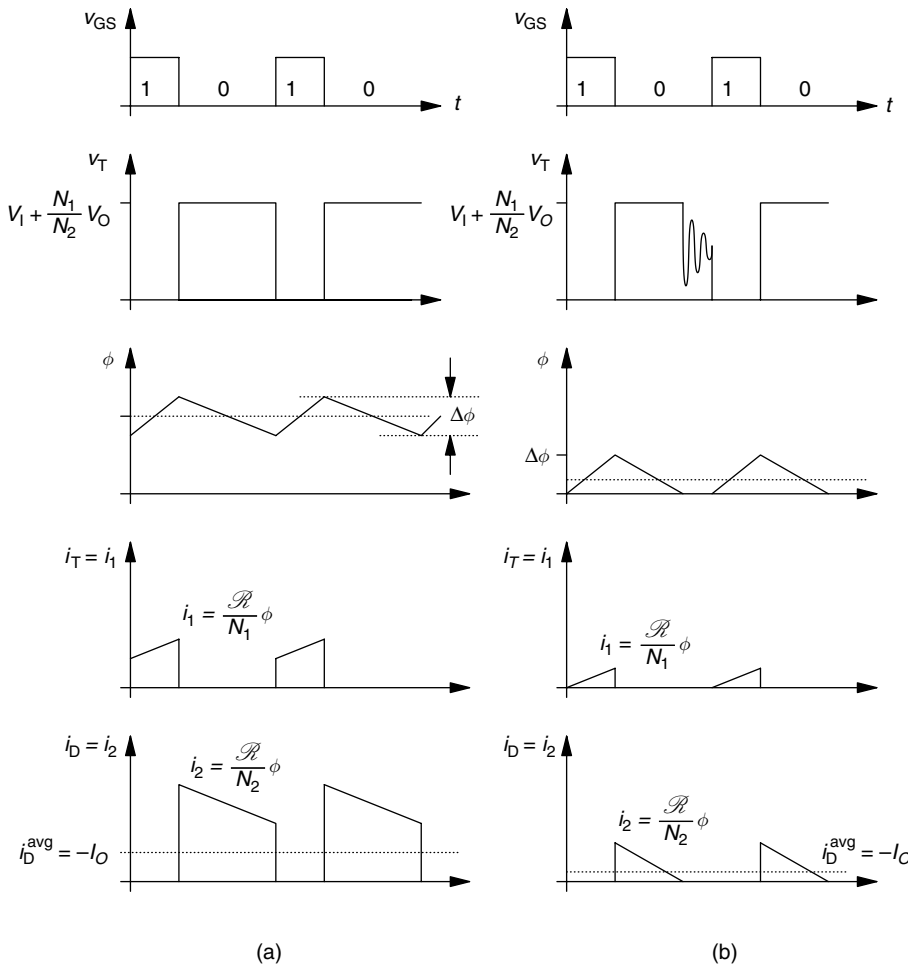

Discontinuous operation is sometimes favoured because it is easy to ensure that the core does not saturate. It is quite useful from a control standpoint because a fixed amount of energy is delivered to the output in each cycle.

The waveforms of *Figure 18.20* were drawn assuming perfect coupling of the flux to each winding. In practice, this will not be the case and each winding will have a leakage field. The consequence of this is that the currents in the primary and secondary cannot rise and fall instantaneously. In particular, when the transistor is switched off the primary current will not cease until the energy in the primary leakage field has been removed. The current will

overcharge the parasitic capacitance of the transistor, as illustrated in *Figure 18.22*.

The overshoot can be estimated by assuming that all of the energy previously stored in the leakage field is transferred to the drain-source capacitance. The voltage overshoot has important implications for the rating of the transistor. Using a resistor-capacitor-diode snubber can reduce the over-voltage<sup>6</sup> but power loss in the snubber is problematic and it is difficult to design it for a wide range of operating currents. More sophisticated clamp-like snubbers are difficult to apply because of the lack of a suitable voltage rail to which to clamp.

The transistor over-voltage problem can be solved, at the expense of another transistor, by switching both ends of the primary winding as shown in *Figure 18.23*. Each transistor can be rated for  $V_1$  rather than  $V_1 + V_O N_1/N_2 + V_{\text{overshoot}}$  which would be required for the single transistor. The energy stored in the leakage field of the primary is returned to the supply via the two diodes. It is important that these diodes do not conduct in place of the output-side diode during normal operation and so the reflected secondary voltage  $V_O N_1/N_2$  must be kept less than  $V_1$ .

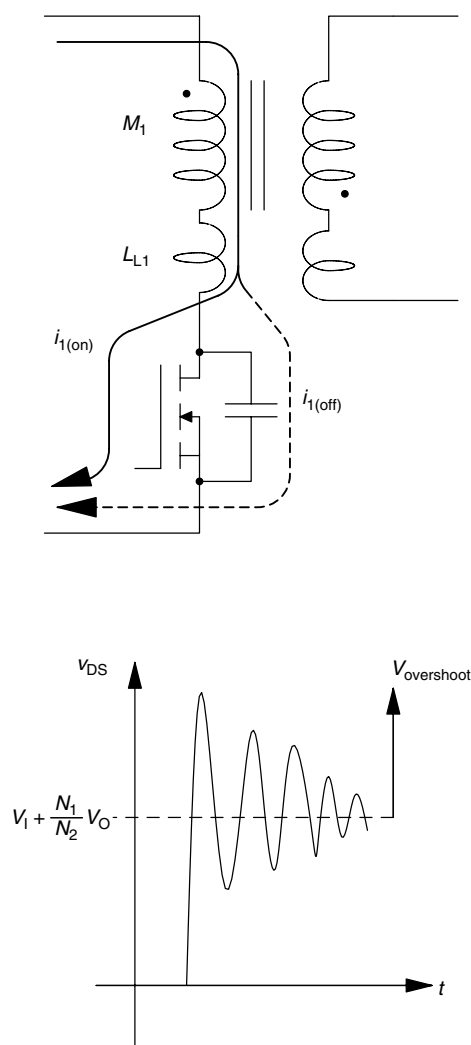

Figure 18.22 Overshoot of transistor voltage at turn-off

### 18.2.6 Transformer isolated buck SMPS

Some SMPS designs do not lend themselves to direct incorporation of a mutually coupled inductor. Instead, the energy storage function occurs in a single inductor and a further mutually coupled pair of inductors is introduced to provide isolation. This is illustrated by the isolated Buck SMPS circuits of *Figure 18.24*. All three versions of the circuit apply an isolated pulse train to the standard LC output stage of a Buck circuit. The transfer characteristic in each case is similar to the Buck SMPS with a scaling factor of the turns ratio of the transformer:

$$\frac{V_O}{V_I} = \frac{N_S}{N_P} \delta \quad (18.27)$$

The differences between the circuits are in the ratings of the transistors, the control of leakage energy and the utilisation of the magnetic core.

The circuit (*Figure 18.24(a)*) has a well-defined path in which to recover the primary leakage energy. It also causes the transformer flux to swing both positive and negative. Thus, the core can be utilised from its saturation limit in one direction to its saturation limit in the other. The transistors in the circuit can be rated for the input voltage with no significant overshoot. These three advantages are gained at the expense of using a 4-transistor full bridge. The duty-cycle should be defined as  $(t_{on1} + t_{on2})/T$  for use in Equation 18.27 (where  $t_{on1}$  and  $t_{on2}$  are the times for which positive and negative voltage are applied to the primary; for the remaining time the voltage should be zero). It is essential to keep  $t_{on1} = t_{on2}$  in order to avoid 'stair-case' saturation of the transformer core (small net increments of flux for each cycle of operation).

The circuit (*Figure 18.24(b)*) uses a bifilar primary winding to achieve bi-directional flux swings with only two transistors. However, the voltages reflected from one primary to the other require the transistors to support twice the input voltage during their off-state. Further, there is no path to discharge the primary leakage energy and voltage overshoot occurs. Again, the duty-cycle is defined by the sum of the two conduction periods for use in Equation 18.27.

The circuit (*Figure 18.24(c)*) (often known as the forward converter) uses only one transistor and can only create a unidirectional flux swing (thus requiring twice the core

Figure 18.23 Half-bridge Flyback SMPS

Figure 18.24 Isolated Buck SMPS: (a) full bridge; (b) push-pull and (c) forward

volume to hold off saturation for the same voltage and frequency conditions as the other circuits). The bifilar primary winding is there only to discharge the magnetising current of the transformer. There is no discharge path for the primary leakage energy and so voltage overshoot occurs.

### 18.2.7 SMPS control

It is rare to see a SMPS run in open loop. Closed loop operation is essential to ensure that the output voltage is accurately maintained at the desired value. The output

voltage can be affected by changes in the output current or input voltage. There are several imperfections in practical SMPS that were not incorporated in the analysis of the previous sections such as voltage drops across the semiconductors and across the resistance of the inductor. The change from discontinuous to continuous mode will also affect the output voltage. All of these factors can be mitigated by feedback control. To achieve this we require a circuit that can vary, or modulate, the pulse-width applied to the transistor under the influence of some other signal. The usual approach is to use a triangle wave or saw-tooth

Figure 18.25 A pulse-width modulator with saw-tooth carrier

wave carrier. The carrier is compared with the modulating signal as shown in Figure 18.25. The comparator gives a high output whenever the modulating signal is greater than the carrier and thus produces pulses with a width proportional to the modulating signal.

A schematic of the closed loop system is shown in Figure 18.26. The forward transfer function,  $F(s)$  of the system is complex. The modulator is linear over its normal range but saturates outside that range. The SMPS circuit is time varying because it has two operating modes. Even in continuous mode, most SMPS have a non-linear transfer function. The parasitic components of the circuit, particularly the ESR of the output capacitor, can form significant terms in the transfer function of the circuit. The output voltage is normally found to decrease as output current is drawn (because of the increased voltage drop across resistances and semi-conductors in the circuit). Variation of the input voltage forms a further disturbance input to the system.

On a simple view, the application of feedback solves many of these problems. The closed loop transfer function, taking into account the two disturbance terms, is:

$$v_O(s) = \frac{C(s)F(s)}{1 + C(s)F(s)G(s)} \cdot v_R(s) + \frac{D_1(s)}{1 + C(s)F(s)G(s)} \cdot v_1(s) + \frac{D_2(s)}{1 + C(s)F(s)G(s)} \cdot i_O(s) \quad (18.28)$$

Provided that the loop gain of the system,  $C(s)F(s)G(s)$ , is large, then the disturbances are largely rejected. Further, the transfer function (from reference to output) is dominated by the feedback attenuator,  $G(s)$ . The feedback attenuator is normally a potential divider and has a simple linear gain.

$$v_O(s) \approx \frac{1}{G(s)} \cdot v_R(s) \approx k v_R(s) \quad (18.29)$$

where  $k$  is the reciprocal of the feedback gain.

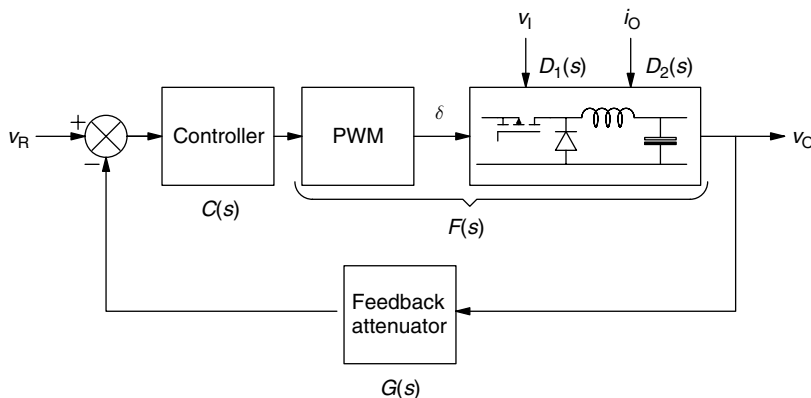

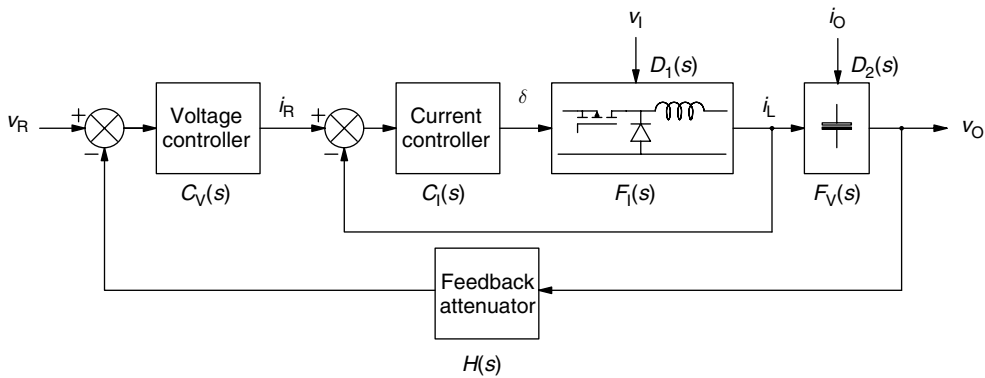

Figure 18.26 A closed loop controller schematic for an SMPS

**Figure 18.27** Current mode control using nested control loops

The control element  $C(s)$  must be chosen with care to ensure stability. Techniques such as state-space averaging<sup>3</sup> can be used to derive linearised dynamic models of the SMPS circuits to facilitate such design. (Note that the transfer characteristics, as functions of  $\delta$ , derived elsewhere in Section 18.2 express only the steady-state properties of the circuits.)

The usual elements of a controller for an SMPS (that is, a pulse-width modulator, error amplifier, an adjustable gain and a gate drive circuit) are available as standard integrated circuits. Often included is some form of current limit. A low value resistor placed in the ground line of the supply is used to monitor the current. Above some threshold value, the pulse-width of the gate-drive is reduced to reduce the output voltage and limit the current.

The non-linear, time-varying nature of the SMPS makes controller design problematic and it is often difficult to ensure stability across a wide range of operating conditions. A technique that can alleviate the problems is known as current-mode control. It is based on the feedback of two signals, in this case through two nested control loops, *Figure 18.27*.

The choice of nested loops follows from recognising that the rate of change of inductor current is much higher than the rate of change of output voltage. Therefore, the inductor current can be controlled in a fast inner loop and the output voltage is controlled in a slower outer loop. If the inner loop tracks the current reference accurately then

the outer loop becomes first-order dominated and is relatively easy to design.

The generation of pulses to drive the transistor is somewhat different from the voltage control case. The current demand set by the outer loop forms a reference. The transistor is turned on at regular intervals and stays on until the current ramps up to the reference level. The transistor then remains off until the next of the regular turn-on events. Thus, the inductor current is controlled within each switching cycle.

A further advantage of current mode control is that feed-forward of input voltage disturbances can be applied readily. There is a stability issue to be addressed at duty-cycles of greater than  $1/2$ , however, this can be overcome by a method known as slope-compensation.<sup>3</sup>

## 18.3 D.c./a.c. conversion

### 18.3.1 Single phase bridge

The full-bridge circuit was introduced in Section 18.2.1.1 as a way of converting d.c. to  $\pm$ d.c. It was used again in Section 18.2.6 to create a bi-directional voltage on the primary of a transformer. We can use the same circuit (repeated but re-labelled here as *Figure 18.28*) to convert d.c. to a.c. We can control the duty-cycle of the switches to produce a waveform with an average that gradually increases in a positive

**Figure 18.28** Full bridge with switching signal assignment of *Figure 18.30*

**Figure 18.29** Sinusoidally modulated pulse-widths

sense and then decreases and turns negative, *Figure 18.29*. The duty-cycle is modulated as:

$$\delta = \frac{1}{2} + \frac{1}{2} M \sin(\omega_M t) \quad \text{where } 0 \leq M \leq 1 \quad (18.30)$$

where  $M$  is known as the depth of modulation and will set the magnitude of the a.c. voltage being synthesised.

Top and bottom switches, such as  $S_A^T$  and  $S_A^B$ , will be operated in anti-phase but not strictly so. Because each switch takes time to turn off and time to turn on, it is important to initiate turn-off of one switch before turn-on of the other. This avoids both switches being partially on at the same time and providing a shoot-through path between the supply rails. This is known as providing dead-time or under-lap.

As indicated in *Figure 18.29*, the modulation of the duty-cycle can be performed through a comparison of the desired sinewave with a triangular carrier. An analogue circuit similar to that described in Section 18.2.7 could be used. It is more common for an inverter (d.c./a.c. converter) to be controlled with a microcontroller or digital signal processor, DSP. The transistors are switched using the timer channels of the processor. The sinewave modulation is achieved by regularly updating the timer values with times calculated using a look-up table of sinewave samples. Scaling the sinewave data controls the magnitude of the output voltage. The rate at which progress is made through the sinewave look-up table determines the frequency of the sinewave synthesised at the output.

It is common to phase shift the carrier waveform of the two sides of the bridge as shown in *Figure 18.30*.

The output voltage waveforms are also shown in *Figure 18.30*. Each side of the bridge can be switched between  $+V_{DC}$  and 0. The voltage appearing across the output can be  $+V_{DC}$ , 0 or  $-V_{DC}$ . These waveforms are known as two-level and three-level pwm respectively. It can be seen that in the case of a phase-shifted carrier the 3-level waveform has twice the frequency of the carrier.

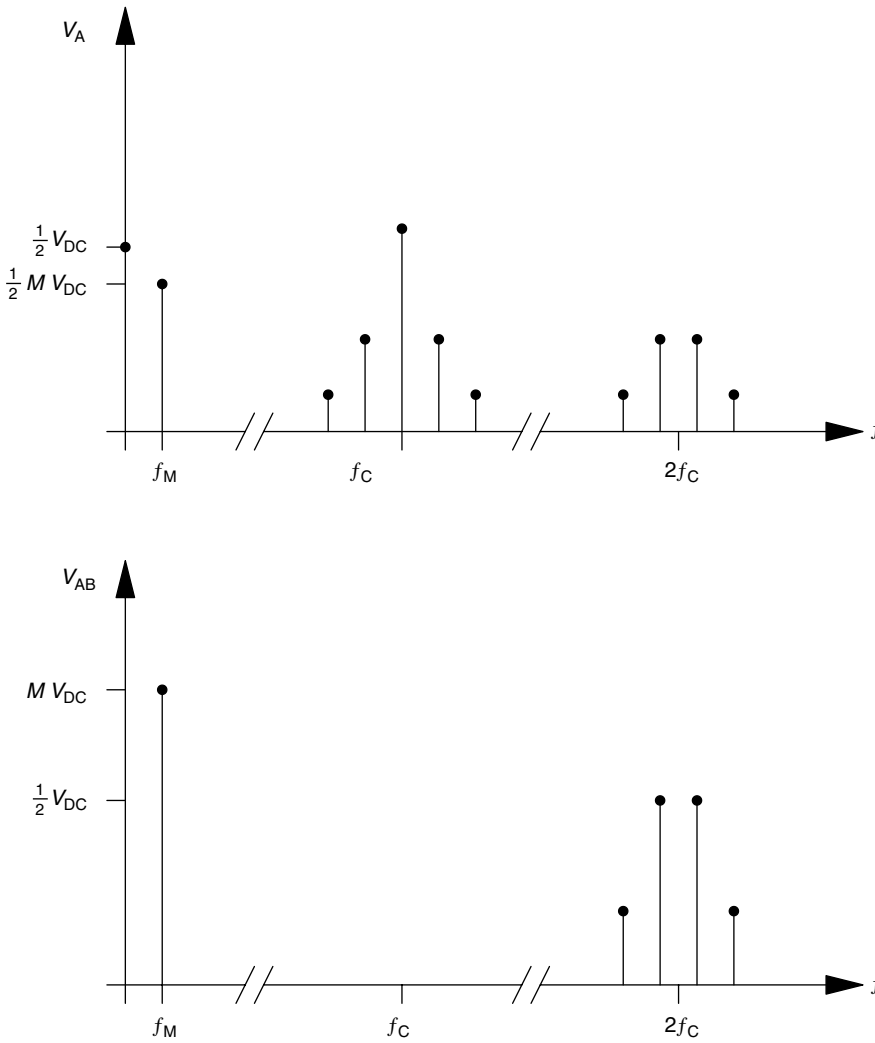

The low-frequency components of these voltages are:

$$\begin{aligned} v_{A0} &= \frac{1}{2} V_{DC} + \frac{1}{2} V_{DC} M \sin(\omega_M t) \\ v_{B0} &= \frac{1}{2} V_{DC} - \frac{1}{2} V_{DC} M \sin(\omega_M t) \\ v_{AB} &= V_{DC} M \sin(\omega_M t) \end{aligned} \quad (18.31)$$

**Figure 18.30** Phase-shifted carrier used to interleave PWM of left and right-hand sides of full bridge.

**Figure 18.31** Frequency spectra of a half bridge voltage and a full bridge voltage with phase-shifted carrier

The d.c. portions of the voltage at each half of the bridge are common mode and do not appear in the output voltage.

The objective of this circuit is to produce sinusoidal voltage but what we have is a sinusoidally modulated rectangular wave. The difference is illustrated in the frequency spectra of *Figure 18.31*. The details of the spectra depend on how the modulation was implemented, but the basic form shown here is typical.

### 18.3.2 Three phase bridge

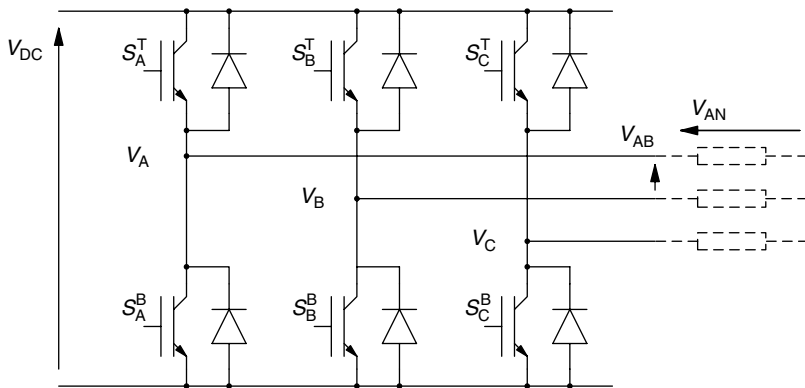

For most three-phase applications, the requirement is to produce a balanced set of voltages for a three-wire system. In this case, a pair of transistors is used to produce an a.c. waveform for each phase voltage. The common mode (or zero-sequence) d.c. component is unimportant in a three-wire system.

The three phase voltages  $V_A$ ,  $V_B$  and  $V_C$  are modulated to give a balanced three-phase set:

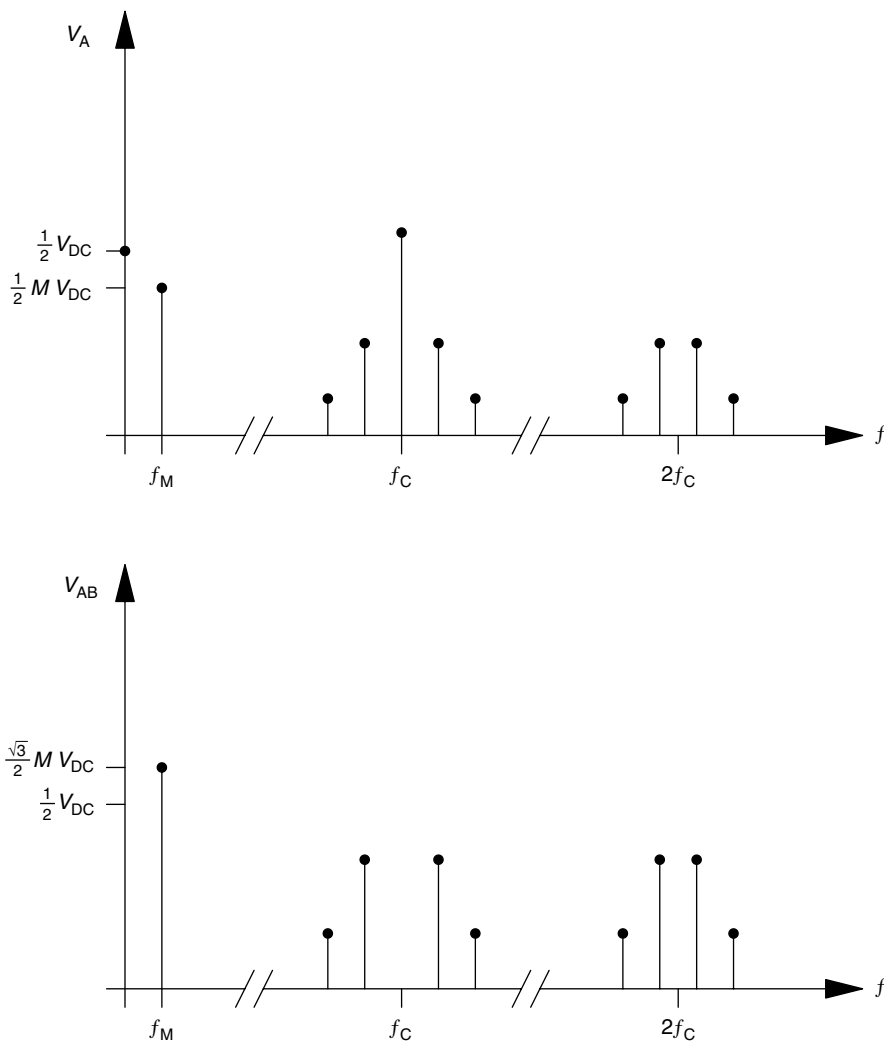

$$\begin{aligned} v_A &= \frac{1}{2} V_{DC} + \frac{1}{2} V_{DC} M \sin(\omega t) \\ v_B &= \frac{1}{2} V_{DC} + \frac{1}{2} V_{DC} M \sin\left(\omega t - \frac{2\pi}{3}\right) \\ v_C &= \frac{1}{2} V_{DC} + \frac{1}{2} V_{DC} M \sin\left(\omega t + \frac{2\pi}{3}\right) \end{aligned} \quad (18.32)$$

$$\begin{aligned} v_{AB} &= \frac{\sqrt{3}}{2} V_{DC} M \sin\left(\omega t + \frac{\pi}{6}\right) \\ v_{BC} &= \frac{\sqrt{3}}{2} V_{DC} M \sin\left(\omega t - \frac{\pi}{6}\right) \\ v_{CA} &= \frac{\sqrt{3}}{2} V_{DC} M \sin\left(\omega t + \frac{5\pi}{6}\right) \end{aligned} \quad (18.33) \Leftarrow$$

All three phases are modulated using the same carrier and so there is no doubling of the effective switching rate as in

**Figure 18.32** A three-phase inverter bridge

**Figure 18.33** Frequency spectra of the phase and line voltages of the three-phase inverter of Figure 18.32

**Figure 18.34** Increase of maximum fundamental by addition of third harmonic

the single-phase bridge. However, the carrier component is zero-sequence and will not appear in the line voltages to the phase voltages at the load. The frequency spectra of the phase and line voltages are shown in *Figure 18.33*.

The fact that zero-sequence components can be inserted into the inverter phase voltage waveforms without affecting the line voltage waveforms can be useful. The peak line voltage indicated above is  $\sqrt{3}/2 V_{DC}$ . It should be possible to achieve a peak line voltage of  $V_{DC}$  by switching on the top switch of one phase and the bottom switch of another. This can be realised for a sinewave pattern by including a zero-sequence third harmonic set in the waveforms as shown in *Figure 18.34*. The fundamental component can be boosted by  $2/\sqrt{3}$  without exceeding a duty cycle of unity if the third harmonic is 1/6th of amplitude of the fundamental.

There is an alternative way of forming the switching waveforms of the inverter known as space-voltage vector modulation, SVM. It is based on the fact that there are only eight useful states of the inverter as indicated in *Table 18.1*. When a bottom switch is on, the voltage of that phase will be zero; and when a top switch is on, the voltage of that phase will be  $V_{DC}$ . We discount states where neither or both of the switches in a phase are on. The zero sequence voltage is the average of the three phase voltages. The overall voltage output of the inverter is represented as a space-voltage vector. That is, the voltage of each phase is taken to have a spatial position matching the spatial positioning of the phase windings in an electrical machine. This is equivalent to a Clarke transform<sup>4</sup> to  $\alpha\beta\gamma$  co-ordinates:

**Table 18.1** Inverter states and resultant space-voltage vector

State	Switches on			Phase voltages			Zero sequence $V_{\gamma} = \frac{1}{3} V_N$	Space-voltage vector $V$
	A	B	C	$V_A$	$V_B$	$V_C$		
0	B	B	B	0	0	0	0	0
1	T	B	B	$V_{DC}$	0	0	$\frac{1}{3} V_{DC}$	$V_{DC} \angle 0^\circ$
2	T	T	B	$V_{DC}$	$V_{DC}$	0	$\frac{2}{3} V_{DC}$	$V_{DC} \angle 60^\circ$
3	B	T	B	0	$V_{DC}$	0	$\frac{1}{3} V_{DC}$	$V_{DC} \angle 120^\circ$
4	B	T	T	0	$V_{DC}$	$V_{DC}$	$\frac{2}{3} V_{DC}$	$V_{DC} \angle 180^\circ$
5	B	B	T	0	0	$V_{DC}$	$\frac{1}{3} V_{DC}$	$V_{DC} \angle 240^\circ$
6	T	B	T	$V_{DC}$	0	$V_{DC}$	$\frac{2}{3} V_{DC}$	$V_{DC} \angle 300^\circ$
7	T	T	T	$V_{DC}$	$V_{DC}$	$V_{DC}$	$V_{DC}$	0

**Figure 18.35** Space-voltage vectors of a three-phase inverter and synthesis of a voltage trajectory by space-voltage vector modulation

$$V = V_{AN} + V_{BN}e^{j\frac{2\pi}{3}} + V_{CN}e^{-j\frac{2\pi}{3}}$$

or

$$V = V_{\alpha\beta} + jV_{\beta\gamma}$$

$$\begin{bmatrix} V_{\alpha\beta} \\ V_{\beta\gamma} \\ V_{\gamma\alpha} \end{bmatrix} = \frac{1}{3} \begin{bmatrix} 1 & -\frac{1}{2} & -\frac{1}{2} \\ \frac{\sqrt{3}}{2} & \frac{\sqrt{3}}{2} & -\frac{\sqrt{3}}{2} \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \end{bmatrix} \begin{bmatrix} V_A \\ V_B \\ V_C \end{bmatrix} \quad (18.34) \Leftarrow$$

The normal objective is to produce a smoothly rotating space-voltage vector and, by implication, produce line voltages that are a balanced three-phase set. *Figure 18.35* shows the desired trajectory of the space-voltage vector. To achieve the point on the trajectory shown (a circle of radius  $0.8 V_{DC}$  in this example) we combine the nearest two non-zero space-voltage vectors with the two zero space-voltage vectors.

For example, to achieve  $V = 0.8 V_{DC} \angle 40^\circ$  we use states 0, 1, 2, 7.

The duty-cycles of the two non-zero space-vectors must satisfy:

$$\delta_2 V_{DC} \sin(60^\circ) = 0.8 V_{DC} \sin(40^\circ) \Leftarrow$$

$$\delta_1 V_{DC} + \delta_2 V_{DC} \cos(60^\circ) = 0.8 V_{DC} \cos(40^\circ) \Leftarrow$$

Thus, in this case,  $\delta_2 = 0.594$  and  $\delta_1 = 0.316$ . The remaining time within the period,  $\delta_0 = (1 - \delta_1 - \delta_2)$  is split equally between the two zero-voltage states; states 0 and 7. A useful switching sequence, because it minimises the number of switch transitions and returns to the original state, is:

State 0 for  $T\delta_0/4$

State 1 for  $T\delta_1/2$

State 2 for  $T\delta_2/2$

State 7 for  $T\delta_0/2$

State 2 for  $T\delta_2/2$

State 1 for  $T\delta_1/2$

State 0 for  $T\delta_0/4$

The sum of the duty-cycles of the two non-zero states is constrained to less than or equal to unity. This means that the synthesised space-voltage vector must lie within the hexagonal limit shown in *Figure 18.35*. The maximum radius circle that can be accommodated is  $\frac{\sqrt{3}}{2} V_{DC}$  which is equivalent to the maximum amplitude sinewave that can be synthesised with simple PWM employing third-harmonic injection.

In high-power applications, particularly large machine drives, the switching frequency may be very low compared to the required sinewave to be synthesised. Special techniques are required involving synchronising the carrier to the sinewave or optimising individual switching times to reduce harmonic distortion. For very large inverters the devices might only be switched at line frequency in what is known as six-step or quasi-square operation. This is illustrated in Section 19.3.4.1 ‘Six-step square-wave inverter’.

### 18.3.3 Current source inverters

There are occasions on which a three-phase current set is required rather than a three-phase voltage set. A class of circuits, known as current source inverters,<sup>6</sup> exist which are duals of the circuits discussed in Section 18.3.2. The d.c.-side is supplied with a current via a smoothing inductor. The output can be pulse-width modulated or simply switched as a low frequency rectangular wave. Such circuits are sometimes used in large thyristor based drive systems as discussed in Section 19.3.4.2 ‘Current source inverters’. There are difficulties in designing a d.c.-side inductor with low resistance and high saturation limit. To achieve a

fast-response controlled current it is normally better to use a voltage source inverter with a local current control-loop.

## 18.4 A.c./d.c. conversion

A.c./d.c. conversion is commonly referred to as rectification. There are well-established rectifier circuits based on diodes but these circuits suffer limitations. They have poor output voltage regulation characteristics and offer no adjustment of output voltage. They also generate harmonically distorted current in the a.c. system. Standards, such as IEC 1000 (adopted as EN 61000 in the EU), place limits on such distortion and lead to the adoption of more sophisticated circuits. The tightest limits imposed by these standards are on even-order harmonic current. This all but prohibits the use of half-wave circuits that draw current during only one half-cycle of the a.c. waveform.

### 18.4.1 Line-frequency-switched rectifiers

The single-phase full-wave diode bridge rectifier is shown in *Figure 18.36*. The diodes can be considered in pairs: one pair ( $D_A^T$  and  $D_B^B$ ) applies the positive half-cycle of the a.c. to the load and the other ( $D_B^T$  and  $D_A^B$ ) applies the negative half-cycle. The three-phase bridge rectifier of *Figure 18.37* is an extension of the single-phase bridge with three pairs of diodes. The line voltage that is highest in magnitude (whether positive or negative) is applied to the load. Each

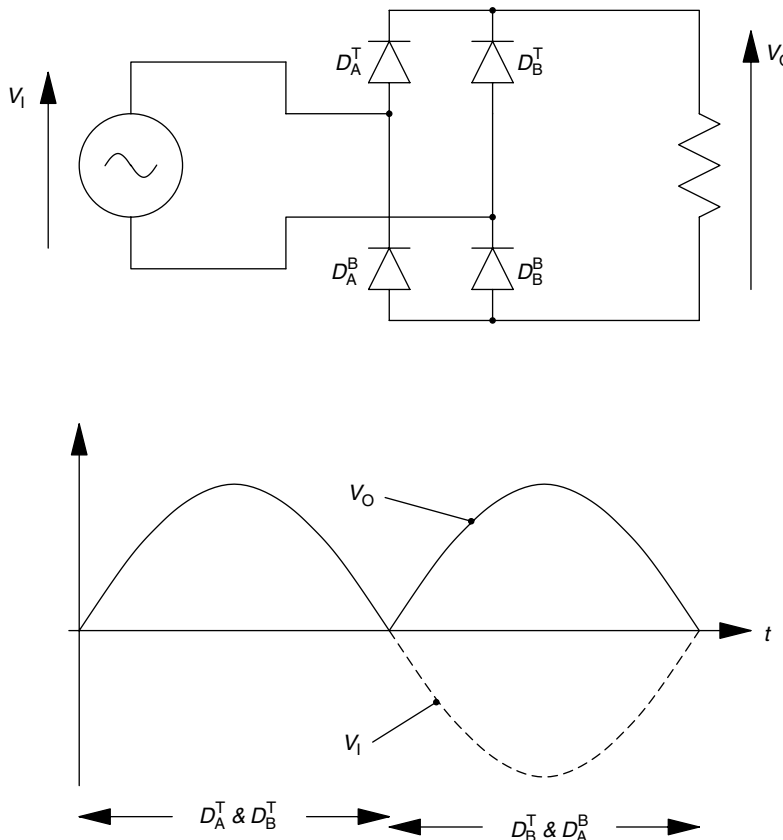

diode conducts for a third of a cycle and shares that conduction period with opposite side diodes from the two other phases.

The general form of load on the d.c.-side of a bridge rectifier is inductive-resistive impedance and a d.c. voltage. This is a reasonable representation of both the armature of a d.c. machine or large valued 'reservoir' capacitor (with either significant ESR and ESL or added inductance). *Figure 18.38* shows a single-phase example. The diodes of this circuit will begin to conduct at angle  $\alpha$  when the magnitude of the a.c. voltage exceeds the voltage on the d.c.-side. Once in conduction the current is dictated by a first order differential equation.

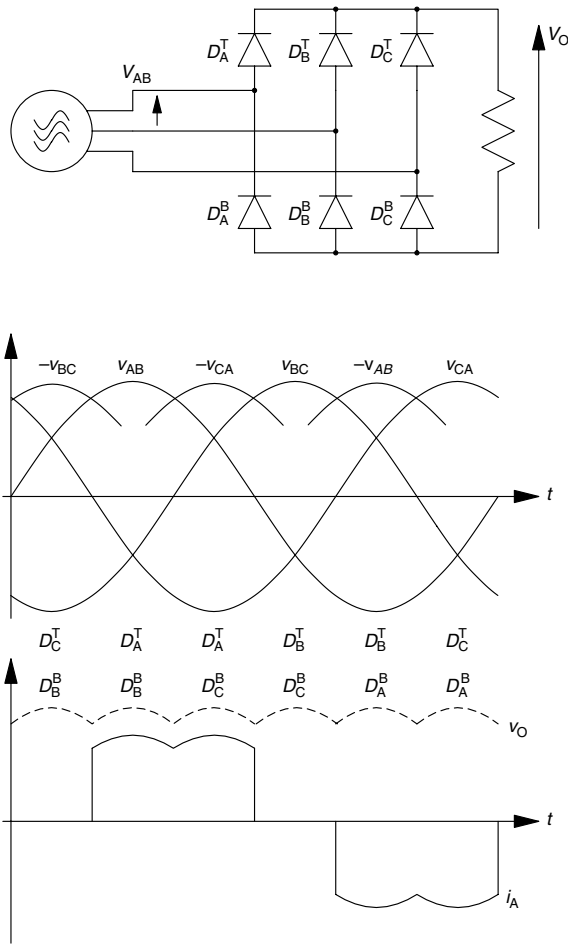

$$L \frac{di}{dt} = |v_i| - iR - E \quad (18.35) \Leftarrow$$

The current rises while the a.c. voltage exceeds the sum of  $E$  and  $iR$  and falls thereafter. When the current reaches zero, the diodes fall out of conduction. The current will re-establish at  $\pi - \alpha$  in the next half cycle. The extinction angle,  $\beta$ , can be found from the 'equal area' criterion as shown in *Figure 18.38*. In other words,  $\beta$  can be found by solving:

$$\int_{\alpha}^{\beta} \frac{V_1 \sin(\omega t) - iR - E}{L} \cdot dt = 0 \quad (18.36) \Leftarrow$$

**Figure 18.36** Single-phase rectifier with resistive load

**Figure 18.37** Three-phase rectifier with resistive load

The solution must be found numerically. Using  $\beta$  we can also find the average voltage applied to the load:

$$V_{O(\text{avg})} = \frac{\hat{V}_1}{\pi} \left[ \cos(\alpha) - \cos(\beta) \right] + E \left( 1 - \frac{\beta - \alpha}{\pi} \right) \quad (18.37)$$

If the current becomes continuous then the first pair of diodes conducts from  $\alpha$  to  $\pi + \alpha$ . The output voltage is found by replacing  $\beta$  with  $\pi + \alpha$ .

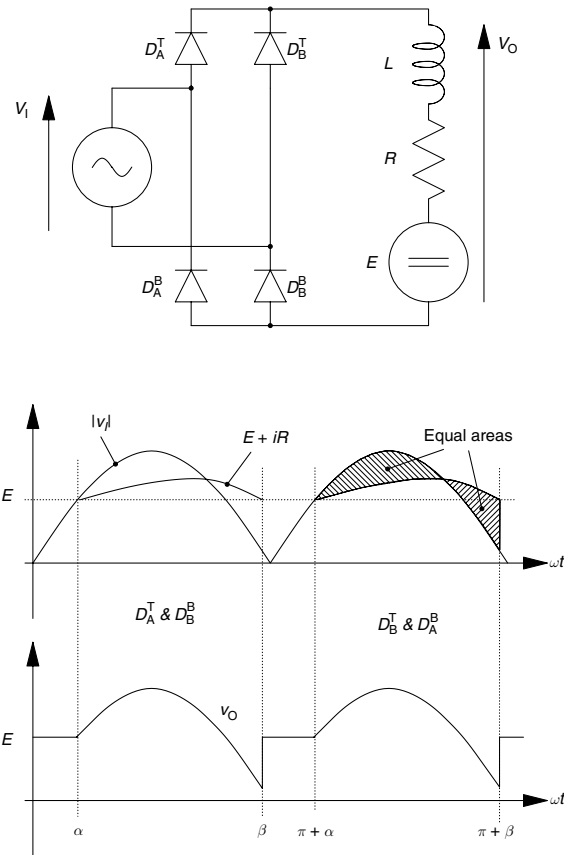

$$V_{O(\text{avg})} = \frac{2\hat{V}_1}{\pi} \cos(\alpha) \quad (18.38)$$

A variant of this circuit is obtained by substituting thyristors for the diodes, *Figure 18.39*. It is now possible to delay the onset of conduction,  $\alpha_1$  beyond the point  $\alpha$  at which conduction is first possible.

$$\alpha = \sin^{-1} \left( \frac{E}{\hat{V}_1} \right) \quad (18.39)$$

$$\alpha \leq \alpha_1 < \pi - \alpha$$

The analysis of the diode circuit can be applied again and it is seen that the average voltage appearing across the load can now be varied.

**Figure 18.38** Single-phase rectifier with ERL load

For some loads, notably d.c. machines, it is possible to make  $E$  negative and it then becomes possible to transfer power from the d.c.-side to the a.c.-side. This can provide regenerative braking of a machine as discussed in Section 19.2.1 'D.c. Motor Drive Systems'. Initiation of conduction is delayed such that current flow is predominantly in the following half-cycle. The power on the d.c.-side is negative since the current is positive while the voltage  $E$  is negative. The power on the a.c.-side is also negative (on average) since, for instance, positive current flows during the negative half-cycle. The negative power indicates a reversal of flow from the assumed direction.

The three-phase versions of the bridge exist such as *Figure 18.40*. Many variations of the rectifier bridge exist based on full or partial replacement of diodes with thyristors. Such circuits are well known for use in high power drives as discussed in Section 19.3.1 'A.c. to d.c. Power Conversion'.

The circuit of *Figure 18.40* has an average output voltage (in continuous conduction) of:

$$V_{O(\text{avg})} = \frac{3\hat{V}_1}{\pi} \cos(\alpha) \quad (18.40)$$

where  $\hat{V}_1$  is the peak line voltage and  $\alpha$  is measured from the cross-over of two line voltages.

These circuits have been popular choices for the supply of d.c. machines from a.c. sources because of the control possibilities they offer. Their use is waning because d.c. machines

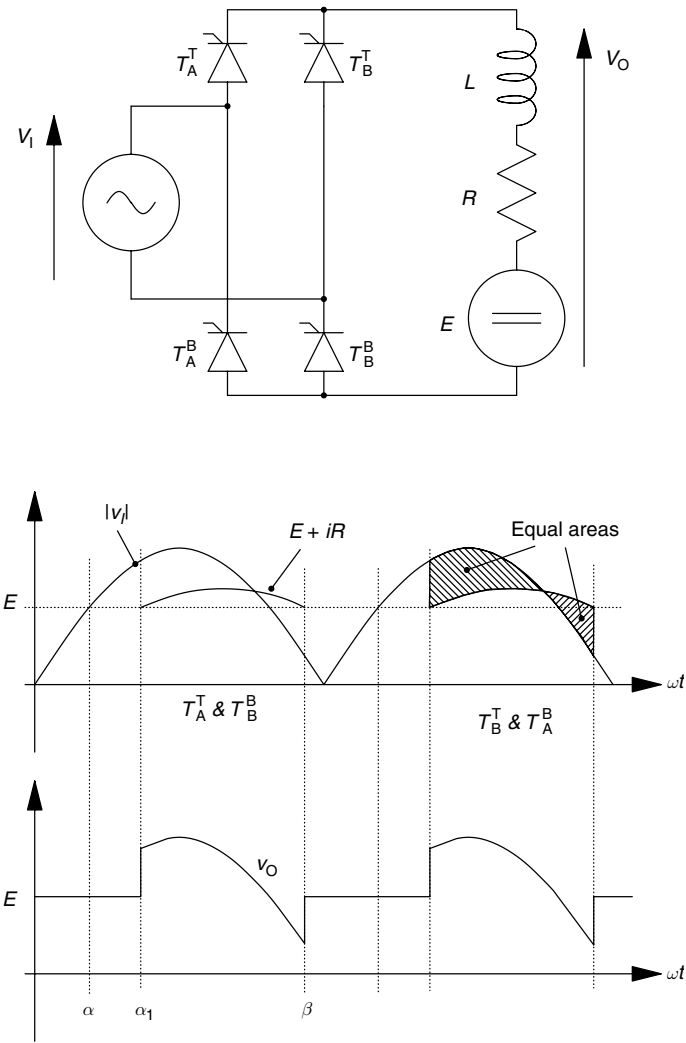

Figure 18.39 Single-phase thyristor rectifier

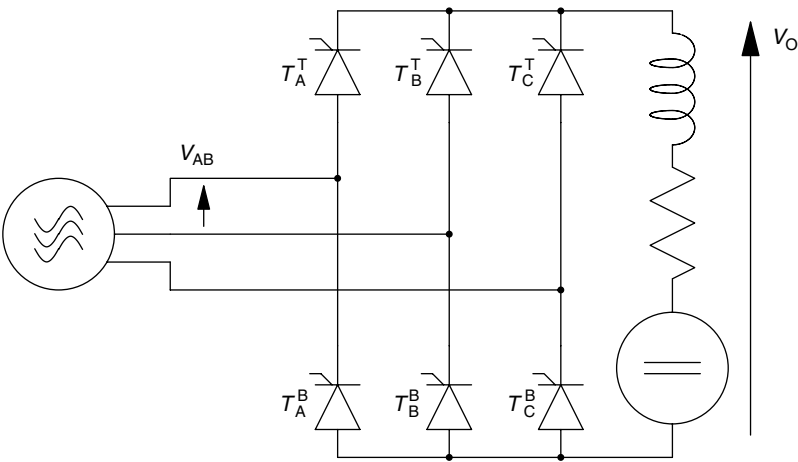

Figure 18.40 Three-phase fully-controlled thyristor rectifier

are losing ground to a.c. machines. Even where d.c. machines are used, other power conversion circuits may be sought because the non-sinusoidal a.c.-side current of these line-frequency-switched rectifiers are problematic. Phase-angle controlled thyristor rectifiers will continue to be used at very high powers where thyristors are the only viable devices and the costs of harmonic mitigation can be met.

#### 18.4.1.1 Non-sinusoidal a.c.-side current

Figure 18.41 shows the results of a circuit simulation of a rectifier like that of Figure 18.40 operated such that the thyristors turn-on  $18^\circ$  after the cross-over of the line voltages. The line voltages were 415 V at 50 Hz. The frequency spectrum shows that there are no even harmonics (as expected of a full wave rectifier with symmetric current wave-shape in the two half cycles). There are also no triplen harmonics (i.e. harmonics of order  $3k$  with  $k$  any integer) as there is no path for these zero-sequence harmonics. The harmonics present are of order  $6k \pm 1$  and this is characteristic of a six-pulse rectifier.

Table 18.2 compares the harmonic amplitudes found in this example circuit with the amplitudes allowed by the standard IEC 1000-3-3.

The fundamental amplitude is recorded as 15.3 A (peak) and so falls within the scope of class-A of IEC 1000-3-3, which applies up to 16 A (RMS). As expected, the largest amplitude emissions are the 5th, 7th and 11th harmonics and, in fact, the converter exceeds the Class-A limits at these points. Harmonic mitigation in the form of filtering or multi-pulse operation (Section 18.7.2 and Paice) may be sufficient to meet IEC 1000. If not, then a rectifier with active waveshape control (Section 18.4.2) will be needed.

Supply waveforms such as those in Figure 18.41 need to be treated carefully when discussed in terms of the power factor. The original definition of power factor, as the ratio of real power to apparent power, must be used and any derived terms, based on sinusoidal conditions, must be ignored. A useful set of definitions follows if the a.c. voltage can be assumed to be perfectly sinusoidal even if the current is not. It then follows that only the in-phase fundamental frequency component of the current transfers real power. All harmonic currents cause oscillating instantaneous power flow that average to zero.

$$P = V_{\text{RMS}} I_{1,\text{RMS}} \cos(\theta) \quad (18.41)$$

where  $I_{1,\text{RMS}}$  is the RMS value of the fundamental frequency component of current and  $\theta$  is the displacement angle between that component of current and the voltage.

This leads to the following definition of power factor:

$$\text{Power factor} = \text{Distortion factor} \times \text{Displacement factor} \quad (18.42)$$

$$\text{where Distortion factor } \mu = \frac{I_{1,\text{RMS}}}{I_{\text{RMS}}}$$

$$\text{and Displacement factor} = \cos(\theta)$$

$$P = V_{\text{RMS}} I_{\text{RMS}} \mu \cos(\theta) \quad (18.43)$$

#### 18.4.2 Wave-shape controlled rectifiers

Just as switch-mode techniques are used to create sinewave supplies from d.c. sources, so they can be used to transform sinewave input currents into d.c. current. Various topologies of power converter exist but the one that has gained greatest acceptance in practice is derived from the Boost SMPS. Figure 18.42 shows the d.c./d.c., 1-phase/d.c. and 3-phase/d.c. variants of the Boost converter. In each circuit, a switch (or switches) can be turned on to provide current path-A that imposes a positive voltage across the inductor and increases the current. Power is taken from the input and is stored in the inductor. The switch can be turned off and current path-B is established. A negative voltage is imposed across the inductor and the current reduces. Energy is transferred from both the input and the inductor to the capacitor, and the capacitor voltage rises.

Two control tasks exist; one to regulate the output voltage and the other to control the increase and decrease of current in order to form a sinewave. Circuits operated in this fashion are often referred to as power factor correctors. They produce a distortion factor (and displacement factor) close to unity in a rectifier that would otherwise have a low power factor.

**Table 18.2** Comparison of simulated circuit with harmonic limits

Harmonic order	Frequency (Hz)	Current amplitude (A)	IEC 1000 class-A (A)	Pass/fail
1	50	15.330	—	—
2	100	0.013	1.080	Pass

**Figure 18.41** A.c.-side current of a thyristor bridge in time and frequency domain

**Figure 18.42** Boost SMPS in d.c./d.c., 1-phase/d.c. and 3-phase/d.c. forms

### 18.4.2.1 Single-phase

The Boost topology is advantageous because it places an inductor in series with input. Thus, the input current can be continuous and composed of a sinusoid with a small ripple superimposed. The step-up of voltage is not normally desired so a second stage step-down converter (such as a Buck or Flyback) is often added. Clearly, this adds expense and the double processing of power means it is also less efficient than a single stage converter<sup>1</sup>. However, the Boost circuit plus second-stage is considered the best solution where good a.c.-side waveform quality is required. The circuit of *Figure 18.43* is similar to that of *Figure 18.42(b)* except that the inductor has been relocated to allow all the required control signals to be referenced to the same potential.

Control of the converter is split into two sections. The first measures the output voltage error and sets a current demand that will correct it. The second stage takes the current demand, creates from it a sinusoidal current reference and modulates the switch to obtain such a current. The circuit is similar to a standard Boost SMPS but with a full-wave rectified input voltage. The duty-cycle is modulated to keep the output voltage constant while the input voltage varies. The sinusoidal reference shape is obtained by measuring the (full-wave rectified) instantaneous voltage.

It is inevitable that there is some distortion of the current immediately following the zero-crossing of the voltage because the input voltage is insufficient to increase the inductor current quickly enough to follow the sinusoidal reference. Careful design can reduce this distortion to the point where the harmonic content is small and standards such as IEC 1000 can be met with ease.

This has become a popular topology and several manufacturers produce ICs that include these control functions. Two variants exist, as illustrated in *Figure 18.44*. The first uses a hysteresis controller for the current loop and results in fast response but a varying switching frequency. The second uses fixed-frequency PWM. The spread spectrum resulting from a varying switching frequency can make filter design difficult but it does have the advantage of spreading emissions thinly over a range rather than producing high level emissions concentrated at particular frequencies.

The control loop for the output voltage must be designed with a limited bandwidth typically around 5 Hz. The energy drawn from a single-phase supply will vary at twice line frequency even if sinusoidal current wave-shape is achieved. Thus, there will be an unavoidable output voltage ripple at twice line frequency which the control loop should not attempt to reject. The output capacitor is chosen to be large to keep this low-frequency ripple of the output-voltage small.

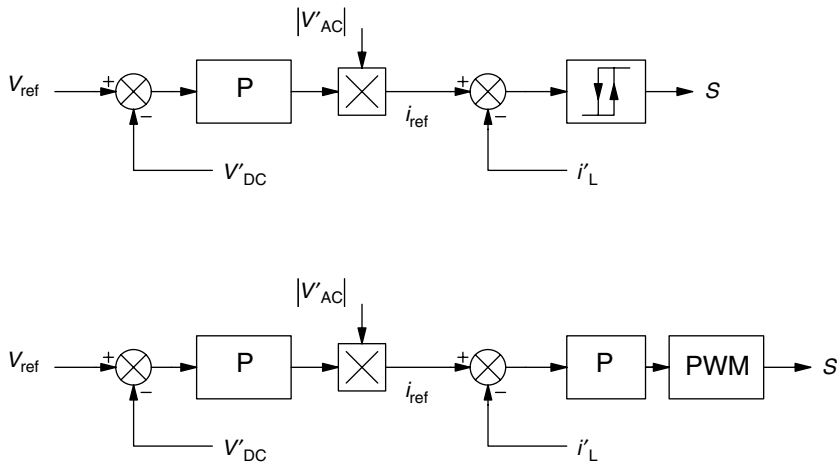

### 18.4.2.2 Three-phase

The three-phase boost topology, *Figure 18.46*, is very similar to a standard three-phase inverter, *Figure 18.32*. PWM of the inverter switches can be used to generate three voltages,  $V'_A, V'_B, V'_C$  similar in phase and magnitude to  $V_A, V_B, V_C$  once a voltage has been established on the d.c. side. (Pre-charge of the capacitor through the diodes of the circuit is problematic and needs some form of in-rush protection.)

Power flow through the Boost converter is controlled in the same manner as a standard synchronous machine. The phase difference (or load angle),  $\delta$ , can be set by the PWM system and used to control the real power flow,

**Figure 18.43** Single-phase Boost a.c./d.c. converter including its measurement points and example waveforms

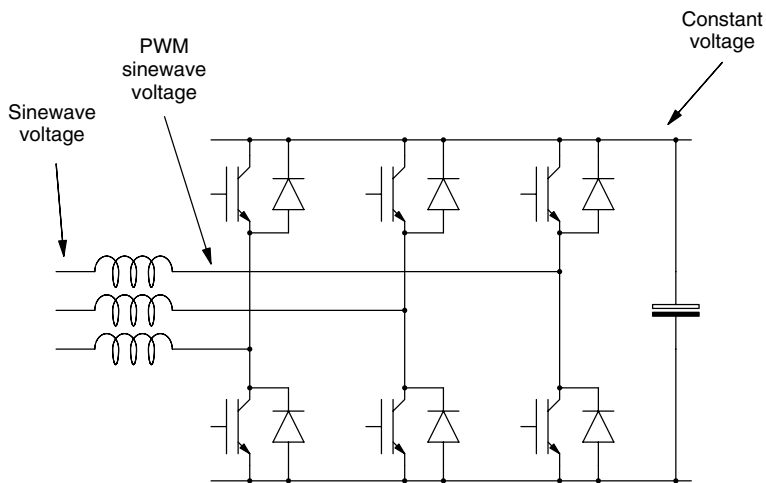

**Figure 18.44** Hysteresis and PWM methods of current control

Figure 18.47. The voltage magnitude could also be used to control the reactive power flow. The Boost converter is able to operate in all four quadrants of the  $S = P + jQ$  plane. This is useful for regenerative systems since power can be

returned to the a.c. system. It is employed in some drive systems where sustained regeneration warrants the extra cost of this converter over a diode rectifier plus 'dump' resistor (Sections 19.3.4.1 'Voltage Source Inverters' and

**Figure 18.45** Frequency spectra of (a) diode rectifier, (b) PWM controlled a.c./d.c. converter and (c) hysteresis controlled a.c./d.c. converter

**Figure 18.46** Three-phase boost a.c./d.c. converter

Rectifier mode

Inverter mode

**Figure 18.47** Bi-directional power flow controlled through phase-shift of voltage

19.4.2.4 'Four Quadrant Operation'). It is common to implement current control in this class of converter and separately control the in-phase (real power) and in-quadrature (reactive power) components of current. This might well be performed in the  $dq$ -domain following Clark and Park transforms of the variables.

## 18.5 A.c./a.c. conversion

There are circuits that will convert directly from one a.c. frequency and voltage to another a.c. frequency and voltage. These are known as cyclo-converters and matrix converters. However, they are not as attractive as might at first appear because they use a greater number of semiconductor switches than indirect methods of a.c./a.c. conversion.

### 18.5.1 A.c. voltage regulator

Where control of voltage amplitude only is required, then the techniques of phase-angle control described in Section 18.4.1 can be used. *Figure 18.48* shows a pair of thyristors in anti-parallel used as a phase-angle controlled switch to regulate the voltage applied to a single-phase load. Conduction of each thyristor can be initiated at any point in the appropriate half-cycle. With an inductive load, conduction will continue part way into the following half-cycle. In low power applications, such as incandescent lamp dimmers and a.c. commutator motors in domestic white-goods, a TRIAC would replace the pair of thyristors. Three-phase versions of this circuit are sometimes used as soft-start circuits for induction machines as discussed in Section 19.3.5.1 'Soft-Starter/Voltage-Regulator'.

Figure 18.48 Phase-angle controlled a.c. voltage regulator

## 18.5.2 Direct frequency converter

### 18.5.2.1 Cyclo-converter

The cyclo-converter is able to provide direct a.c. to a.c. transformation with control over both the output voltage magnitude and output frequency. It uses phase-angle-controlled bridges to synthesise voltages. The most common form is the three-phase to three-phase converter of *Figure 18.49*. Each output requires two three-phase thyristor bridges of the same form as the rectifiers of *Figure 18.40*. One bridge is used to synthesise positive voltages at the output; the other is connected in reverse and synthesises negative voltages. The phase-angles of the bridges are gradually altered to give an approximately sinusoidal variation of the voltage at the output. Both the output voltage and the input current are rich in harmonics and some form of filtering is normally required. The frequency of the output voltage is constrained to less than about  $1/3$  of the input frequency by the allowable distortion of the input current. To prevent shoot-through paths between the phases while thyristors are commutating, the input phases are isolated using transformers. Cyclo-converters are employed for very high power, low speed machine drives where the complexity of the circuit is less of a problem and where line-frequency thyristors are the only viable device (Section 19.3.5.2 'Cycloconverter'). Cyclo-converters are able to transfer power in either direction and can form the basis of a four-quadrant drive (c.f. the choppers of Section 18.2.1.1).

### 18.5.2.2 Matrix converter

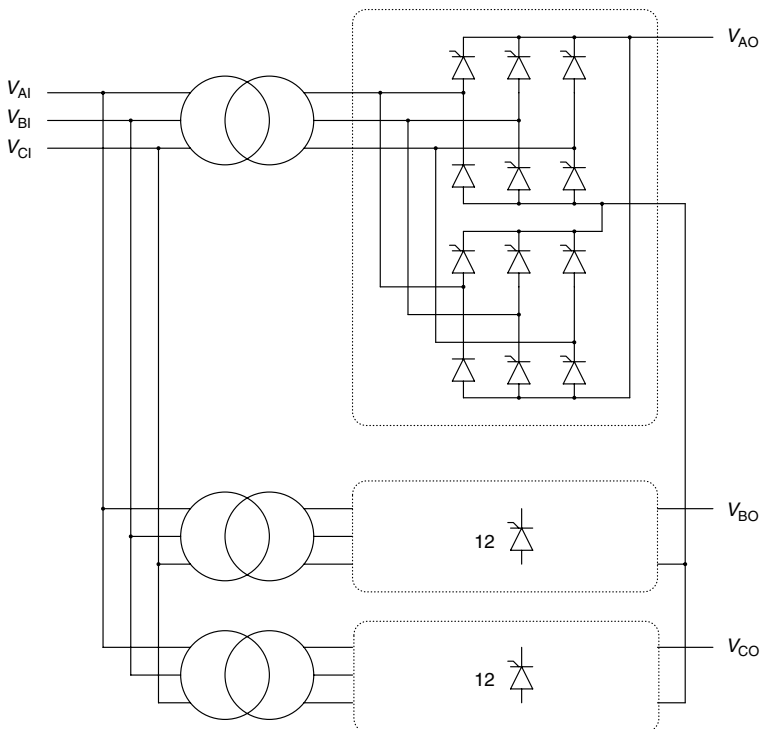

The matrix converter performs a similar function to the cyclo-converter but employs semiconductors that can be

commutated off (in contrast to thyristors). The switches are operated at high frequency to synthesise high-quality waveforms free of low-order harmonics. In its three-phase to three-phase form, *Figure 18.50*, the matrix converter requires 9 bi-directional switches to provide connections between every input phase and every output phase. There are no suitable intrinsically bi-directional semiconductor switches so each switch is made up of two uni-directional semiconductor switches. There are several possible ways to configure the uni-directional switches to achieve this. Like the cyclo-converter, the matrix converter is able to transfer power in either direction and can form the basis of a four-quadrant drive.

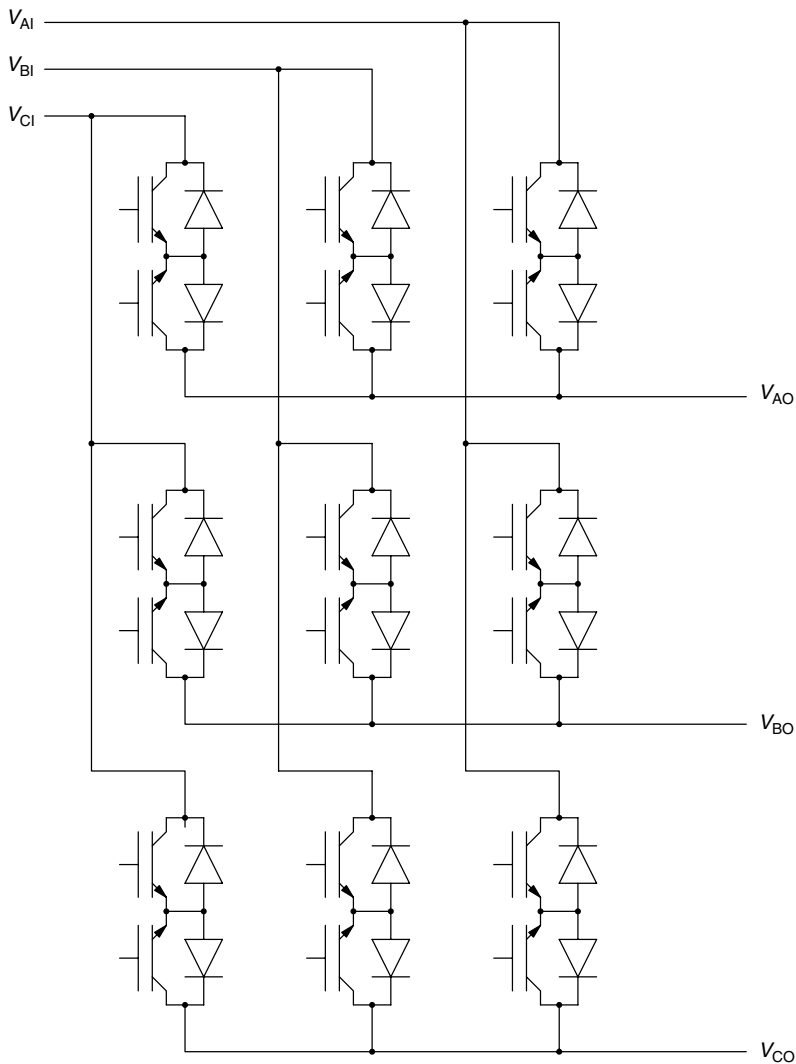

The circuit is normally placed between a voltage-source input and a current-sink (or inductive) output. It is imperative that there is always a path for each output current to flow and that there is never a short circuit path between two input connections. Given the finite switching times of devices this requires care. There are commutation sequences that meet these constraints provided that the two uni-directional halves of the switches are individually controlled in keeping with the prevailing voltages and currents.

## 18.5.3 Indirect frequency converter

We can convert a.c. to a.c. via d.c. using a pair of converters and a d.c.-link, *Figure 18.51*. The a.c. to d.c. converter will require 6 semiconductor switches and the d.c. to a.c. converter a further 6 switches. The total, 12 switches, is less than the 18 (uni-directional) switches required for the matrix converter or the 36 required for the cyclo-converter. However, the indirect conversion requires an energy storage component in the d.c.-link.

**Figure 18.49** A three-phase to three-phase cyclo-converter

**Figure 18.50** A three-phase to three-phase matrix converter

The inverter on the output-side can naturally transfer power in either direction. The rectifier on the input-side could be diode based on *Figure 18.37* and therefore capable of only uni-directional power flow. This would suit a two-quadrant drive system. If a four-quadrant drive system is required then a bi-directional rectifier based on *Figure 18.46* should be used. There is, of course, a cost penalty in using the more complex bi-directional circuit. If the drive system is re-generative for only brief periods (short periods of deceleration for instance) then a uni-directional rectifier

and a resistive energy dump might be used as discussed in Section 19.4.2.4 'Four Quadrant Operation'.

The most common form of indirect conversion is using voltage source converters and a capacitive link. The d.c.-link capacitor is both a strength and a weakness of this circuit. It must exist to provide the short-term (switching cycle) energy storage to attenuate voltage ripple. In practice the capacitor is much larger than this and can provide sufficient energy storage to enable a system to operate through a momentary loss of supply. Its energy storage can also prevent low frequency variation of power flow on one side feeding through to the other (provided that the controller is so designed). This is useful for avoiding 'flicker' problems, i.e. voltage disturbances at a point of common coupling that would cause flicker of light output at frequencies (circa 12 Hz) that are irritating to the human eye.

The weakness of the d.c.-link capacitor is that it will normally be an electrolytic capacitor that has a relatively short

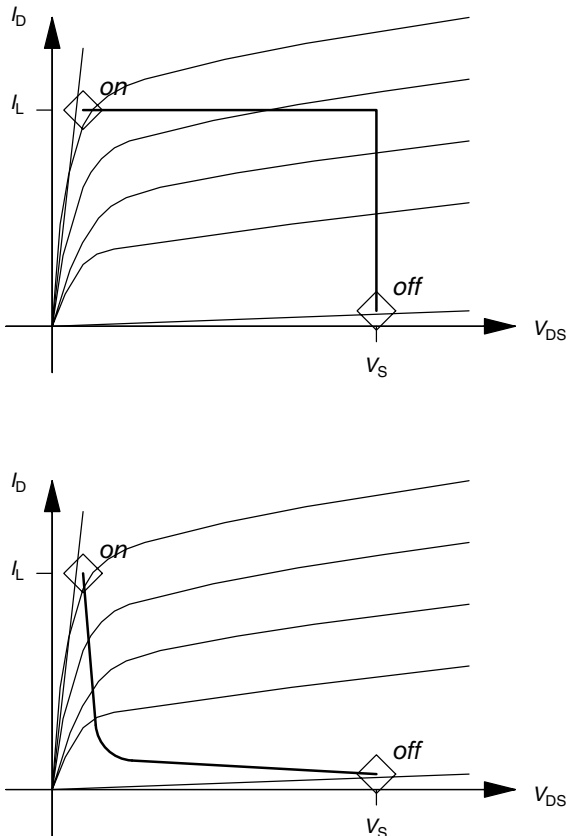

**Figure 18.51** Indirect frequency conversion using a d.c.-link

lifetime. The lifetime is degraded at elevated temperatures and this can be a severe limitation in some applications.

## 18.6 Resonant techniques

Section 18.1.2 discussed the power dissipation in a semiconductor switch when a transition is made between on- and off-states. It was shown that in commutating the current in an inductive load, the switch is subjected to a coincidence of voltage drop and current flow and as a consequence the instantaneous power dissipation is high. Because there is a certain energy loss per commutation, the operating frequency (commutations per second) must be limited. However, there are ways to break this limit. The switching trajectory has to be modified so that either the current or the voltage or both are held at zero while commutation is performed. This is illustrated in *Figure 18.52*. The hard-switched trajectory shown is idealised. The trajectory will be modified, and energy loss increased, both by diode recovery at turn-on and voltage overshoot at turn-off.

There are two approaches to modifying the switching trajectory. One is to add a snubber circuit to the switch and control the rise of current at turn-on and rise of voltage at turn-off. Snubbers are discussed in Section 17.2.1 and several circuits are described.<sup>6,3</sup> The other approach is to modify the load circuit so that the load seen by the switch naturally has periods of zero voltage or zero current that

**Figure 18.52** Hard-switched and soft-switched trajectories on the voltage/current plane

present opportunities to turn on or off without incurring power dissipation. This second method covers techniques known as soft-switching and resonant power converters. As will be seen in this section, additional current flow is necessary to ensure that the correct switching conditions are achieved. Thus, there is a penalty to be paid in conduction losses for the reduction in switching losses.

Two examples will be given here of the resonant circuit technique. The technique has been applied to almost every power converter circuit configuration.

### 18.6.1 Quasi-resonant SMPS

The term quasi-resonant describes a circuit that has one stable condition (one of either on- or off-states) and a resonant condition initiated when the switch changes state. The circuit is operated such that one cycle of resonant action occurs and then the circuit resumes its stable state.

#### 18.6.1.1 Zero-current switched Buck SMPS

The circuit of *Figure 18.53* is a standard Buck SMPS with a resonant inductor–capacitor pair,  $L_R C_R$ , and an extra diode added. The circuit has a stable state when the transistor is off and the current in  $L_O$  flows through main diode  $D$ . For the purpose of the following analysis, the current in  $L_O$  is assumed to be constant and equal to the output current,  $I_O$ . A resonant cycle is initiated by turning the transistor on. As shown in *Figure 18.54*, this creates a pulse of voltage across  $C_R$  that is applied to the LC filter at the output. The duration of the pulse is fixed by the resonant frequency of  $L_R C_R$ , but the period between the pulses can be controlled by setting the off-time of the transistor. Thus the output voltage can be regulated.

The stages of operation are:

- (I) The transistor is off and  $I_O$  flows in  $D$ . This state is stable.
- (II) The transistor is turned on and the input voltage is imposed across  $L_R$ . As a consequence  $i_{LR}$  rises linearly.  $D$  stays in conduction (and  $v_{CR}$  is held close to zero) because  $i_{LR}$  is less than  $I_O$ . This period lasts until  $i_{LR} = I_O$ .
- (III)  $D$  falls out of conduction and  $L_R C_R$  form a resonant circuit governed by:

$$\begin{aligned} V_i &= \frac{1}{C_r} + \frac{1}{L_r} \frac{d}{dt} (i_{C_r} + I_O) \Leftarrow \\ &= \frac{1}{C_r} + \frac{1}{L_r} C_r \frac{d^2 v_{C_r}}{dt^2} \Leftarrow \end{aligned} \quad (18.44)$$

with initial conditions of  $i_{LR} = I_O$  and  $v_{CR} = 0$ . Solving this differential equation yields:

$$\begin{aligned} I_{LR} &= I_O + \frac{V_1}{\omega_R L_R} \sin(\omega_R t) \Leftarrow \\ V_{CR} &= \frac{1}{C_r} (1 - \cos(\omega_R t)) \Leftarrow \end{aligned} \quad (18.45)$$

$$\text{where } \omega_R = \frac{1}{\sqrt{L_R C_R}}$$

It is important that  $i_{LR}$  swings negative, period IIIb. When this happens,  $i_{LR}$  is carried by  $D_R$  and the transistor carries no current. The transistor can be switched off any time during period IIIb without incurring power dissipation. The circuit must be designed

Figure 18.53 Zero-current switched Buck SMPS

Figure 18.55 Zero-voltage switched Buck SMPS

Figure 18.54 Waveforms of the resonant components of a ZCS QR Buck SMPS

such that  $\frac{V_1}{\omega_R L_R}$  safely exceeds  $I_O$  so that the zero-voltage condition is ensured. This can lead to substantial extra current flow and raised conduction loss.

Period III ends when the  $i_{LR}$  rises again to zero but is blocked from becoming positive because the transistor is off.

- (IV) When period III ends there is residual charge on  $C_R$  that is discharged (linearly) by the continued flow of  $I_O$ . This period ends when  $v_{CR}$  reaches zero and  $D$  is brought into conduction. The circuit then re-enters the stable state I.

If period IV is short then the average voltage during period III is  $V_1$  and the output voltage is given by:

$$\frac{V_O}{V_1} \approx \frac{t_R}{T} \approx \frac{2\pi f}{\omega_R} \quad (18.46) \Leftarrow$$

#### 18.6.1.2 Zero-voltage switched Buck SMPS

The zero-voltage switched Buck SMPS, Figure 18.55 is the dual of the zero-current switched circuit. Its stable state is with the

transistor on, and resonance is initiated by turning the transistor off. As shown in Figure 18.56, this produces a dip in the voltage applied to the output LC filter. The output voltage can be regulated by controlling the on-time of the switch.

The stages of operation are:

- (I) The transistor is on and  $I_O$  flows through the transistors,  $D_R$  and  $L_R$ . This state is stable.
- (II) The transistor is turned off and the current  $I_O (=I_{ER})$  is diverted into  $C_R$ .  $C_R$  holds the voltage across the transistor low while it switches. The diversion of  $I_O$  causes  $v_{CR}$  to rise linearly. This continues until  $v_{CR} = V_1$  at which point the main diode  $D$  becomes forward biased and provides an extra current path.
- (III) With  $D$  in conduction,  $i_{LR}$  is free to change and  $L_R C_R$  form a resonant circuit governed by:

$$V_1 = \frac{1}{C_R} \int i_{LR} dt + \frac{1}{L_R} \int \frac{d^2 v_{CR}}{dt^2} dt \quad (18.47) \Leftarrow$$

with initial conditions of  $i_{LR} = I_O$  and  $v_{CR} = 0$ .

Figure 18.56 Waveforms of the resonant components of a ZVS QR Buck SMPS

Solving this differential equation yields:

$$\begin{aligned} I_{LR} &= I_O \cos(\omega_R t) \\ V_{CR} &= V_I + \frac{I_O}{\omega_R C_R} \sin(\omega_R t) \end{aligned} \quad (18.48)$$

It is important that  $v_{CR}$  swings negative, period IIIb. When this happens,  $D_R$  is reverse biased and the transistor no longer has to support voltage. The transistor can be switched on at any time during period IIIb without incurring power dissipation. The circuit must be designed such that  $\frac{I_O}{\omega_R C_R}$  safely exceeds  $V_I$  so that the zero-voltage condition is ensured. Period III ends when the  $v_{LR}$  rises again to zero but is prevented from becoming positive because the transistor is on.

- (IV) When period III ends, the current  $i_{LR}$  is less than  $I_O$ .  $L_R$  has the input voltage imposed across it (because  $D$  must still be in conduction to carry the short fall in  $I_O$ ) and so the current rises. This period ends when  $i_{LR}$  reaches  $I_O$  and  $D$  is released from conduction. The circuit then re-enters the stable state I.

### 18.6.2 Resonant SMPS

The difference between quasi-resonant and resonant circuits is not distinct. The terms are used here to differentiate between circuits that are operated at or slightly off resonant frequency with essentially continuous resonant action and those of the previous section in which the resonant action is paused for a period.

Figure 18.57 is an example of a half-bridge used to excite a series combination of inductance and capacitance. A load, comprising a full-wave rectifier and reservoir capacitor, is connected in series with the resonant circuit. This is known as a series-loaded resonant converter.

The parallel-loaded variant (that is, a load connected in parallel with the capacitor) is shown in Figure 18.58. This circuit also incorporates transformer isolation.

There are various operating modes of these circuits depending on the ratio of the resonant frequency to the switching frequency of the switches. The modes are defined by whether more than one, less than one or less than a half of a resonant cycle is completed between each commutation of the switches.<sup>3</sup> The output of the circuit is controlled by varying the operating frequency. In the case of the series-loaded circuit this varies the current delivered to the output filter; in the case of the parallel-loaded circuit, this varies the voltage applied to the output filter.

Figure 18.57 A series-loaded resonant SMPS

Figure 18.58 A transformer isolated, parallel-loaded resonant SMPS

An advantage of these circuits is that the parasitic capacitance of the semiconductors can be utilised in the normal operation of the circuit and may be supplemented with additional parallel capacitance. Thus, the voltages across the devices have limited rates-of-change.

Many forms of resonant SMPS exist. In addition, circuits without the full-wave rectifier are used to supply high frequency a.c. for applications such as induction heating furnaces.

## 18.7 Modular systems

For some applications power converters are built from modules. There are several reasons why this might be done.

First, device ratings are limited and for power converters of very high rating no single device can match the required rating. This is sometimes solved by series or parallel connection of devices to form composite switches (often known as valves in the power industry). An alternative is to form lower rated power converter modules from individual

Figure 18.59 A pair of interleaved Buck SMPS showing a reduction of amplitude and increase in the effective frequency of the current ripple

Figure 18.60 A 12-pulse rectifier

Figure 18.61 5-level staircase and PWM waveforms

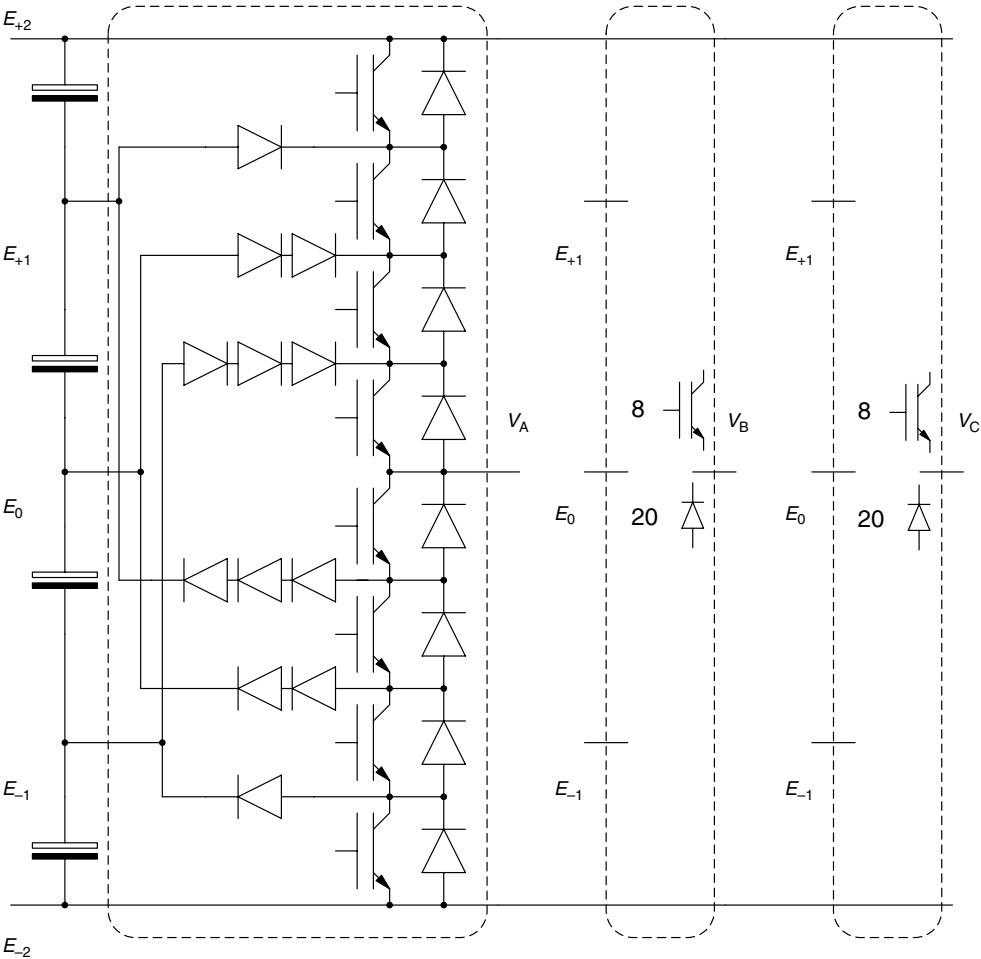

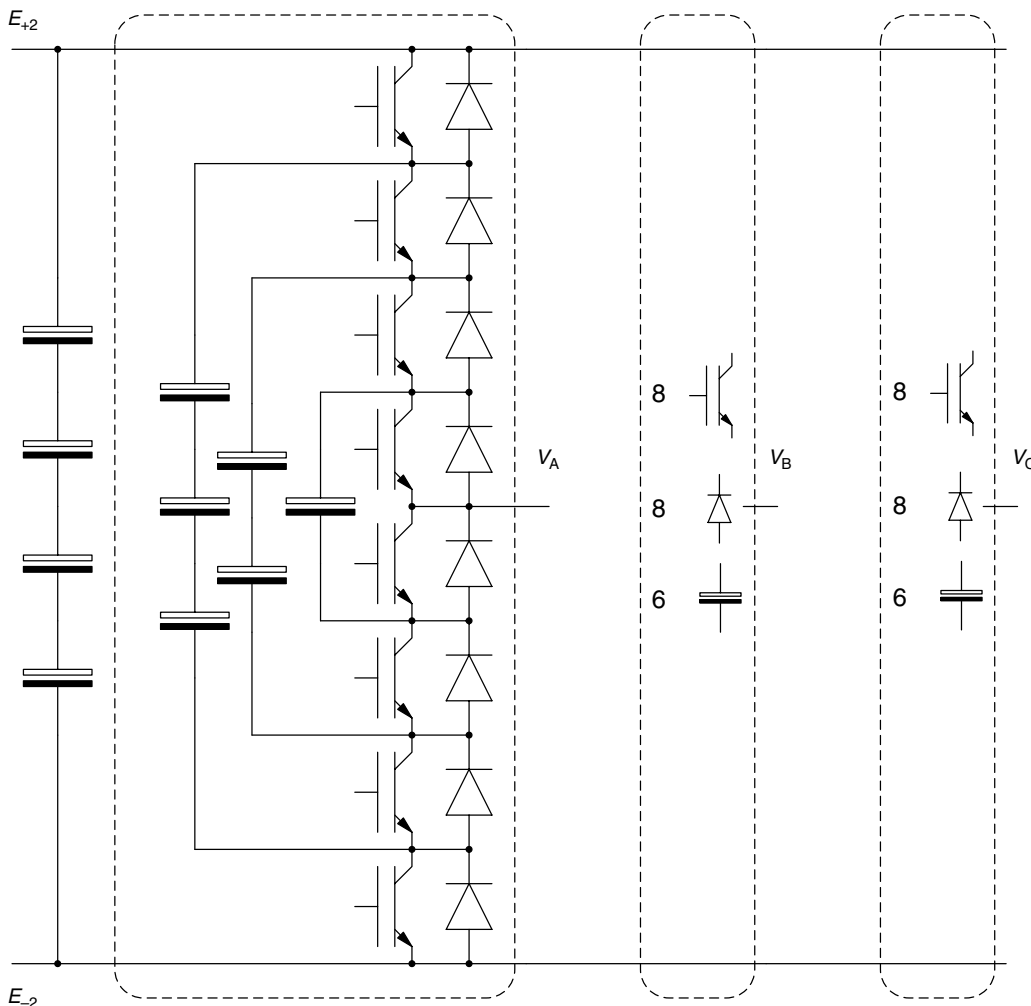

Figure 18.62 A 5-level multi-point clamped inverter

**Figure 18.63** A 5-level nested cell inverter

switches and then connect the modules in series or parallel to achieve the desired rating.

Second, switching power loss limits the maximum frequency at which a power converter may operate. If several modules are operated with interleaved switching, then the overall circuit has an effective switching frequency equal to the switching frequency of each individual module multiplied by the number of modules. Each module is rated for a fraction of the voltage (series connection) or fraction of the current (parallel connection).

Third, in applications where reliability is a major concern, redundancy may be provided through modular construction with a greater number of modules than necessary to meet the power rating. The ‘more-electric aircraft’ and ‘more-electric ship’ are example application areas.

Some application areas combine all of three reasons. The STATCOM (a d.c./a.c. converter used for reactive power support) presently being commissioned by Alstom for National Grid PLC in the UK is a modular, chain-cell design. In this case:

(i) the voltage ratings are such that no single switch is suitable,

- (ii) the switching frequency of high-rating GTO thyristors is low and good waveform quality can only be achieved through independent operation of multiple devices and
- (iii) the availability requirement specified by the user is such that the equipment must continue to operate after the failure of one or possibly two devices and, therefore, each chain must contain redundant elements.

### 18.7.1 Interleaved SMPS

There is a strong desire in SMPS design to reduce output voltage ripple and input current ripple (especially in mains connected equipment subject to EMC constraints). *Figure 18.59* shows an example of parallel connected output stages with interleaved operation of the switches. It can be seen that the resultant current ripple is at twice the frequency of operation of the switches and that each switch has processed half of the current. Viewed in the frequency domain, we would see ripple current components at all of the even multiples of the switching frequency, whereas those at odd multiples created by one module will have been cancelled by those created (in anti-phase) by the other module. The same

principle was used in the single-phase d.c./a.c. converter of Section 18.3.1 in which the two halves of the bridge were operated with phase-shifted carriers.

This idea can be extended to series connection of modules and to any number of modules. It can be applied to the input connection, output connection or both. In general, an  $n$ -module system has an effective switching rate (ripple frequency) of  $n f_s$ . In all cases it is important to match components and operating conditions in the modules in order to achieve the desired cancellation of ripple components.

### 18.7.2 Multi-pulse rectifiers

The diode and thyristor rectifiers of Section 18.4.1 were seen to create distorted a.c.-side currents with harmonic distortion of order  $6k \pm 4$  for three-phase systems. This situation can be improved by operating rectifier modules with phase-shifts between them such that some of the harmonics created by one module are cancelled by those of another. These rectifiers are described by their pulse number. The standard rectifier creates a voltage (or current) waveform on the d.c.-side with 6 pulses per cycle. Adding a second unit with appropriate phase shift creates 12 pulses. Any number of 6-pulse modules can be combined to produce higher pulse number rectifiers. Combining  $n$  modules creates a  $6n$ -pulse rectifier that generates a.c.-side harmonics of order  $6nk \pm 4$ . That is, the first  $(n-1)$  pairs of characteristic harmonics (and their multiples) are cancelled.

Figure 18.60 shows an example of a 12-pulse rectifier with parallel connection on the d.c.-side. One 6-pulse module is supplied through a delta-delta transformer (with no phase shift) and the second is supplied through a star-delta trans-

former providing  $30^\circ$  of phase advance. The thyristors of the second module are fired ahead of those of the first module by a time-shift equivalent to  $30^\circ$  of a mains cycle. This gives a 12-pulse pattern on the d.c.-side. The current drawn by the second module is also time-shifted forward but the fundamental is re-aligned with the first module by the  $30^\circ$  phase-shift of the transformer. Each harmonic is affected differently by the time-shift created by the thyristor firing and the phase-shift (which is phase-sequence dependent) of the transformer. For example, the 5th and 7th harmonics created by the two modules are in anti-phase and cancel whereas the 11th and 13th harmonics are in phase and add.

Zig-zag or differential delta transformers can be used to give the small phase-shifts necessary to construct high pulse-number rectifiers ( $n$  increments of  $60^\circ/n$  for a  $6n$ -pulse system).<sup>5</sup>

### 18.7.3 Multi-level inverters

The multi-pulse techniques of Section 18.7.2 have also been used for inverters and reactive power compensators. However, the complexity and bulk of the transformer system is a considerable disadvantage. Instead, inverters can be constructed in which the output voltages can be synthesised by switching between many voltage levels rather than the two levels of the circuit in Figure 18.32. In high-power inverters, the switches are operated at line frequency and the waveform synthesised as a staircase, Figure 18.61. In medium-power inverters, PWM or SVM can be used to operate the switches at high frequency. In the line-frequency-switched case, the angle of each transition can be optimised to meet harmonic distortion criteria.

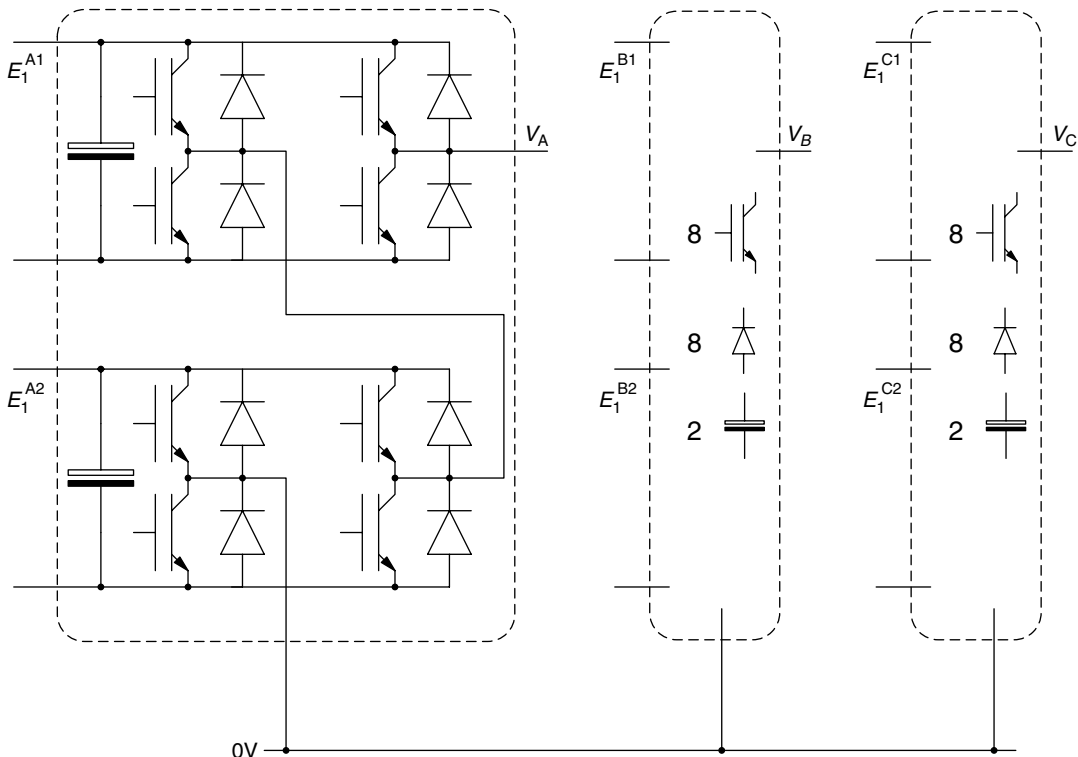

Figure 18.64 A 5-level chain cell inverter

There are several types of circuit for implementing multi-level inverters. Three examples of 5-level inverters are shown in *Figure 18.62*, *Figure 18.63* and *Figure 18.64*. Note that each circuit uses 8 transistors per phase and each transistor has a voltage rating of one level and a current rating of the full phase current. The differences between the circuits lie in how the numbers of other components (diodes and capacitors) increase with the number of levels.

The multi-point clamped circuit, *Figure 18.62*, has the advantage that the capacitor chain is shared between the three phases. This reduces the ripple in the capacitors (for balanced conditions) and allows smaller volume capacitors to be used than with the other implementations. Its principal disadvantage is the number of clamping diodes required (and that some of these must be series connections to span multiple voltage levels). Charge drawn from each capacitor must be managed to ensure that the capacitors remain balanced. To some extent this can be achieved in SVM by utilising redundant states. This cannot be achieved under all conditions (where suitable states do not exist) and auxiliary balancing circuits are required.

The nested-cell circuit, *Figure 18.63*, (also known as the flying capacitor inverter) avoids high voltage clamp diodes but requires capacitors to set the voltage levels. Operation of the circuit must be managed to ensure that the correct voltage is maintained on each capacitor. Only one of the capacitor chains is common to all phases. The volume of capacitance required is greater than for the other designs.

The chain-cell converter, *Figure 18.64*, avoids both a larger number of diodes or a large volume of capacitance. It is the only circuit in which the component numbers increase linearly with the number of modules. However, each module requires an isolated d.c.-link. This makes the circuit difficult to apply where a.c./d.c./a.c. conversion is required, for instance, in a drive system. The chain-cell inverter is suitable for floating (i.e. supply-less) applications. It has been used for reactive power compensation as mentioned in the introduction to this section.

## 18.8 Further reading

This chapter has given a flavour of the opportunities afforded by power electronics in power conversion. It has also introduced some of the analysis necessary for design. However, there are several topics that need further treatment before practical design could be attempted.

In all but the simplest circuits, the semiconductor devices need to be operated in the correct environment. Texts such as<sup>6,3</sup> give details of the gate drive circuits (including electrical isolation of signal and power), protection against over-voltage and over-current, snubber circuits and thermal management. Power electronic circuits put unusual voltage and current stresses on passive components too and so these components need to be chosen with care.

As indicated in the main text, there is a huge variety of SMPS circuits and almost any combination of voltage transfer characteristics, isolation and resonant action can be found.<sup>2,3,6</sup> There is a similarly large variety of single-phase a.c./d.c. converter circuits and a good review of these has been provided by<sup>1</sup>. This review also discusses the usefulness of circuits that fall short of perfectly sinusoidal current but still meet distortion standards. Control of SMPS is a large subject in itself.<sup>3</sup>

Line-frequency-switched converters can cause serious distortion to a.c. systems. The severity of the distortion needs to be analysed and harmonic mitigation will often be required.<sup>5</sup>

Control of power converters with a 3-phase a.c. connection is often best achieved in a rotating co-ordinate system in which the sinusoidal variation of the signals is removed. This is discussed in several texts in terms of control of a.c. machines, for instance.<sup>4</sup>

## 19.1 Introduction

It is now generally considered that 25–50% of all electrical power passes through semiconductor conversion. The importance of this technology is therefore self evident though the selection of appropriate equipment is often less clear. It would be a difficult, if not impossible, task to detail every power conversion circuit available, concentration will be given to those of greatest practical importance of the broad base of industry, particularly in the area of electrical variable speed drives.

In some respects semiconductor based power converters perform rather badly the functions of voltage and frequency changing which rotating machine based converters perform rather well. Economic and certain other factors are, in other than a few specialised applications, now so heavily in favour of electronic converters that only their performance will be considered.

Control philosophy and choice of semiconductor switching device are important aspects of any system but are sadly (from the standpoint of review) heavily dependent upon manufacturer. It is therefore useful to first consider the basic power conversion circuits, together with their inherent characteristics and then look at the available control strategies, their features and how they apply and impact upon converter systems. Basic power conversion circuits are considered in the Power Electronics chapter, however, it is helpful to consider salient circuits and characteristics here in the specific context of drives.

The existence of so many power conversion technologies reflects the diverse requirements industry demands. No single technology is the 'optimum' for all applications (despite some manufacturers' claims). Good drive selection demands a good understanding of the application in regard torque/speed and dynamic characteristics together with the site environment. Simple guidelines are given.

Aspects of electrical variable speed drives vital for trouble free installation and ease of operation are also discussed. These include supply distortion/harmonics and communication systems the latter of growing importance for drives employed in an automated environment.

## 19.2 Fundamental control requirements for electrical machines

### 19.2.1 D.c. motor control

History will recognise the vital role played by d.c. motors in the development of industrial power transmission systems. The d.c. machine was the first practical device to convert electrical power into mechanical power, and vice versa in its generator form. Inherently straightforward operating characteristics, flexible performance and high efficiency encouraged the widespread use of d.c. motors in many types of industrial drive application.

The majority of standard d.c. motors, both wound-field and permanent-magnet, are now designed specifically to take advantage of rectified a.c. power supplies. Square, fully laminated frame construction allows minimal shaft centre height for a given power rating, and affords reduced magnetic losses, which in turn greatly improves commutating ability.

Over the last few years the use of permanent magnet motors, usually in the fractional to 3 kW range, has become commonplace in general-purpose drive applications. In this design the conventional wound field is replaced by

Figure 19.1 Shunt wound d.c. motor

permanent magnets bonded into the motor frame. The magnets have a curved face to offer a constant air gap to the conventional armature.

The circuit of a shunt-wound d.c. motor, *Figure 19.1*, shows the armature, armature resistance ( $R_a$ ) and field winding. The armature supply voltage  $V_a$  is supplied typically from a controlled thyristor system and the field supply voltage  $V_f$  from a separate bridge rectifier.

As the armature rotates an EMF  $E_a$  is induced in the armature circuit and is called the back-EMF since it opposes the applied voltage  $V_a$  and the flow of current produced by  $V_a$ . This back-EMF  $E_a$  is related to armature speed and main field flux by:

$$E_a = k_1 n \Phi \quad (19.1) \Leftarrow$$

where  $n$  = speed of rotation  
 $\Phi$  = field flux  
 $k_1$  = motor constant

Also the applied, or terminal armature voltage  $V_a$  is given by:

$$V_a = E_a + I_a \cdot R_a \quad (19.2) \Leftarrow$$

where  $V_a$  = applied armature voltage  
 $I_a$  = armature current  
 $R_a$  = armature resistance

Multiplying each side of Equation (19.2) by  $I_a$  gives:

$$V_a \cdot I_a = E_a \cdot I_a + I_a^2 \cdot R_a \quad (19.3)$$

Total power supplied = Power output + Armature losses

Interaction of the field flux and armature flux produces an armature torque. Thus:

$$\text{Torque } M = k_2 \cdot I_f \cdot I_a \quad (19.4) \Leftarrow$$

where  $k_2$  = constant  
 $I_f$  = main field current  
 $I_a$  = armature current

This confirms the straightforward and linear characteristic of the d.c. motor and consideration of these simple equations will show its controllability and inherent stability.

The speed characteristic of a motor is generally represented by curves of speed against input current or torque and its shape can be derived from Equations (19.1) and (19.2):

$$k_1 n \Phi = V_a - (I_a \cdot R_a) \Leftarrow$$

Figure 19.2 Schematic of series d.c. motor

Figure 19.3 Compound d.c. motor

If the flux is held constant, which is achieved by simply holding the field current constant in a properly compensated motor then:

$$n = \frac{1}{k_2} [V_a - (I_a \cdot R_a)] \propto$$

The circuits of Shunt wound and Series d.c. motors are shown in Figures 19.1 and 19.2 respectively.

With the Shunt motor the field flux  $\Phi$  is only slightly affected by armature current, and the value of  $I_a R_a$  at full load rarely exceeds 5% of  $V_a$ , giving a torque-speed curve shown typically in Figure 19.4(a), where speed remains sensibly constant over a wide range of load torque.

The compound-wound d.c. machine combines the shunt and series characteristics. The circuits of the compound d.c. motors is shown in Figure 19.3.

The exact shape of the torque/speed characteristic is determined by the resistance values of the shunt and series fields. The slightly drooping characteristic, Figure 19.4(b), has the advantage in many applications of reducing the mechanical effects of shock loading.

The series motor curve, Figure 19.4(c), shows initial flux increase in proportion to current, falling away due to magnetic saturation. In addition the armature circuit includes the resistance of the field winding and the speed becomes roughly inversely proportional to the current. If the load falls to a low value the speed increases dramatically, which may be hazardous: the series motor should not normally be used where there is a possibility of load loss; but because it produces high values of torque at low speed and its characteristic is falling speed with load increase, it is useful in applications such as traction and hoisting or some mixing duties where initial friction is dominant.

The power speed limit for d.c. machine manufacture is approximately  $3 \times 10^6$  kW rev/min. This limit together with the maintenance attributable to d.c. motors can be blamed on the otherwise commendable commutator.

Under semiconductor converter control, with speed feedback from a tachogenerator, the shape of the speed/load curve is largely determined within the controller. It has become standard to use a plain shunt d.c. motor on the basis of reduced cost, even though the speed/load curve on open loop control is often slightly rising.

## 19.2.2 A.c. induction motor control

The a.c. squirrel cage induction motor is the basic, universal workhorse of industry, converting some 70–80% of all electrical power into mechanical energy. This type of motor nonetheless exhibits some quite unattractive performance characteristics in spite of intensive development, notably instability and a non-linear load-current characteristic.

Figure 19.4 Torque/speed characteristic: (a) shunt wound d.c. motor; (b) compound d.c. motor; (c) series d.c. motor

It is invariably designed for fixed speed operation, larger ratings having such features as deep rotor bars to limit Direct on Line (DOL) starting currents. Electronic variable speed drive technology is able to provide the necessary variable voltage/current, variable frequency supply that the 3-phase a.c. machine requires for efficient, dynamic and stable variable speed control.

Modern electronic control technology is able not only to render the a.c. induction motor satisfactory for many modern drive applications but also to greatly extend its application and enable advantage to be taken of its low capital and maintenance costs. More striking still, micro-electronic developments have made possible the highly dynamic operation of induction motors by the application of flux vector control. The practical effect is that it is now possible to drive an a.c. induction motor in such a way as to obtain a dynamic performance in all respects better than could be obtained with a phase controlled d.c. drive combination.

### 19.2.2.1 Fundamental equations and performance

Consider the stator winding of a simple three-phase 2-pole a.c. cage induction motor, each phase winding having only one slot per pole per phase as shown in *Figure 19.5*. End-connections for the winding coils are not shown, but R and R1 represent the start and finish of the red phase winding and similarly for the Y and B phase conductors. The R, Y and B phase windings are displaced  $120^\circ$  in space relative to one another.

**Figure 19.5** Three-phase rotating field

Assuming that when stator current is positive it is flowing inwards in conductors R, Y and B, and therefore outwards in R1, Y1, B1; that the current in phase R in *Figure 19.5(a)*, is at its maximum positive value and that in phase windings Y and B the currents at the same instant are negative and each equal to half maximum value: then these currents produce the magnetic fluxes represented in *Figure 19.5(a)* and the flux axis is horizontal.

Thirty degrees later in the supply cycle, the currents in phases R and B are  $0.866 (\sqrt{3}/2)$  of their maximum, and zero in the Y phase. The pattern of the flux due to this current is shown in *Figure 19.5(b)*. It will be noted that the axis of this field is now in line with coil Y–Y1 and therefore has turned clockwise through  $30^\circ$  from that of *Figure 19.5(a)*.

After a further  $30^\circ$  in the supply cycle the current in phase winding B has reached maximum negative value, the currents in R and Y are both positive, at half their maximum value. These currents produce the magnetic flux shown in *Figure 19.5(c)*, the flux axis being displaced clockwise by a further  $30^\circ$  compared with that of *Figure 19.5(b)*.

Thus for every time-interval corresponding to  $30^\circ$  in the supply cycle, the axis of the flux in a 2-pole a.c. stator rotates  $30^\circ$  in space. With a 2-pole stator (one pair of poles) the flux rotates through one revolution in space in one cycle of the power supply. The magnetic flux is said to rotate at synchronous speed. The rotational speed of the flux is:

$f/p$  revolutions in one second

where  $f$  = supply frequency in Hertz, and  
 $p$  = number of pole pairs

Note: A 2-pole motor has 1 pole pair.

It is more usual to express speed in revolutions per minute:

$60 \cdot f/p$  revolutions per minute (r.p.m.)

The e.m.f. generated in a rotor conductor by transformer action is at a maximum in the region of maximum flux density. The e.m.f. generated in the single rotor conductor produces a current, the consequence being a force is exerted on the rotor tending to move it in the direction of the flux rotation. The higher the speed of the rotor, the lower the speed of the rotating stator flux field relative to the rotor winding, and therefore the smaller is the e.m.f. generated in the rotor winding.

If the speed of the rotor became the same as that of the rotating field, i.e. synchronous speed, the rotor conductors would be stationary in relation to the rotating flux. This would produce no e.m.f. and no rotor current and therefore no torque on the rotor. Because of friction and windage, the rotor could not continue to rotate at synchronous speed. The rotor speed must therefore fall below synchronous, and as it does so rotor e.m.f. and current, and therefore torque, will increase until it matches that required by the losses and by any load on the motor shaft.

The difference in rotor speed relative to that of the rotating stator flux is known as the slip. It is usual to express slip as a percentage of the synchronous speed. Slip is closely proportional to torque from zero to full load.

The most popular squirrel cage induction motor in sizes up to about 5 kW is of 4-pole design. Its synchronous speed with a 50 Hz supply is therefore:

$60 \cdot f/p = 60 \cdot 50/2 = 1500$  (r.p.m.)

Slip accounts for about 5%, and a typical nameplate speed is 1425 r.p.m.

**Voltage–frequency relationship** If it is desired to convert a constant speed motor operating direct-on-line to a variable speed drive using an inverter it is necessary to consider the effect of frequency on flux and torque. An induction motor on a normal supply operates with a rotating field set up by three-phase currents in the stator winding. The magnitude of the field is controlled broadly by the voltage impressed upon the winding by the supply. This is because the resistance of the windings results in only a small voltage drop, even at full load current, and therefore in the steady-state the supply voltage must be balanced by the e.m.f. induced by the rotating field. This e.m.f. depends on the product of three factors:

- (1) The total flux per pole (which is usually determined by the machine designer);
- (2) The total number of turns per phase of the stator winding; and
- (3) The rate of field rotation or frequency.

Exactly the same factors are valid for transformer design, except that the field is pulsating instead of rotating. For inverter operation the speed of field rotation for which maximum voltage is appropriate is known as the ‘base speed’.

The consequence of reducing the supply frequency can readily be deduced from the relationship described above. For the same flux the induced e.m.f. in the stator winding will be proportional to frequency, hence the voltage supplied to the machine windings must be correspondingly reduced in order to avoid heavy saturation of the core. This is valid for changes in frequency over a wide range. The voltage/frequency relationship should therefore be linear if a constant flux is to be maintained within the machine, as the designer intended. If flux is constant so is the motor torque for a given stator current, hence the drive has a constant torque characteristic.

Although constant  $V/f$  control is an important underlying principle, it is appropriate to point out departures from it which are essential if a wide speed range is to be covered. Firstly, operation above base speed is easily achieved by increasing the output frequency of the inverter above the normal mains frequency; two or three times base speed is easily obtained. The output voltage of an inverter cannot usually be made higher than its input voltage therefore the  $V/f$  characteristic is typically like that shown in *Figure 19.6(a)*. Since  $V$  is constant above base speed, the flux will fall as the frequency is increased after the output voltage limit is reached. The machine flux falls (*Figure 19.6(b)*) in direct proportion to the actual  $V/f$  ratio. Although this greatly reduces the core losses, the ability of the machine to produce torque is impaired and less mechanical load is needed to draw full load current from the inverter. The drive is said to have a constant-power characteristic above base speed. Many applications not requiring full torque at high speeds can make use of this extended speed range.

The second operating condition where departure from a constant  $V/f$  is beneficial is at very low speeds, whereby the voltage drop arising from the stator resistance becomes significantly large. This voltage drop is at the expense of flux, as shown in *Figure 19.6(b)*. To maintain a truly constant flux within the machine the terminal voltage must be increased above the constant  $V/f$  value to compensate for the stator resistance effect. Indeed, as output frequency approaches zero, the optimum voltage becomes the voltage equal to the stator  $IR$  drop. Compensation for stator resistance is normally referred to as ‘voltage boost’ and almost all inverters offer some form of adjustment so that the degree of voltage boost can be matched to the actual winding resistance. It is normal for the boost to be gradually

tapered to zero as the frequency progresses towards base speed. *Figure 19.6(c)* shows a typical scheme for tapered boost. It is important to appreciate that the level of voltage boost should increase if a high starting torque is required, since in this case the  $IR$  drop will be greater by virtue of the increased stator current. In this case automatic load-dependent

**Figure 19.6** Voltage/frequency characteristics: (a) linear  $V/f$  below base speed; (b) typical motor flux with linear  $V/f$  (showing fall in flux at low frequency as well as above base speed); (c) modified  $V/f$  characteristic with low frequency boost (to compensate for stator resistance effects in steady state)

boost control is useful in obtaining the desired low speed characteristics. Such a strategy is referred to as constant  $V/f$  (or  $V/Hz$ ) control and is a feature of most commercially available a.c. drives though more advanced open-loop strategies are now becoming more available.

So far the techniques described have been based on achieving constant flux within the air gap of the machine or, if that is not possible, then the maximum flux. Constant flux is the ideal condition if the largest capability of torque is required because the load cannot be predicted with certainty, or if the most rapid possible acceleration time is desired. A large number of inverters are used however for variable air volume applications where control of airflow is obtained by variable speed fans. The torque required by a fan follows a square law characteristic with respect to speed and reducing the speed of a fan by 50% will reduce its torque requirement to only 25% of rated. As the load is entirely predictable there is no need for full torque capability and hence flux to be maintained, and higher motor efficiency can be obtained by operating at a reduced flux level. A further benefit is that acoustic noise, a major concern in air conditioning equipment, is significantly reduced. It is therefore common for inverters to have an alternative square law  $V/f$  characteristic or, ideally, a self-optimising economy feature so that rapid acceleration to meet a new speed demand is followed by settling to a highly efficient operating point.

**Slip ring induction motor** The wound rotor or slip-ring a.c. machine whilst introducing the negative aspect of brushes does address some of the disadvantages of the cage induction motor but with the handicap of cost compared to the equivalent rated d.c. shunt-wound machine.

With the correct value of (usually) resistance inserted in the rotor circuit, near-unity relationship between torque and supply current at starting can be achieved, i.e. 100% full load torque, with 100% full load current, 200% FLT with 200% FLC etc., (i.e. comparable with the starting capability of the d.c. machine). Not only the high starting efficiency but also the smooth controlled acceleration historically gave the slip-ring motor great popularity for lift, hoist and crane applications. It has had similar popularity with fan engineers, to provide a limited range of air volume control, either 2:1 or 3:1 reduction, at constant load, by the use of speed regulating variable resistances in the rotor circuit. Although a fan possesses a square law torque-speed characteristic, so that motor currents fall considerably with speed, losses in the rotor regulator at lower motor speeds are still relatively high, severely limiting the useful speed range.

Rotor slip-ring systems, used with this type of motor, offer a similar service life to that of the d.c. motor commutator system.

Efficient variable speed control of slip-ring motors can be achieved by converters based upon the slip energy recovery principle first proposed by Krammer. Such schemes are based upon converting the slip frequency on the rotor to supply frequency. It is also possible to retrofit variable frequency inverters to existing slip-ring motors. This can be done simply by shorting out the slip-ring terminations (ideally on the rotor thereby eliminating the brushes) and treating the motor as a cage machine.

Variable voltage control of slip-ring motors has been used extensively, notably in crane and lift applications, though these are now largely being replaced by flux vector drives and will therefore not be considered further.

### 19.2.3 A.c. synchronous motors

A.c. induction motors produce shaft torque which is proportional to percentage slip, implying that with zero slip the machine produces zero torque. In a synchronous motor, torque can be produced at synchronous speed.

This is achieved by a field winding, generally wound on the rotor, and d.c. excited so that it produces a rotor flux which is stationary relative to the rotor. Torque is produced when the rotating three-phase field and the rotor field are stationary relative to each other, hence there must be physical rotation of the rotor at speed  $n_s$  in order that its field travels in step with the stator field axis. At any other speed a rotor pole flux would approach alternately a stator north pole flux, then a south pole flux, changing the resulting torque from a positive to a negative value at a frequency related to the flux speed difference, the mean torque being zero.

A typical inverter for variable speed control automatically regulates the main stator voltage to be in proportion to motor frequency. It is possible to arrange an excitation control loop which monitors the main stator voltage and increases the excitation field voltage proportionately.

The a.c. synchronous motor appears to have some attractive features for inverter variable speed drive applications, particularly at ratings of 40 MW and above. Not least is overall cost when compared with an a.c. cage motor plus inverter, or d.c. shunt wound motor and converter alternatives. In applications requiring a synchronous speed relationship between multiple drives or precise speed control of single large drives the a.c. synchronous motor plus inverter control system appears attractive: freedom from brushgear maintenance, good working efficiency and power factor are the main considerations.

### 19.2.4 Brushless servomotors

The synchronous machine with permanent magnets on the rotor is the heart of the modern brushless servo motor.

The synchronous motor stays in synchronism with the supply, though there is a limit to the maximum torque which can be developed before the rotor is forced out of synchronism. 'Pull out torque' will be typically between 1.5 and 4 times the continuously rated torque. The torque-speed curve is therefore simply a vertical line, which indicates if we try to force the machine above the synchronous speed it will become a generator.

The industrial application of brushless servomotors has grown significantly for several reasons: reduction of price of power conversion products; establishment of advanced control of PWM inverters; development of new more

**Figure 19.7** Steady-state torque speed curve for a synchronous motor supplied at constant frequency

powerful and easier to use permanent magnet materials; development of highly accurate position sensors, and the manufacture of all these components in a very compact form. They are, in principle, easy to control because the torque is generated in proportion to the current. In addition, they have high efficiency and high dynamic responses can be achieved.

Brushless servomotors are often called brushless d.c. servomotors because their structure is different from that of d.c. servomotors. Brushless servomotors rectify current by means of transistor switching within the associated drive/amplifier, instead of a commutator as used in d.c. servomotors. In order to confuse, brushless servomotors are also called a.c. servomotors because brushless servomotors of synchronous type with a permanent magnet rotor detect the position of the rotational magnetic field to control the three-phase current of the armature. It is now widely recognised that BRUSHLESS AC refers to a motor with a sinusoidal stator winding distribution which is designed for use on a sinusoidal or PWM inverter supply voltage. BRUSHLESS DC refers to a motor with a trapezoidal stator winding distribution which is designed for use on a square wave or block commutation inverter supply voltage.

The brushless servomotor lacks the commutator of the d.c. motor, and has a device (the drive sometimes referred to as the amplifier) for making the current flow according to the rotor position. In the d.c. motor, torque variation is reduced by increasing the number of commutator segments. In the brushless motor, torque variation is reduced by making the coil three-phase and, in the steady state, by controlling the current of each phase into a sine wave.

**Stationary torque characteristics** A motor which uses permanent magnets to supply the field flux is represented by the simple equivalent circuit of *Figure 19.8*. This is a series circuit of the armature resistance,  $R_a$ , and back e.m.f.,  $E$ .

If we ignore the voltage drop across the transistors, the equation for the voltage is

$$V = R_a I_a + K_e \Omega$$

$K_e$  is known as the back-e.m.f. constant of the motor. The armature current  $I_a$  is

$$I_a = \frac{V - K_e \Omega}{R_a}$$

Therefore, from above, the torque  $T$  is

$$T = K_t I_a = \frac{K_t (V - K_e \Omega)}{R_a}$$

$K_t$  is known as the torque constant of the motor.

**Figure 19.8** Simplified equivalent circuit

**Figure 19.9** Torque-speed characteristic

*Figure 19.9* shows the relation between  $T$  (torque) and  $\Omega$  (rotational speed) at two different voltages. The torque decreases linearly as the speed increases. The slope of this function is a constant  $K_t K_e / R_a$  and is independent of the terminal voltage and the speed. Such characteristics make the speed or position control of a d.c. motor relatively easy.

The starting torque and the no load speed (assuming no bearings friction and windage loss) are given by

$$T_s = \frac{K_t V}{R_a}$$

$$\Omega_o = \frac{V}{K_e}$$

### 19.2.5 Reluctance motors

The reluctance motor is arguably the simplest synchronous motor of all, the rotor consisting of a set of iron laminations shaped so that it tends to align itself with the field produced by the stator.

The stator winding is identical to that of a three phase induction motor. The rotor is different in that it contains saliency (a preferred path for the flux). This is the feature which tends to align the rotor with the rotating magnetic field making it a synchronous machine. The practical need to start the motor means that a form of 'starting cage' needs also to be incorporated into the rotor design, and the motor is started as an induction motor, which then the reluctance torque 'pulls in' the rotor to run synchronously in much the same way as a permanent magnet rotor.

Reluctance motors may be used on both fixed frequency (mains) supplies and inverter supplies. These motors tend to be one frame size larger than a similarly rated induction motor and have low power factor (perhaps as low as 0.4) and poor pull in performance. As a result of these limitations their industrial use has not been widespread except for some special applications such as textile machines where large numbers of reluctance motors may be connected to a single 'bulk' inverter and maintain synchronism. Even in this application, as the cost of inverters has reduced, bulk inverters are infrequently used and the reluctance motor is now rarely seen.

### 19.2.6 Switched reluctance motors

The SR motor is very different from the other polyphase machines described in that both the stator and the rotor have salient poles. The motor can only be used in conjunction with

its specific power converter and control, and consequently only overall characteristics are relevant. SR drives are increasing in popularity. They are finding application in high volume appliances and industrial applications which can take good advantage of their characteristics notably high starting torque.

### 19.3 Drive power circuits

Converter circuits and their characteristics have been described in the Power Electronics chapter of this book. For convenience, the most important configurations used in drive systems are described here.

#### 19.3.1 A.c. to d.c. power conversion

The three-phase controlled converters dominates all but the lowest powers where single-phase converters are used. Two power circuits are of practical importance:

- Fully controlled—This is by far the most important practical bridge arrangement. *Figure 19.10* shows the power circuit together with associated a.c./d.c. relationships. *Figure 19.11* shows how the d.c. voltage can be varied by adjusting the firing delay angle  $\pi$ . The pulse number,  $p$ , of this bridge equals 6. Energy flow can be from a.c. to d.c. or d.c. to a.c.
- Half Controlled—In this circuit either the top three devices of *Figure 19.10* (Ap, Bp and Cp) or the bottom three devices (An, Bn and Cn) are replaced by diodes. The pulse number of this bridge equals 3. Only energy flow from a.c. to d.c. is possible. The voltage ripple is much greater than in the case of the fully controlled bridge, *Figure 19.12*, but the a.c. current drawn is lower at reduced d.c. voltage.

CONDUCTING THYRISTORS AC/DC RELATIONSHIPS

TOP ROW	BOTTOM ROW	Vd	ia	ib	ic
Ap	An	0	0	0	0
	Bn	Vab	+id	-id	0
	Cn	Vac	+id	0	-id
Bp	An	Vba	-id	+id	0
	Bn	0	0	0	0
	Cn	Vbc	0	+id	-id
Cp	An	Vca	-id	0	+id
	Bn	Vcb	0	-id	+id
	Cn	0	0	0	0

Figure 19.10 Three-phase fully controlled bridge

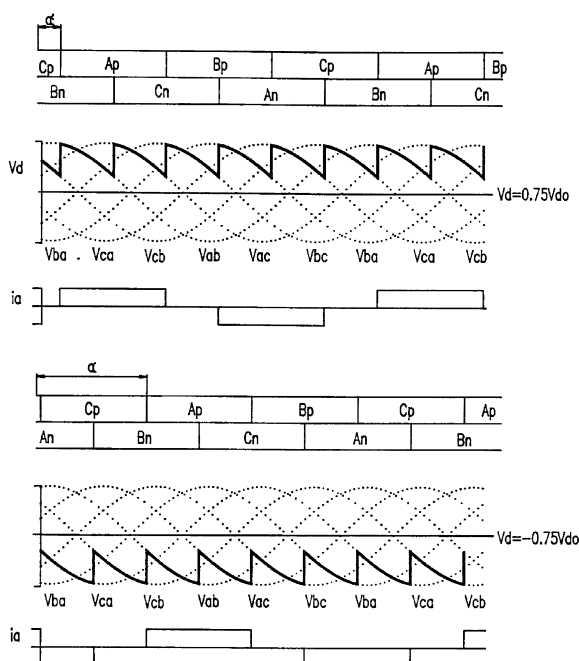

Figure 19.11 Three-phase fully controlled bridge—d.c. voltage control

*Summary of characteristics* Table 19.1 shows the salient characteristics of the three-phase a.c. to d.c. converters described above.

*Practical effects* The characteristics in Table 19.1 have, for the most part, been based upon idealised conditions of negligible a.c. inductance and constant d.c. current. Whilst these assumptions provide a convenient means for comparison they are not often valid in practice. It is not practicable to consider all such effects here. The effect of d.c. link current ripple on a.c. supply harmonics is of great practical industrial importance mainly in relation to 3-phase bridges (ignoring single-phase traction requirement). Practical experience has led to the adoption by many of the following values:

$$\begin{aligned}
 I_5 &= 0.25I_1 \quad (\text{'Ideal'} = 0.2I_1) \ll \\
 I_7 &= 0.13I_1 \quad (\text{'Ideal'} = 0.14I_1) \ll \\
 I_{11} &= 0.09I_1 \quad (\text{'Ideal'} = 0.11I_1) \ll \\
 I_{13} &= 0.07I_1 \quad (\text{'Ideal'} = 0.08I_1) \ll
 \end{aligned}$$

In general, the amplitudes of higher harmonics are rarely of significance, in regard to supply distortion. Under conditions of very high d.c. current ripple, the 5th harmonic can assume a considerably higher value than that quoted above. A practical example would be an application with a very capacitive d.c. load (e.g. a voltage source inverter) in such a case where no smoothing choke is used  $I_5$  could be as high as  $0.5I_1$ .

#### 19.3.2 D.c. motor drive systems

In principle little has changed since 1896 when Harry Ward Leonard presented his historic paper 'Volts versus Ohms—the speed regulation of electric motors'. In practice,

**Figure 19.12** Three-phase half controlled bridge—d.c. voltage control

however, many advances have been made from auxiliary machines through mercury arc rectifiers to thyristors.

The d.c. motor is still the most versatile machine for variable-speed drive systems and is often the preferred choice when considerations such as freedom from maintenance or operation under adverse conditions are not paramount.

Earlier, it has been shown that complete control of a d.c. machine can be achieved by controlling the armature voltage,  $V_a$  and the field current,  $I_f$ . Two power converters are employed for this purpose in most variable speed drives which employ the separately excited d.c. machine. (In refer-

ring to the number of converters in a drive, it is common to ignore the field converter—this nomenclature will be adopted below). It is relatively common in simple drives for the field converter to be a single-phase uncontrolled bridge thereby applying fixed field voltage.

In applications where the variation in motor resistance with temperature, or on sites with poorly regulated supplies, which results in unacceptable variations in field current, a controlled power converter is employed with current control. Such field controllers are further discussed later as applied to field weakening control.

**Table 19.1** Three-phase converter characteristics

Bridge	Fully controlled	Half controlled
Firing angle	$\alpha$	$\alpha > \pi/3$ $\alpha$ $\alpha < \pi/3$
$V_{do}$	$\frac{3\sqrt{2}}{\pi} V_s$	$\frac{3\sqrt{2}}{\pi} V_s$
$P_{do}$	$\frac{3\sqrt{2}}{\pi} V_s I_d$	$\frac{3\sqrt{2}}{\pi} V_s I_d$
$V_d/V_{do}$	$\cos \alpha$	$0.5 (1 + \cos \alpha)$
$I_s/I_d$	$\sqrt{3/2}$	$\sqrt{(\pi - \alpha)/\pi}$ $\sqrt{3/2}$
Overall power factor	$(3/\pi) \cdot \cos \alpha$	$\frac{\sqrt{3} \cdot (1 + \cos \alpha)}{\sqrt{(\pi - \alpha)}}$ $(3/2\pi) \cdot (1 + \cos \alpha)$
Maximum corrected power factor	$\frac{\cos \alpha}{\sqrt{(\pi^2/9 - \sin^2 \alpha)}} \leftarrow$	$\frac{1 + \cos \alpha}{\sqrt{2\pi(\pi - \alpha) - \sin^2 \alpha}} \leftarrow$ $\frac{1 + \cos \alpha}{\sqrt{4\pi^2/9 - \sin^2 \alpha}} \leftarrow$
Input power/ $P_{do}$	$\cos \alpha$	$0.5 (1 + \cos \alpha)$
Input VARs/ $P_{do}$	$\sin \alpha$	$0.5 \sin \alpha$
Supply current $n$ th harmonic/ $I_d$	0 for $n = 3, 6, 9, \dots$ 0 for $n$ even $\sqrt{6/n\pi}$ for $n$ odd	0 for $n = 3, 6, 9, \dots$ $\sqrt{3/n\pi} \cdot \sqrt{1 - \cos n\alpha}$ for $n$ even $\sqrt{3/n\pi} \cdot \sqrt{1 + \cos n\alpha}$ for $n$ odd
Phase of supply current harmonics	$n\alpha$	$n\alpha/2$

voltages from the rectifying and inverting bridges cannot be identical, and reactors  $L_p$  are included to limit the current circulating between them. The principal advantage of this system is that when the motor torque, and hence current, is required to change direction (polarity), there need be no delay between the conduction of one bridge and the other. This is the dual converter bridge *with circulating current*.

In the other, the circulating current-free dual converter only one bridge at a time is allowed to conduct. The cost and losses associated with the  $L_p$  reactors can then be eliminated, and economies can also be made in the drive control circuits. However, the penalty is a short time delay, as the current passes through zero, while it is ensured that the thyristors in one bridge have safely turned off before those in the second are fired. This delay introduces a 'torque-free' period of typically 10 ms. Speed reversal for a 3 kW drive of this type from  $-1500$  to  $+1500$  rev/min can still be achieved in approx 200 ms.

This circulating current-free dual converter is by far the most common industrial four-quadrant drive and is used in many demanding applications—paper, plastics and textile machines where rapid control of tension is required, are good examples.

**Field control** The output power of a motor is the product of torque and speed. If torque reduces in proportion to speed increases, the motor is said to have a constant power characteristic.

In applications where material is coiled or uncoiled at constant tension, the torque required to produce that tension varies in proportion to coil diameter, whilst rotational speed required to maintain a constant peripheral speed (and therefore line speed) is inversely proportional to diameter. A motor having a constant power characteristic is well suited to this type of application, the advantage being that a smaller motor can be used than would otherwise be the case. Machine tool drives also make use of constant power operation, since loads are small at high speeds, whilst heavy work is done at low speed.

The torque produced by a d.c. motor is proportional to the product of armature current and field flux. By weakening the field as speed increases, a constant power characteristic can be achieved.

In practice there are two major techniques for field weakening both of which rely on a field controller which itself is a simple thyristor converter operating in a current control mode.

In the first method, suitable for coiler and uncoiler applications, the field current reference is arranged to be inversely proportional to coil diameter (measured directly, or calculated from the ratio of line speed to motor speed). Since flux is not strictly proportional to field current, this method does not give a true constant-power characteristic unless compensation for the non-linear part of the motor field curve is applied.

The second method is to use the field controller with an outer, voltage loop having a fixed reference, and to use motor armature voltage as the feedback signal. At low speeds, the voltage loop saturates, providing maximum field current, since armature voltage is below the set value. As speed increases, the armature voltage rises to the point where it matches the preset reference in the field controller. Above that speed, an error signal is produced by the voltage loop, which causes the field controller to weaken the motor field current and thereby restore armature voltage to the setpoint level. The resulting characteristics are shown in *Figure 19.16*.

As regenerative braking depends on the return of power from the motor to the mains, it cannot work if the mains supply fails due to a blown fuse or a power cut. Dynamic braking of 4Q drives is often encountered as a fail-safe means of stopping the motor and its load, and as the only means of (reverse) braking of single-ended drives. This involves switching in a resistor across the d.c. motor.

Since the kinetic energy of the motor and its load is converted into heat by the braking resistor, it is important to rate it correctly for the duty it is expected to perform, taking account of load inertia and the number of stops per hour.

### 19.3.3 D.c. to d.c. power conversion

#### 19.3.3.1 General

D.c.–d.c. power converters (often referred to as 'choppers') provide the means to change one d.c. voltage to another. It is more usual for the conversion to be to a lower voltage, although step-up converters are available and have significant potential for the future.

D.c.–d.c. power converters are fed from a d.c. supply usually comprising an uncontrolled a.c. to d.c. converter or alternatively a battery supply; the controlled d.c. output can then be used to control a d.c. machine as in the case of the controlled a.c. to d.c. converters.

D.c. drives employing controlled a.c. to d.c. converters have several important limitations which are overcome by the d.c.–d.c. converter:

- The inability of a thyristor to interrupt current means that an alternating supply is necessary to commutate the converter—this precludes operation from a d.c. supply. This is a common requirement on battery vehicles and d.c. fed rail traction.
- The d.c. ripple frequency is determined by the a.c. and is, for a 50 Hz supply frequency, 100 Hz for single-phase and 300 Hz for three-phase fully-controlled bridges. This means that additional smoothing components are often required when using high speed machines, permanent magnet motors or other special motors with low armature inductance.
- As a result of the delay inherent in thyristor switching (3.3 ms in a 50 Hz 3-phase converter) the current control loop band width of the converter is limited to approximately 100 Hz, which is too low for many servo drive applications.
- Thyristor controlled a.c.–d.c. converters have an inherently poor input power factor at low output voltages. (Near unity power factor can be achieved using an uncontrolled rectifier feeding a d.c.–d.c. converter).
- Electronic short-circuit protection is not economically possible with thyristor converters. Protection is normally accomplished by fuses.

D.c.–d.c. converters are however more complex and somewhat less efficient than a.c.–d.c. converters. They find application mainly in d.c. servodrives, rail traction drives and small fractional kW drives employing permanent magnet motors.

Since step-down converters are of greatest practical importance emphasis shall be placed on their consideration. For the purpose of illustration bipolar transistors will be considered however MOSFET, IGBT and GTO's are widely used.

Figure 19.16 Constant power operation using a field controller

### 19.3.3.2 Step-down d.c.–d.c. converters

**Single-quadrant d.c.–d.c. converter** The most basic d.c. to d.c. converter is shown in Figure 19.17. The output voltage is changed by pulse-width modulation (PWM)—that is, by varying the time for which the transistor T is turned on. The voltage applied to the motor is therefore in the form of a square wave of varying periodicity. Because the motor is inductive the current waveform is smoothed, the flywheel diode D carrying the current whilst the transistor is turned off.

The basic formulae relating the variables in this circuit are as follows:

$$V_a = V_{dc} \cdot \frac{t_{on}}{T}$$

$$\Delta I_a = \frac{V_{dc}}{4 \cdot f \cdot L} \cdot \frac{t_{on}}{T}$$

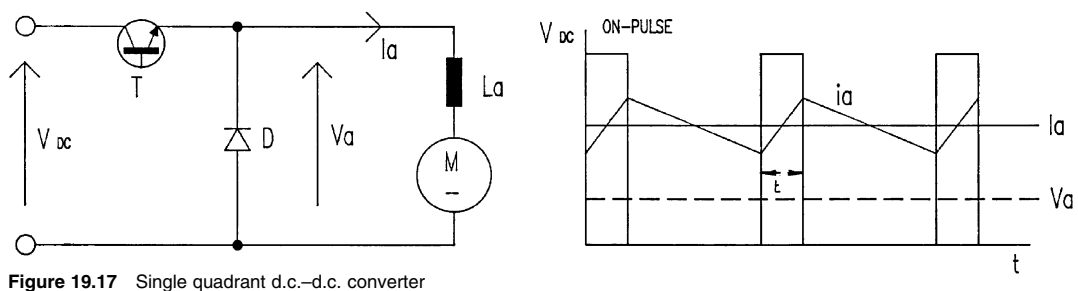

where  $f$  = frequency of transistor 'on pulse' (Hz)  
 $\Delta I_a$  = maximum deviation of armature current  
 $L$  = motor inductance  
 $t_{on}$  = on pulse duration (s)  
 $V_{dc}$  = source d.c. voltage

The circuit is only capable of supplying unidirectional current and voltage to the motor and is therefore not capable of four-quadrant operation, that is reversing or regenerating.

Applications for this circuit are normally limited to drives below 5 kW and simple variable-speed applications.

**Two-quadrant d.c.–d.c. converter** In order to achieve full four-quadrant operation a converter must be capable of supplying reversible voltage and current to the motor. A circuit that is capable of two-quadrant operation—that is motoring and braking in one direction only—is shown in Figure 19.18. This converter is able to reverse the current flow to the motor but unable to reverse the motor terminal voltage and hence the speed. During motoring, the converter operates as the basic 'chopper' with T1 and D2 carrying the current. During braking (or regeneration) T1 is inoperative and T2 controls the current. During its on-periods, motor current builds up negatively, limited by motor inductance  $L$ . When T2 turns off, the only path for the current is via D1 back into the supply; hence the circuit is regenerative.

Since this circuit is not capable of motor speed reversal it is normally only used in unidirectional applications. However

**Figure 19.18** Two-quadrant d.c.-d.c. converter

**Figure 19.19** Four-quadrant d.c.-d.c. converter

because of its simplicity it is sometimes used in traction applications where reversing is carried out by means of a change-over switch to reverse the armature or field supply.

*Four-quadrant d.c.-d.c. converter* Figure 19.19 shows a basic four-quadrant converter capable of supplying reversible voltage and current i.e. of reversing and regeneration.

During motoring, positive output transistors T1 and T4 are switched on during the on-period, whilst diodes D2 and D4 conduct during the off-period. When D2 and D4 conduct, the motor supply is reversed and consequently the voltage is reduced to zero at 50% duty cycle. Any reduction

of duty cycle below 50% will cause the output voltage to reverse but with current in the same direction; hence the speed is reversed and the drive is regenerating. With transistors T2 and T3 conducting, the current is reversed and hence the full four-quadrant operation is obtained.

One disadvantage of this converter is that the amplitude of the output ripple voltage is twice that of the simple converter—and the current ripple is therefore worse. This problem can be overcome by a technique known as double-edged modulation. With this technique the flywheel current is circulated via a transistor and a diode during the off-period. For example, after T1 and T4 have been

Figure 19.20 Step-up d.c.-d.c. converter

conducting, T4 is turned off and T3 on, so that the flywheel current circulates via T1 and D3. The net effect is a reduction in ripple voltage and a doubling of ripple frequency.

These four-quadrant converters are widely used in high performance d.c. drives such as servos.

### 19.3.3.3 Step-up d.c.-d.c. converters

As with step down converters many alternative configurations exist for step-up converters. Whilst a full description is not necessary, the principle is of value.

Figure 19.20 shows a much simplified arrangement of a step-up converter. When T is turned on, current builds up in inductor L. When T is turned off, the energy stored in L is transferred to Capacitor C via D. When the capacitor voltage, which is the same as the motor armature voltage reaches the desired level, T is turned on once more. C cannot discharge via T as diode D is reverse biased.

In this way a stabilised voltage typically twice the input d.c. voltage can be obtained. This circuit is particularly useful when operating on low voltage supplies and can lead to very cost effective converter designs.

### 19.3.4 A.c. to a.c. power converters with intermediate d.c. link

This category of a.c. drive commonly termed 'Variable Frequency Inverters' is by far the most important in respect of

the majority of industrial applications. It is being considered here as a complete converter, however the input stages have been considered earlier in isolation, and their individual characteristics so described are, of course, applicable. Alternative input stages to some of the drives are applicable.

Also some converters may be used with a variety of machine types. Only practically important combinations are described.

The concept of these 'inverter' drives is well understood—'rectification of fixed frequency, smoothing and then inverting to give variable frequency/variable voltage to feed an a.c. machine'. Within this broad concept two major categories of drive exist: Firstly, voltage source in which the converter impresses a voltage on the machine, and the machine impedances determine the current. Secondly, current source in which the converter impresses a current on the machine, and the machine impedances determine the voltage.

#### 19.3.4.1 Voltage source inverters

**General characteristics** The fixed frequency mains supply is a voltage source behind an impedance. Voltage source inverters can be similarly considered, and consequently are very flexible in their application. Major inherent features included:

- Multi-motor loads can be applied—this can be very economical in applications such as roller table drives, spinning machines etc.
- Inverter operation is not dependent upon the machine—indeed various machines (induction, synchronous or even reluctance) can be used provided the current drawn is within the current rating of the inverter. Care should be taken where a low power factor motor is used (e.g. reluctance) to ensure the inverter can provide the required VARs.
- Inherent open-circuit protection, very useful in applications where the cables between the inverter and motor are in some way insecure (e.g. fed via slip-rings, subject to damage etc.).

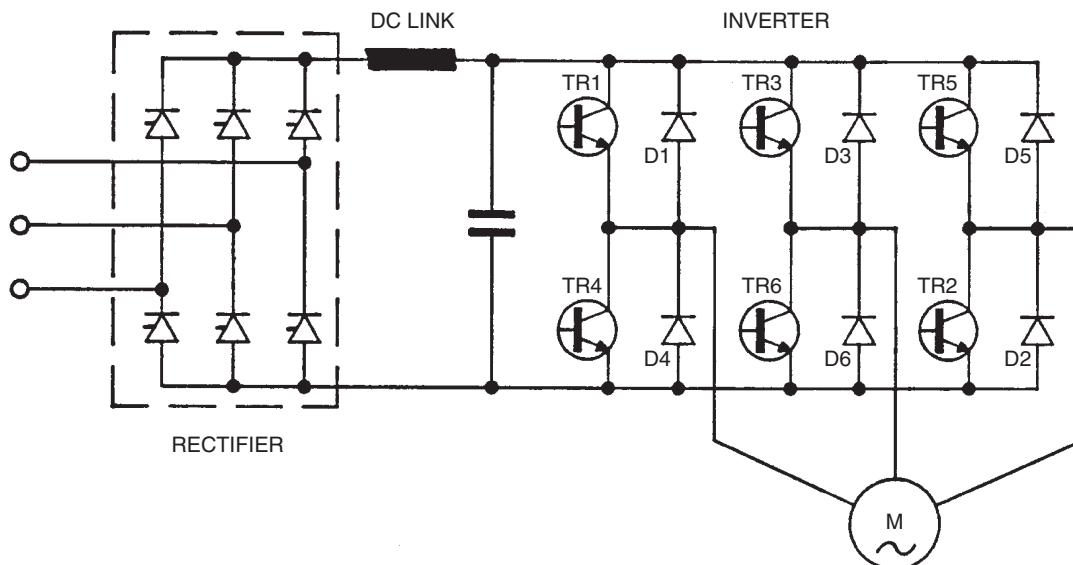

Figure 19.21 Square wave voltage-fed inverter

- Facility to 'ride-through' mains dips can easily be provided by buffering the d.c. voltage link with capacitance or, where necessary, a battery.
- Motoring operation only in both directions is possible without the addition of resistive dumps for braking energy or expensive regenerative converters to feed energy back to the supply.

*Six step square wave inverter* A typical d.c. link square wave voltage-fed inverter drive is shown in *Figure 19.21*. The three-phase a.c. supply is converted to d.c. in the phase-controlled rectifier stage. The rectified d.c. power is then filtered and fed to the inverter. Note that the d.c. link reactor is small compared to that used in current source designs. Indeed in drives up to about 4 kW it is not practically necessary. Some manufacturers omit the reactor in designs to 400 kW and above, however this has a significant effect upon supply harmonics and unduly stresses the rectifier and filter capacitor.

The inverter switching elements shown as transistors TR1 to TR6 are gated at  $60^\circ$  intervals in the sequence in which they are numbered in the diagram, and each transistor conducts for  $180^\circ$ . The feedback diodes D1 to D6 are connected in inverse-parallel with the transistors, and permit the return of energy from reactive or regenerative loads through the inverter to the d.c. link.

For a star-connected motor, synthesis of inverter output voltage waveforms is shown in *Figure 19.22*. The phase-to-neutral voltage of the inverter has six-step waveshape while the corresponding phase-to-phase voltage has  $120^\circ$  conduction angle. The output frequency is controlled by the rate at which the inverter transistors are triggered into conduction by the inverter control circuitry. Reversing the firing sequence of transistors in the inverter changes the direction of rotation of the motor, and no switching of power leads, either on the incoming supply or to the motor itself, is necessary.

The phase-controlled rectifier regulates the d.c. link voltage and this, in turn, determines the magnitude of the output voltage from the inverter. Thus, the output voltage/frequency relationship may be controlled to regulate the motor flux in the desired manner.

The advantages of the square-wave inverter are high efficiency (98%), suitability to standard motors, potential good reliability and high-speed capability. However, it suffers from low-speed torque pulsations and possible low-speed instability.

In a square wave inverter, each harmonic voltage amplitude is inversely proportional to the harmonic order and hence there are no pronounced high-order harmonics. These are filtered by the motor leakage inductances.

Very high speed motor operation is possible by increasing the output frequency. Faster switching devices such as MOS transistors and insulated gate bipolar transistor (IGBT) can be used to achieve this performance.

It is known that the square wave inverter gives objectionable torque pulsation at low frequency operation, below approximately 5 Hz. This pulsating torque is due to the interactions of low order harmonics with the fundamental voltage, causing a stepping or cogging motion to the rotor running at low speed. Hence, the pulsating torque limits the low frequency operation of the square wave inverter. Appropriate feedback control techniques or flux weakening can attenuate the low speed pulsating torque problems.

The existence of a phase-controlled rectifier to control the voltage of the inverter as illustrated in *Figure 19.21* is an inherent weakness of this circuit. The phase-controlled rectifier will present a low power factor to the a.c. supply, at

low speeds, and the d.c. link filter capacitor is large and reduces the response time of the system to voltage and hence speed changes. If the drive system is one for which regenerative braking operation is a requirement, the rectifier has to be of inverse-parallel type. The input power-factor and response time of the drive can be improved by replacing the phase-controlled rectifier with a diode rectifier feeding a d.c. chopper which regulates the input voltage to the inverter. For recovering regenerative energy of the load, a two-quadrant chopper will be necessary. The alternative supply converter arrangement of a diode bridge plus chopper also provides a fixed voltage link which is more economically buffered if mains dip ride-through is required.

The voltage-fed square-wave drive is usually used in low power industrial applications where the speed range is limited to 10 to one and dynamic performance is not important. Recently, this type of drive has largely been superseded by PWM type voltage-fed inverters. Nevertheless, the voltage-fed square wave inverter can be easily adapted to multimotor drives where the speed of a number of induction motors can be closely tracked. It is also used in some high frequency ( $> 1$  kHz) and some high power applications.

*Pulse width modulated (PWM) inverter* In the PWM inverter drive, the d.c. link voltage is uncontrolled and derived from a simple diode bridge. The output voltage can be controlled electronically within the inverter by using PWM techniques. In this method, the transistors are switched on and off many times within a half cycle to generate a variable-voltage output which is normally low in harmonic content.

A PWM waveform is illustrated in *Figure 19.23*.

A large number of PWM techniques exist each having different performance notably in respect to the stability and audible noise of the driven motor.

Using the PWM technique, low-speed torque pulsations are virtually eliminated since negligible low-order harmonics are present. Hence, this is an ideal solution where a drive system is to be used across a wide speed range.

Since voltage and frequency are both controlled with the PWM quick response to changes in demand voltage and frequency can be achieved. Furthermore, with a diode rectifier as the input circuit a high power-factor, approaching unity, is offered to the incoming a.c. supply over the entire speed and load range.

PWM inverter drive efficiency typically approaches 98% but this figure is heavily affected by the choice of switching frequency—the higher the switching frequency the higher the losses in the drive. In practice the maximum fundamental output frequency is usually restricted to 100 Hz in the case of gate turn-off thyristors (GTO) or about 1 kHz for a transistor based system. The upper frequency limit may be improved by making a transition to a less sophisticated PWM waveform with a lower switching frequency and ultimately to a square wave if the application demands it. However, with the introduction of faster-switching power semiconductors, these restrictions to switching frequency and minimum pulse-width have been eased.

In general, a motor with a large leakage reactance is desirable to limit the flow of harmonic currents and thereby minimise losses.

#### 19.3.4.2 Current source inverters

Whereas each voltage feeding inverter can be used with most forms of a.c. machine, a different design is usually

**Figure 19.22** Square wave voltage-fed inverter—output voltage and current

adopted for synchronous and induction motors. Current source drives are usually, but not always, single-motor systems, and since current is controlled, have simple short-circuit protection.

In contrast to voltage source inverters full four quadrant operation is inherently possible.

*Converter-fed synchronous machine* Once rotating a synchronous machine generates a.c. voltages which can be used for the natural commutation of a converter connected to its

terminals. Indeed the connected synchronous machine behaves as the mains in respect of the a.c. to d.c. converters described earlier.

Figure 19.24 shows the basic components of the drive system. A low-impedance or 'stiff' d.c. current source is required and is obtained from a controlled rectifier and a series reactor. With a stiff current source, the output current wave is not greatly affected by the magnitude of the load.

The synchronous machine can be approximately represented by a counter-emf in series with an equivalent leakage

Figure 19.23 Sinusoidal PWM line and phase voltages

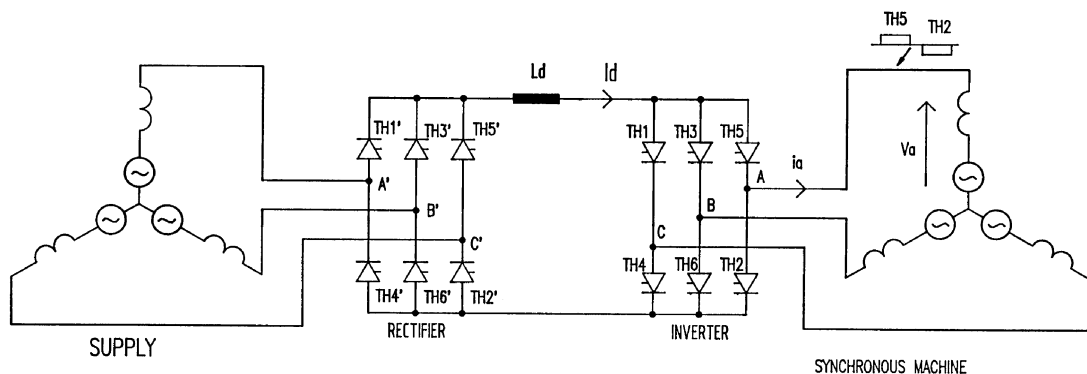

Figure 19.24 Converter-fed synchronous machine

inductance. The d.c. current is switched through the inverter thyristors so as to establish three-phase, six-stepped symmetrical line current waves. Each thyristor conducts for  $120^\circ$  and at any instant one upper thyristor and one lower thyristor remain in conduction.

It is necessary to maintain an approximately constant angular relationship between the rotor and stator m.m.f.s and hence automatically maintain the correct inverter frequency. This is an important point. The inverter does not impose a frequency upon the machine, rather the machine itself determines the frequency. The motor cannot therefore pole-slip. The drive is accelerated by increasing

the current fed to the drive which then accelerates and thereby increases the frequency.

As in the d.c. drives, the a.c. supply power factor is poor at low speeds. Full four-quadrant operation is possible without additional components.

Special procedures are necessary for starting these drives since at standstill the machine voltage is not available to commutate the current. In essence this is usually achieved by momentarily switching off the d.c. link current every sixth of a cycle. This allows the thyristors in the inverter to turn off so that the next pair can be fired. Above approximately 5% of rated speed the machine generates sufficient voltage for natural commutation and control is undertaken in a similar manner to that of a d.c. drive.

Applications for this type of drive fall into two main categories. Firstly, starting converters for large synchronous machines, the converter being rated only for a fraction of the machine rating. Secondly, as large high power (and sometimes high speed) variable speed drives for a variety of applications. Power ratings, typically from 1.5 to 30 MW at speeds up to 8000 rpm are available. Also of import is the fact that high voltage drives are offered with supply voltages up to 5 kV typical, but systems up to 25 kV are in service where the high voltage converter technology is similar to that used for HVDC power converters.

*Converter-fed induction motor drive* Unlike the Synchronous machine, the induction motor is unable to provide the VARs, or terminal voltage to commutate a converter connected to its terminals. Commercial schemes are available however which are closely based upon the converter fed synchronous machine drive having additional components to provide VAR compensation.

Figure 19.25 shows a basic power circuit. The diagram somewhat belies the potential complexity of the VAR

compensator. In its simplest form this could comprise capacitors plus appropriate switches. Control of such a system is somewhat involved. It is often better to use a cycloconverter or even an auxiliary synchronous machine to provide the commutation, and motor VARs.

This system is only appropriate for high power drives, generally above 4 MW where an induction motor is preferred.

*Forced commutated induction motor drive* This is the most widely used current source inverter at power levels in the range 50–3500 kW at voltages up to normally 690 V.

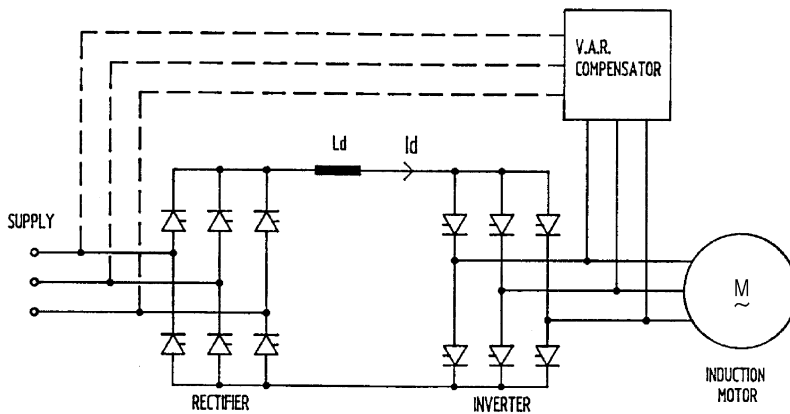

Figure 19.25 Converter-fed induction motor

Figure 19.26 Forced commutated induction motor

(High voltage versions 3.3 kV/6.6 kV have been developed however they have not proved to be economically attractive.)

Figure 19.26 shows the inverter and motor of the drive. The d.c. link current  $I_d$ , taken from a 'stiff' current source is sequentially switched at the required frequency into the stator windings of the induction motor. The motor voltage waveform is approximately sinusoidal apart from the superposition of voltage spikes caused by the rise and fall of

machine current at each commutation. Further distortion is caused by the effects of slot ripple and d.c. current ripple.

The operating frequency range is typically 5–60 Hz, the upper limit being set by the relatively slow commutation process. Special motors with low leakage inductance do offer advantage with this converter and allow reduced capacitance in the inverter and/or higher operating frequency. Below 5 Hz, torque pulsations can be problematic but PWM of the current can be used at low frequencies to ease the problem.

This system is most commonly used for single motor applications such as fans, pumps, extruders, compressors etc. where very good dynamic performance is not necessary and a supply power factor which decreases with speed is acceptable.

**Static Kramer drive** The static Kramer drive is shown in Figure 19.27. The drive comprises a slip-ring (wound rotor) induction motor together with an uncontrolled converter, d.c. smoothing reactor and a fully-controlled converter in the rotor circuit.

The diode bridge gives an output voltage  $V_d$  which is proportional to the slip of the motor.  $V_d$  is opposed by the d.c. voltage of the fully-controlled bridge, a small potential difference being sufficient to circulate current corresponding to the required load torque. Ideally, neglecting losses, the fully-controlled bridge d.c. voltage sets the speed to which the motor will accelerate. Control is therefore very similar to a d.c. drive.

Power can flow in only one direction via the diode bridge which means that motoring torque can be developed only at subsynchronous speeds. For reverse running it is necessary to reverse the phase sequence of the stator supply.

This drive can be very economic when designed for operation over a limited speed range below synchronous

Figure 19.27 Static Kramer drive

speed—this is the useful operating region for fans, pumps etc. The converter bridges required for such limited speed range operation need only be rated at a fraction of that of the machine it is controlling. It is necessary in such designs to provide a starter, usually a resistance to run the motor up to the lowest controllable speed. This means that should there be a fault with the converter equipment, the system can be easily designed to run at full speed without the controller.

Note that the supply harmonic currents and VARS associated with the converter part of the drive may be substantially reduced by adopting a limited speed range solution.

The static Kramer drive finds application mainly at ratings between 1 and 20 MW, with induction motors with 4 or more poles. (Stability problems exist with 2-pole motors which can only be resolved with care.) Speed ranges of 30% are typical (i.e. 70–100% rated speed). The induction motor stator can be wound for any conventional voltage e.g. 6.6 kV, 11 kV.

### 19.3.5 Direct a.c. to a.c. power converters

This final category of power converters converts the fixed frequency, fixed voltage a.c. supply to a variable frequency and/or variable voltage without an intermediate d.c. link.

#### 19.3.5.1 Soft starter/voltage regulator

Figure 19.28, shows a typical soft start comprising inverse parallel connected thyristors in each supply line to an induction motor. Alternative connections are available but the principles are similar. The converter is used to control the voltage applied to the motor and in this way 'soften' the effects of switching an induction motor direct-on-line (DOL). Whilst the converter will control the current drawn from the supply, its most usual application is in controlling torque to provide smooth 'jolt' free acceleration.

Because the stator frequency is unchanged, a reduced running voltage, and hence flux, equates to a large slip which results in additional rotor losses—care must therefore be taken in its application.

In a number of specialised cases, purpose designed high resistance rotors (or slip-ring motors with external rotor

resistors) are used to form a variable speed drive—the rationale for such a system is based more on history than technology.

More recently such converters have been employed as combined soft starters/power-factor controllers/energy saving devices. The case for significant energy saving by this form of converter is often hard to prove.

A crude form of frequency control is possible by modulating (varying cyclically) the thyristor firing angles at the required output frequency. Whilst commercial systems are available they are of limited value since supply current and motor torque are of poor quality.

#### 19.3.5.2 Cycloconverter

A typical scheme for a cycloconverter drive is shown in Figure 19.29. Each motor phase is supplied, in effect, from a dual a.c. to d.c. converter which was described earlier. It is usual to employ circulating current-free converters. To avoid line to line short-circuits isolating transformers are used on the supply side. By modulating the firing angles of the dual bridge converters, a controllable three-phase set of voltages can be produced suitable for feeding polyphase a.c. machines.

The drive is inherently 4-quadrant. The maximum output frequency is limited to approximately half the supply frequency by considerations related to harmonics in the motor currents and torque, stability and dimensions of the drive components. The cycloconverter therefore finds application in low-speed drives. The complexity of the drive also means that only high power systems (>1 MW), or specialised applications (e.g. conveyor drives for use in hazardous environments) are economic.

They are used on large ball mills, minewinders etc. They are also used to feed multimotor loads such as roller tables.

Due to the modulation of the converter firing angles, the harmonic content of the a.c. supply is complex and designs for appropriate harmonic filters somewhat involved.

The cycloconverter is suitable for feeding both induction and synchronous machines. In specialised applications such as wind generators, cycloconverters have been placed in the rotor circuit of a slip-ring induction motor. Such a

Figure 19.28 Typical soft start

Figure 19.29 Cycloconverter

system, known as a static Scherbius drive which is detailed below.

### 19.3.5.3 Static Scherbius drive

The static Scherbius drive is closely related to the static Kramer drive, with the single quadrant diode bridge in the rotor circuit replaced by a cycloconverter.

The cycloconverter is used as the voltage and frequency changer between the rotor and the supply. The cycloconverter is inherently regenerative, and the output can be controlled up to half the supply frequency in both phase sequences. It is thus possible for the system to operate as a full 4-quadrant drive. For a given converter rating the range of speed control is therefore twice that of a static Kramer drive.

The relative complexity of the drive limits its application to somewhat specialised high power applications where a very limited speed range only is required and perhaps stringent harmonic current limits have been imposed by the supply authority.

### 19.3.5.4 Matrix converter

Recently attention has been refocused on the matrix converter shown in *Figure 19.30*. Whilst the basic circuit is not new, recent advances in power devices offer the potential to overcome many of the drawbacks inherent in the circuit when the switches comprise inverse parallel thyristors. Limitations in the maximum output voltage (86% input) means that its application in the commercial industrial market could be problematic. There are prospects in regard to integrated motors and some servo systems where machine voltage is not seen as critical.

Commercial systems are available only for very specialised applications at present. It has yet to be proven to be a practical and cost effective industrial drive although some major drives companies are working on this technology.

Figure 19.30 Matrix converter

## 19.4 Drive control

### 19.4.1 D.c. drive control

Most medium and large size industrial d.c. motor drives are based on a separately excited motor. The flux is generated by a field winding and the torque by a higher current armature winding fed via a commutator. These two windings are completely independent, and so the flux and torque can be controlled independently as shown below in *Figure 19.31(a)*. Although the field winding usually has a long time constant, the armature winding time constant is normally very short allowing fast changes of armature current and hence torque.

**Flux controller** The field converter is either a half or fully controlled thyristor converter. The half controlled converter can only apply positive voltage to the field winding, and so the current in the winding can be increased quickly, but decays slowly. The fully controlled converter can apply positive or negative voltages, and so the performance is the same whether the current is increasing or decreasing. When the motor is rotating at a speed below base speed the field current reference is constant at the rated level for the motor, and so the motor armature voltage increases with speed. The armature voltage reaches its rated level at base speed, and above this speed the flux controller reduces the field current reference,  $i_F^*$ , to keep the voltage at the rated level as the speed increases further. The armature voltage feedback can include armature resistance compensation to avoid the effects of the armature resistance drop on the voltage control loop.

**Torque controller** For four-quadrant operation two thyristor bridges are used as shown in *Figure 19.31(b)*. Both bridges can apply positive or negative voltage to the motor, but the positive bridge can only supply positive current and the negative bridge negative current. Therefore the positive bridge conducts when positive torque is required and the negative bridge when negative torque is required. The bridges are phase controlled to apply the voltages required by the reference,  $V_A^*$ , to the motor. Due to the high voltage ripple in the converter output and the unidirectional nature of thyristors, the current in the armature can be continuous or discontinuous. While the current is continuous the relationship between the voltage reference and the actual applied voltage is a cosine function and the voltage reference can be used directly to control the firing angle of the converter. When the current is discontinuous the relationship is highly non-linear and varies with the voltage level applied to the motor. The drive stores the relationship between the firing angle and motor current for different output voltage levels, and during discontinuous current operation the correct firing angle is selected by the firing angle prediction block for a given current reference. Any errors are trimmed out by an integrator operating on the current error.

When a change in direction of torque is required one bridge must stop conducting and the other bridge must become active. It is clear from the power circuit diagram that only one bridge must conduct at a time during this changeover to avoid a short circuit across the armature supply. It is important that this changeover occurs as quickly as possible to give good dynamic torque control. Modern microprocessor controlled drives enable intelligent methods to be used to keep the bridge changeover delay as short as possible.

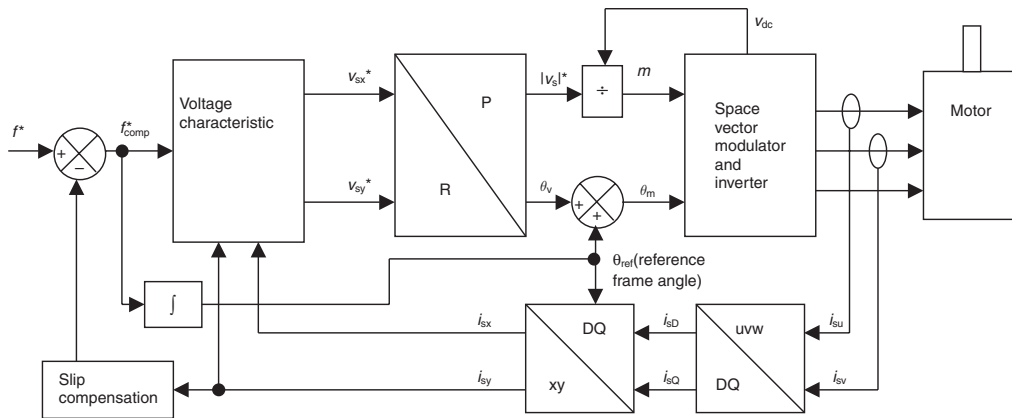

Figure 19.32 Open-loop drive control system

#### 19.4.2.1 General purpose open-loop a.c. drive

The open-loop a.c. drive is a high power variable frequency voltage source. In its simplest form, the output frequency is defined by the user's reference and a suitable fixed frequency to voltage characteristic used to define the output voltage. Although this type of drive is normally designed to supply one or more induction motors connected in parallel, it can also supply other types of a.c. motor or it can be used as a variable frequency/variable voltage power supply. The following description relates to the operation of an open-loop a.c. drive with an induction motor.

Figure 19.32 shows a block diagram of a typical general purpose open-loop drive. For this type of control system feedback is required from the output current of at least two phases of the inverter and the voltage from the d.c. side of the inverter. These feedback signals can be derived from within the drive itself, and so no external feedback, such as the motor speed or position, is required. The control system allows a simple 'open-loop vector strategy' to be implemented. In common with all other a.c. drive control strategies described in this chapter the control system is based on a 'reference frame'.

**Performance and applications** The performance characteristics of the open-loop drive control system applied to an induction motor can be summarised as:

- Moderate transient performance.
- Full torque production down to approximately 3% of rated motor speed.
- Although a good estimate of stator resistance ( $R_s$ ) improves torque production at low speeds, the control system will work with an inaccurate estimate, albeit with reduced torque. The stator resistance can be measured by the drive with a simple test.
- Although a good estimate of motor slip improves the ability of the drive to hold the reference speed, the control system will work with an inaccurate estimate, albeit with poorer speed holding. The motor slip depends on the rotor time constant of the motor ( $T_r$ ) and this cannot be measured easily.
- No position or speed feedback is required from the motor shaft.

This type of drive is used in many applications where moderate performance is required and where providing position feedback would be unacceptable because of the

environment or cost, or is simply not necessary. The following are some examples of applications where open-loop drives are used:

- Fans and pumps
- Conveyors
- Centrifuges

#### 19.4.2.2 Closed-loop induction motor drive

The closed-loop induction motor drive, often referred to as a closed-loop vector drive, is used in many applications requiring better performance than an open-loop drive with an induction motor. To obtain the best performance with this type of drive position feedback is required from the rotor, but unlike the permanent magnet servo drive only the change of position and not the absolute position is required. The control system is similar to that used with a permanent magnet servo motor as shown below.

**Performance and applications** The performance characteristics of the closed-loop induction motor drive can be summarised as:

- Good dynamic performance at all speeds.
- Full torque operation down to standstill.
- A position feedback device that gives the incremental position of the rotor is required.
- Wide power range of motors available so that this type of drive can be used for applications requiring less than 1 kW up to more than 1 MW.
- Suitable for field weakening applications where motors can be operated up to many times base speed.
- The drive can be used in torque control, without the speed controller. The estimate of the flux position to align the reference frame is important as this affects the absolute level of torque produced for a given torque reference. The flux position calculation is dependent on an estimate of the rotor time constant which varies significantly with rotor temperature. However it is possible to include a rotor time constant estimator in the drive control system, so that the drive gives consistent torque control.

Closed-loop induction motor drives are used in many applications where good dynamic performance is required and especially where an induction motor drive is required

**Performance and applications** The performance characteristics of the permanent magnet servo drive can be summarised as:

- Good dynamic performance at all speeds.
- Full torque operation down to standstill.
- Permanent magnet servo motors usually have low inertia. Combined with a fast sample rate for the speed controller and fast torque control, this gives a speed controller with a very high bandwidth.
- Position feedback is required that gives the absolute electrical position of the motor.
- Permanent magnet motors exhibit an effect called cogging related to the geometry of the motor, which results in ripple in the motor torque. This effect can be minimised by good motor design, but can still be a problem.
- The control system described has a zero current reference in the  $x$  axis, and so the rotor flux cannot be altered by the drive. This limits the maximum speed of operation as the motor voltage increases with speed. Field weakening is possible, but due to the large effective air gap of a permanent magnet motor, a large amount of current is required to reduce the flux making the drive inefficient in the field weakening region. It is also necessary to limit the maximum speed with field weakening, because although the motor terminal voltages are reduced by reducing the flux whilst the drive is enabled, when the drive is disabled the voltages return to the level that would be produced without field weakening and may damage the power electronics in the drive.
- The drive can be used in simple torque control, without the speed controller shown in Figure 19.33.

The following are some examples of applications where permanent magnet servo drives are used:

- Machine tools where precise and dynamic performance is required.
- Pick and place applications where the requirements are less precise, but where rapid movements are required.

- More recently permanent magnet motors with high numbers of poles (e.g. 32 poles) have been in low speed applications such as direct (gearless) drives for lifts.

#### 19.4.2.4 Four-quadrant operation

A.c. voltage source inverter drives are normally based on the power circuit shown below in Figure 19.35(a). This power circuit has the following drawbacks:

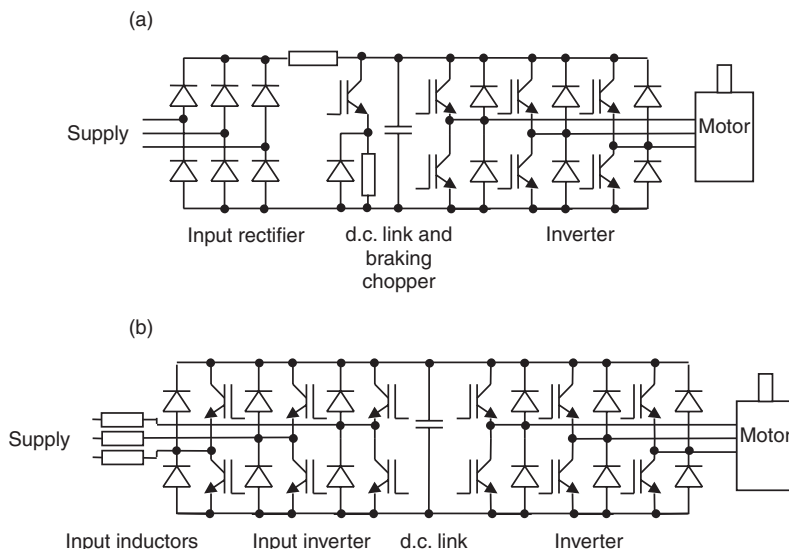

- Although the inverter allows power flow in either direction, the diode rectifier only allows power to flow from the supply into the drive. Therefore the chopper circuit must be used to dissipate unwanted energy in the resistor when braking power is fed from the motor to the drive.
- The currents taken from the supply generally contain significant harmonics.
- The voltage at the inverter input is theoretically limited to the peak line voltage of the supply. In practice this is reduced further by voltage drops in the converter. This limits the maximum output voltage without over-modulation to less than the supply voltage.

If the diode rectifier is replaced with an inverter as shown in Figure 19.35(b), the input currents can then be controlled to give almost sinusoidal waveforms with unity displacement factor. It is also possible for power to flow in either direction through the input inverter so that the drive gives full four-quadrant operation.

The input inverter can be controlled in a similar way to an inverter supplying a motor, using the reference frame based control system described in previous sections. A control system for the input inverter is shown in Figure 19.36.

**Performance and applications** The performance characteristics of the four-quadrant drive described here can be summarised as:

- Full four-quadrant operation.
- Approximately unity displacement factor and minimal input current harmonics.

**Figure 19.35** Alternative a.c. drive power circuits: (a) standard a.c. drive power circuit; (b) four-quadrant drive power circuit

the estimates of torque, flux and speed is complex and is heavily dependent on the motor parameters. The following list gives a comparison between direct torque control and a control system based on a space vector modulator:

- The calculations for the current controllers, reference frame translation and space vector modulator are more complex than the direct torque control hysteresis comparators and switching table. However the sample rate required for direct torque control (typically 40 kHz) is much higher than that for a space vector modulator (6–12 kHz), because direct torque control uses a hysteresis method.
- As well as supplying a single induction motor, most induction motor drives can also supply more than one motor in parallel where the motors are different sizes, or the drive can be used as a general purpose variable frequency/variable voltage power supply. Direct torque control cannot be used in these applications, and so a direct torque control drive must also be able to operate with space vector modulation for these applications.
- Because direct torque control is based on hysteresis controllers the inverter has a continuously variable switching frequency. This is considered to be an advantage in spreading the spectrum of the audible noise from the

motor, but the range must be controlled so that it does not exceed the maximum allowed by the power electronics of the inverter. Care must also be taken with direct torque control to ensure that changes from one voltage vector to another more than 60° away do not occur repetitively as this can increase the stress on motor insulation.

- A direct torque control drive inherently delivers a change in torque in the shortest possible time within the limits of the sample rate. Because of the sampling and calculation delays usually associated with space vector modulator based systems a change in torque can take several samples. However, deadbeat type algorithms can be used with a space vector modulator systems giving performance which compares well to that of direct torque control.

## 19.5 Applications and drive selection

### 19.5.1 General

In order to successfully select and apply the optimum drive system, it is necessary to understand the essential features of both the alternative drive technologies and the load to be driven. The following listing of common loads could prove useful when selecting a drive:

#### 19.5.1.1 Metals industries

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments/ drive type</i>
Rolling Mill	Up to 1000s of kW	High impact torque loading, constant kW speed range, steel works specification and difficult environment. Closed loop induction motor drives and d.c. drives.
Strip Mill	Up to 100s of kW	Normal torque loading (150% max) constant kW speed range, steel works specification and difficult environment. Closed loop induction motor drives and d.c. drives.
Slitters and perforators	50 to 150 kW	In metal finishers plant, environment and specification easier—normally IP23 enclosure, forced ventilation with filter is acceptable. Drive often integrated with wind/unwind stand drives. Closed loop induction motor drives and d.c. drives.
Wind/unwind	Up to 200 kW	Constant kW rating over build-up range. Regenerative braking with four-quadrant operation. Steel works specification and difficult environment. In metal finishers plant easier conditions apply as above. Closed loop induction motor drives and d.c. drives.
Tube mill	Up to 300 kW	Constant kW rating over pipe diameter range. Usually 4-quadrant with regenerative braking. Environment can be difficult with oil spray present. Closed loop induction motor drives and d.c. drives.
Cast tube spinner	20 to 50 kW	High values of acceleration and deceleration torque required. 4-quadrant regenerative. Typical 4–6 speeds required: clean, spray, fill, spin 1 and spin 2. Difficult environment. Single pipe vent or box enclosed motor with filtered air supply. Closed loop induction motor drives and d.c. drives.
Machine tool spindle	Up to 150 kW 5 to 30 kW typical	Mostly flange mounting and timer belt drive to 30 kW gearbox coupled above. Always field range control, reversible, 4-quadrant drive. Often with encoder for spindle orientation. Forced-vent with filter; often coaxial fan unit to 60 kW. Closed loop induction motor drives. At low powers permanent magnet servo drives and at very high powers d.c. drives are used.

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Machine tool table	Up to 200 kW 20 to 75 kW typical	Foot or flange mounting gearbox otherwise as above. Permanent magnet servo drives. At higher powers closed loop induction motor drives and d.c. drives are used.
Wire drawing	5 to 75 kW	Constant kW speed range with individual motor field control on multi block drives with single controller. Progressive speed increase between heads as wire diameter reduces and speed increases. Dancer arm tension control between heads and tension controlled winder take off. Forced-vent motors require filter against wire end entry. 4-quadrant. Acceleration/deceleration. Closed loop induction motor drives or at higher powers d.c. drives.

#### 19.5.1.2 Plastics

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Extruder	5 to 400 kW	Constant torque drive with high torque required to start a stiff extruder screw. Environment can be difficult with plastic particles and fume risk. Single pipe vent of motor is advisable. Closed loop induction motor drives and d.c. drives. Open loop induction motor drives may be used in some applications.
Sheet line Reeler	1.5 to 15 kW	Constant kW drive over reel build-up ratio but often sized as constant torque drive. Braking usually mechanical. Environment can be difficult. TEFC IP55 used for low kW ratings. Closed loop induction motor drives and d.c. drives.

#### 19.5.1.3 Rubber

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Banbury Mixer	Up to 1000 kW	Very heavy peak duty, duty cycle rated typically: 250% full load torque for 10 s, 150% for 20 s, 100% for 120 s, 10% for 30 s repeating continuously. Difficult environment with particle rubber and carbon black, single and double pipe vent is usual with some CACA and CACW motors used. Check through Banbury manufacturer's drive specification—safety environment. D.c. drives predominate but closed loop induction motor drives growing in use.
Callender	Up to 500 kW	Environment as above, with easy duty, constant torque, but 200% dynamic braking. Check through manufacturers' drive specification—safety involvement. Closed loop induction motor drives and d.c. drives.

#### 19.5.1.4 Chemical

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Mixer	Up to 150 kW	Generally constant torque but could be rising torque requirement with increasing mix stiffness. Often explosion proof or hazardous location enclosure requirement; environment can be difficult. Closed loop induction motor drives and d.c. drives.
Extruder	Up to 100 kW	Usually constant torque often explosion proof or hazardous location enclosure requirement. Environment can be difficult. Closed loop induction motor drives and d.c. drives.
Stirrers and agitators	Up to 400 kW	High reliability requirement to avoid loss of mix through drive shutdown. Often rising torque with mix stiffness. Energy saving of importance as process can occupy many days. Drive often outdoor mounting with CACA weatherproof enclosed motor. In particularly exposed positions motor and gearbox should have additional protection. Closed loop induction motor drives and d.c. drives.

## 19.5.1.5 Materials handling

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Conveyor	0.5 to 20 kW	Cascading of multiple drives can be a requirement with progressive speed increase or synchronised drives. Constant torque application with dynamic or regenerative braking. Open loop induction motor drives predominate unless synchronisation/close coordination required where closed loop induction motor drives are used.
Automated warehousing	As above	Usually 3 axis systems, constant torque 4-quadrant 150% full load torque at starting to duty cycle rating. Closed loop induction motor drives predominate. D.c. drives can be used and in less demanding applications open loop a.c. is used.

## 19.5.1.6 Hoist &amp; Crane

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Lift and hoist	30 to 100 kW	Four-quadrant with 200% full load torque at starting. Starting duty 90–200 starts/hour. Smooth, quiet response very important. Closed loop induction motor drives are widely used. D.c. drives are used. Open loop drives are applied to non safety critical applications and installations where smooth ride quality is not critical.
Crane	3 to 75 kW	Four-quadrant high torque requirement. Sometimes weatherproof enclosure. Operating duty cycle requires evaluation. As for lift and hoist.

## 19.5.1.7 Concrete pipe manufacture

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Pipe spinner	10 to 100 kW	D.c. motor needs particular protection against water, cement and vibration. Four-quadrant multi-speed drive requirement with regenerative braking. Duty cycle requires evaluation. Closed loop induction motor drives can also be used.

## 19.5.1.8 Fans and blowers

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Axial flow fan	0.5 to 40 kW	As cage motors specially adapted for air stream use with impeller on motor shaft. Existing motors will be retained under inverter control and may require slight de-rating or slightly reduced max speed. Inverse cube law relationship between fan kW load and speed. Noise falls as the fifth power of fan speed. Open loop induction motor drives are most widely used.
Centrifugal fan	0.5 to 500 kW	Cube law kW/speed relationship extend acceleration time on large fans to moderate starting current requirement. Power saving important on large fans as is top speed fan noise. Open loop induction motor drives are most widely used.
Rootes type blowers	3 to 200 kW	Positive displacement blowers are constant torque and kW loading is linear with speed into a fixed system resistance. Load pulsates heavily. Rootes blowers are noisy but easily started. Power saving can be important. D.c. drives and closed loop induction motor drives predominate. Open loop induction motor drives can be used with care.

*19.5.1.9 Pumps*

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Centrifugal pumps	0.5 to > 500 kW	Early cage motors with 'A' and 'E' class insulation require care over winding temperature under inverter control. Power saving on large drives important. Open loop induction motor drives predominate.

*19.5.1.10 Paper and tissue*

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Paper machine and pumps	Up to 500 kW	Environment difficult with water, steam and paper pulp present. Pipe vent motors common. Often non standard a.c. and d.c. motors. Usually closely co-ordinated drives in a paper line. Closed loop induction motor drives and d.c. drives.
Winders and reelers	5 to 100 kW	Constant kW range over build-up range. Four quadrant operation with regenerative braking. IP23 motor enclosure with filter is common. Closed loop induction motor drives and d.c. drives.

*19.5.1.11 Printing*

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Printing press	Up to 200 kW	Some special co-axial motor designs for series connection on line. Field weakening for wide speed range. 4-quadrant with slow ramp acceleration and inch/crawl control plus emergency stop. Pipe vent where ink fumes may be a hazard. Closed loop induction motor drives and d.c. drives.
Folders, unwind & rewind stands	Up to 100 kW	Often integrated in printing line drive with press drive and unwind stand drive under 'master' control. Otherwise as above. Closed loop induction motor drives and d.c. drives.

*19.5.1.12 Packaging*

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Boxing, stamping, folding, wrapping	Up to 75 kW	Mostly 4-quadrant with slow ramp acceleration with inch/crawl and E/stop. Often integrated line control. PM Servo drives are widely used in precision packaging machines. Closed loop induction motor drives and some d.c. drives are also used.

*19.5.1.13 Engineering industries*

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Test rigs of many types	Up to >45 MW	Test rig drives require careful engineering. Often high speed with fast response, accurate speed and torque measurement, usually 4-quadrant with field weakening control. Engine test rigs require special knowledge of throttle control drive/absorb changeover and power measurement. Drive control/monitoring particularly important. Closed loop induction motor drives and d.c. drives. PM servo drives are also used for precision applications.

## 19.5.1.14 Wire and cable

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Bunchers and stranders	10 to 150 kW	Generally multiple drives with cage or bow, capstan plus take up drives under integrated control. Constant torque except take-up with 4-quadrant acceleration/deceleration with inch/crawl/E-stop controls. Motors require filter protection against metal dust entry.
Capstan	5 to 100 kW	Closed loop induction motor drives and d.c. drives. As above.
Take-up and unwind stands	5 to 50 kW	As above but constant kW over build-up ratio.
Extruders	5 to 150 kW	See extruders under plastics industry but control often be integrated in cable line drives.
Armourers	10 to 150 kW	As Buncher/Strander drive above.
Caterpillars	1.5 to 30 kW	Constant torque duty and low kW rating in view of low haul off cable speeds. Often integrated in cable line drives. Motor protection generally no problem. Closed loop induction motor drives and d.c. drives.

## 19.5.1.15 Hydraulics

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Pump and motor test rigs	Up to 250 kW	Hydraulic fluid is a contamination risk. Pipe vent often used. Generally constant torque to medium/high speeds with 4-quadrant drive. Speed torque and power measurement often required with full drive monitoring on endurance rigs. Closed loop induction motor drives and d.c. drives.

## 19.5.1.16 Electric motors and alternators

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
A.c. and d.c. motors/ generators/alternators test bed rigs	Up to >15 MW	All rotating electrical machine manufacturers have elaborate test bed rigs, supplying their own rotating machines and obtaining control systems from the drives industry to their own requirements. Closed loop induction motor drives and d.c. drives.

## 19.5.1.17 Textiles

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Ring frame machines, carding machines, looms	Up to 150 kW	Difficult environment in which IP55 enclosure has become a standard; ring frame Schrage and d.c. thyristor drive. Use pipe ventilation. All drives constant torque 4-quadrant for speed modulation (ring frame) or best speed holding accuracy with slow ramp acceleration/deceleration on carding drives. Special a.c. cage loom motors are high torque, high slip designs. Today a.c. inverter drives predominate since their characteristics are particularly suitable.

## 19.5.1.18 Foods, biscuit and confection

<i>Drive duty</i>	<i>Rating range</i>	<i>Comments</i>
Extruder	5 to 400 kW	Hose proof motors for plant cleaning. Continuous production requiring high levels of reliability, control and monitoring. Otherwise as plastics industry extruders.
Mixer	5 to 150 kW	As above and see chemical industry mixer drive.
Conveyors	0.5 to 120 kW	As above and see material handling industry conveyor drive.

## 19.6 Electromagnetic compatibility

Electromagnetic compatibility of electrical drive system is a complex but vitally important subject. By their very nature by rapidly switching voltages and/or currents, drives can form very effective noise generators. The design of the drive must therefore be very carefully considered from the early stages firstly to ensure that the drives own controls are not interfered with and secondly that the drive can be applied in a system without adverse effects on other equipment.

Various national and international standards exist for EMC—few have been written with power electronic drives in mind. Drive manufacturers are now making great efforts to design drives compliant with the existing and future standards—they should be consulted for advice on appropriate standards and compliance thereto.

## Bibliography and further reading

## 20.1 Energy conversion

Electromagnetic machines convert electrical into mechanical energy in devices with a limited stroke (actuator, brake, relay etc.) or continuous angular rotation (motor), or linear motion (linear motor).

Mechanical energy involves a force  $f_m$  acting over a distance  $x$  or a torque  $M_m$  acting over an angular displacement  $\theta$ . Electrical energy involves the displacement of a charge  $q$  (a current  $i$  for a time  $t$ ) through a potential difference (p.d.)  $v$ . The energies  $W$  and corresponding powers  $P = dW/dt$  are

Mechanical:

$$W_m = f_m x \quad P_m = f_m (dx/dt) = f_m u \quad (\text{linear})$$

$$W_m = M_m \theta \quad P_m = M_m (d\theta/dt) = M_m \omega_r \quad (\text{rotary})$$

Electrical:

$$W_e = vq \quad P_e = v(dq/dt) = vi$$

where  $u = dx/dt$  is the translational speed and  $\omega_r = d\theta/dt$  is the rotational speed. In an electromagnetic machine the basic physical conversion mechanism between the two forms of energy is the magnetic field, a characteristic property of electric current. The elements of electromagnetic/mechanical conversion are set out in Sections 2.4.1 to 2.4.3.

## 20.2 Electromagnetic devices

### 20.2.1 Electromagnets

Electromagnets for stroke-limited devices (e.g. actuators) are such that estimation of the flux distribution in the air gap (the working region) is difficult. The total magnetomotive force (m.m.f.) produced by a current  $i$  in an  $N$ -turn coil is  $F = Ni$ .

#### 20.2.1.1 Coil windings

Most coils for magnetic-circuit excitation are wound by one of the following (usually automated) methods: (1) on a former with end-cheeks; (2) on a bobbin that forms an integral part of the coil and comprises a moulded or fabricated construction of a suitable insulant; or (3) by a winding machine that feeds insulated wire into a self-supporting form, with an epoxy-resin binder.

The coil design is based on the provision of the required m.m.f. for a specified voltage (or current), with an acceptable coil temperature rise on a specified duty cycle.

*D.c. excitation* For direct current (d.c.), the current  $i$  at a coil terminal voltage  $v$  is determined by the coil resistance  $R = V/i = \rho L_{mt} N/a$ , where the  $N$  turns have a mean turn length  $L_{mt}$  and the conductor, of resistivity,  $\rho$ , has a cross-sectional area  $a$ . Then

$$a = \rho L_{mt} (Ni) / V = \rho L_{mt} F / V$$

for a total m.m.f.  $F$ . The current cannot be determined until the cooling conditions are established. Let the conductor current density be  $J$ , so that  $i = Ja$ ; then  $N = F/Ja$ . The total conducting cross-section of the coil is  $Na$  and the gross cross-sectional area of the wound coil is  $Na/k$ , where  $k$  is the *space factor*.

The power taken by the coil is  $P = Vi$ , and the consequent temperature rise on continuous operation is  $\theta_m = P/cS$ . Here  $c$  is a cooling coefficient representing the power dissipation per unit of the coil surface area  $S$  per degree Celsius rise of surface temperature above ambient. The value of  $\theta_m$  for continuously rated coils is usually specified. On intermittent or short-time rating the rise is a function of the thermal capacity of the coil.

*A.c. excitation* For alternating current (a.c.) the current  $i$  at voltage  $V$  is determined by the coil impedance  $Z = R + j\omega L$  at angular frequency  $\omega$ . An a.c. coil therefore tends to have fewer turns than one for d.c. Further, the coil inductance  $L$  varies widely, depending on the saturation of the ferromagnetic parts and in particular on the length of the air gap. A wide gap increases the magnetic reluctance and reduces  $L$ , but as the gap length reduces (e.g. by movement of the working parts) the inductance rises. If  $\omega L \gg R$ , as is usual, the root-mean-square (r.m.s.) value of the m.m.f. approximates to  $F = VN/\omega L$  with  $L$  estimated for the range of air gap lengths.

In practice, performance is based on data obtained on test. A particular feature is the double-frequency fluctuation of the mechanical force, which produces a characteristic 'chatter' in the closed position of the device; this may have to be mitigated by means of a shading ring.

#### 20.2.1.2 Coil design

*Space factor* A simple coil wound from a circular-section wire of diameter  $d$ , and insulated to a diameter  $d_i$ , will pack down in a manner that is affected by the method of winding, one layer partly occupying the troughs in the layer beneath it; the space factor may then approximate to  $k = 0.85(d/d_i)^2$ . Conductors of small diameter bed less effectively, and the space factor is reduced.

*Cooling coefficient* A typical value of the cooling coefficient  $c$  is  $0.075 \text{ W/m}^2$  per  $^\circ\text{C}$  above ambient. However, cooling conditions vary widely with the efficacy of ventilation.

#### 20.2.1.3 Operating conditions

Whether d.c. or a.c. excited, the current in an operating coil is affected by that movement of the working parts that closes or opens the air gap. Let a quiescent spring-loaded relay (*Figure 20.1(a)*) in the open position be connected to a direct source voltage  $V$ . The coil current begins to rise exponentially, but the armature does not move until the magnetic force exceeds the spring restraint. Thereafter, the shortening gap increases the coil inductance, setting up a counter electromotive force (e.m.f.) and checking the current rise and the attracting force. Finally, the armature reaches the closed position at the end-stop, dissipating kinetic energy in noise, bounce and mechanical deformation. The sequence of events, in terms of the gap length  $x$ , armature speed  $u$ , coil current  $i$  and time  $t$ , is shown in *Figure 20.1(b)*.

If the coil is energised from an a.c. source there are two further effects: the closing time depends on the instant in the cycle at which the voltage is applied and (more importantly) the operating force fluctuates. Ferromagnetic parts must be laminated to prevent excessive core loss and the counter-effects of eddy currents. Suitable sheet steel for the purpose has a core loss of less than  $5 \text{ W/kg}$ .

The force fluctuation can be reduced (but not eliminated) by a *shading ring* (*Figure 20.2*) embedded in one of the pole faces flanking the gap. Currents induced in the ring delay part of the pole flux. Thus the combination of shaded and unshaded flux gives a resultant that still fluctuates but does not at any instant fall to zero.

### 20.2.2 Tractive electromagnets

Two forms of tractive electromagnet are shown in *Figure 20.3*. Type (a) usually has cylindrical poles, sometimes with shouldered ends to retain the coils, a rectangular yoke to which the

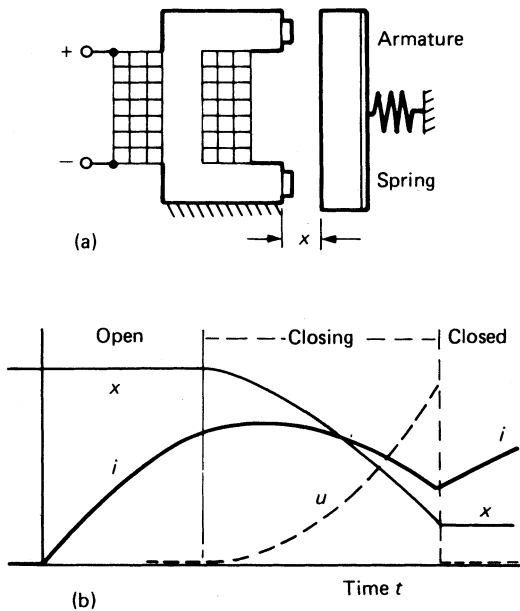

Figure 20.1 Operation of a d.c. relay

Figure 20.2 Shading coil or ring

Figure 20.3 Tractive electromagnets

poles are screwed or bolted, and a rectangular armature. Two exciting coils are used; they are connected to give opposite polarities at the respective pole ends. Type (b) has a single coil mounted on a cylindrical core to which the rectangular pole-pieces are attached. In both cases the total air gap length is the sum of the gaps at the respective poles; in some designs, however, the armature is hinged to the pole-piece at one end. In this case the free end forms the major gap.

In (a) let each polar surface have an area of  $250 \text{ mm}^2$  and be required to exert a total force of  $1.0 \text{ N}$  on the armature when both gaps are  $3.0 \text{ mm}$  long. Then with d.c. excitation,

$f = 400\,000 B^2 A$  giving  $B = 70 \text{ mT}$ , for which  $H = 57\,000 \text{ A-t/m}$ . For a total gap of  $6 \text{ mm}$  the gap m.m.f. required is  $340 \text{ A-t}$ . Adding 10% for the iron circuit and 25% for leakage, the total excitation required is about  $450 \text{ A-t}$ , from which the coil design follows.

With a.c. excitation it is necessary to estimate the inductance in the open and closed positions, and to adjust the number of turns for a given operating voltage so that adequate force is available. The change of magnetic flux between the two extreme armature positions is very much less than with d.c. operation, so that for the same (average) force in the open position, that in the closed position is only a little greater.

## 20.2.3 Actuators

### 20.2.3.1 D.c. actuators

Three typical arrangements for d.c. actuators are shown in Figure 20.4. Form (a) is convenient for small devices as the frame can be bent from strip; it is common for overcurrent and undervoltage relays. Form (b) may have a cast frame, and provides parallel flux paths through the iron. In (c) the cylindrical iron circuit presents a low reluctance, the circuit being completed by a lid attached by studs or screwed into the cylindrical body.

The iron end-stop should project well into the coil to improve flux concentration. It may be integral with the frame or screwed into it (in which case it can be used to locate and secure the operating coil). The plunger passes through the frame at the throat, the reluctance of which can be reduced by minimising the annular gap and extending the effective axial length, as shown at (b) and (c).

A typical iron clad actuator in part section is shown in Figure 20.5. With the dimensions  $a = 220 \text{ mm}$ ,  $d = 65 \text{ mm}$ ,  $x = 63 \text{ mm}$  and  $y = 450 \text{ mm}$ , the coil may develop about  $15 \text{ kA-t}$  to give a pull of  $400 \text{ N}$  across a  $25 \text{ mm}$  gap in the open position. The brass pin forms a stop, and cushions the plunger by expelling air through the vent.

With a flat-ended plunger the stroke is equal in length to the magnetic air gap. Maximum work (force  $\times$  displacement) occurs with a short stroke. By using a coned plunger (see Figure 20.5), maximum work is obtained with a longer stroke. If the cone angle is  $60^\circ$ , the comparable stroke is twice that for a flat-ended plunger for about the same magnetic pull. It is possible to obtain a wide variety of characteristics by modifying the shapes of the stop and plunger ends.

Figure 20.4 D.c. actuators

Figure 20.5 Iron clad 'pot' actuator

### 20.2.3.2 A.c. actuators

A common arrangement for a single-phase device is that shown in Figure 20.6. The E-type laminations are clamped. In the plunger, rivets should lie in a line in the flux direction to minimise eddy currents. To keep down the 'holding' current the plunger and stop ends should be flat.

Because of the many variables concerned, the design is complicated. An empirical rule is to allow  $1.5 \text{ mm}^2$  of plunger cross-section for every 1 N of force; this corresponds to a peak flux density of 0.8 T in the laminations. The size of the coil (and therefore the main dimensions) may be taken as having a length 2.5–3 times the stroke and a depth equal to the stroke. The number of turns  $N$  is estimated from

$$N = \frac{4}{4.4f} B_m A$$

where  $B_m A$  is the peak flux and  $f$  is the frequency. Final adjustment of  $N$  is made on test; it is reduced if the force is too low.

### 20.2.3.3 Polyphase actuators

A three-phase actuator has three limbs. Because of the phasing, the net force on the laminated bar armature assembly is never zero, and shading is not necessary.

The typical unit (Figure 20.7) is for operating a brake. It has three limb-coils E connected in star. The armature A is shown in the lifted (energised) condition. The plunger

Figure 20.7 Three-phase actuator

rod, fitted with a piston in the dashpot D, cushions the end of the stroke. A valve in the piston allows unretarded drop-out for quick brake application.

## 20.2.4 Lifting magnets

Lifting magnets are of use in the handling of iron and steel, as they dispense with hooks and slings. The maximum load of a magnet varies with the material to be lifted. A magnet capable of lifting 1 t of scrap may raise a 20 t load in the form of a thick solid piece with a flat upper surface. As the excitation is limited by temperature rise of the coil, the lifting capacity is also dependent on the duty cycle. For the comparatively arduous conditions normally ruling in industrial use, a robust and weatherproof construction is essential.

### 20.2.4.1 Circular magnets

The essential features of a circular magnet are shown in Figure 20.8. As the magnetic properties of the material lifted and the air gaps between the magnet poles and the material are both arbitrary and subject to wide variation, the design of a lifting magnet is generally based on thermal considerations. A given carcass and winding are assigned an empirically derived power rating such that the temperature rise of the coil is not excessive. The designer's aim is then to secure the maximum effective ampere-turn excitation and working flux density by adjustments of iron and conductor materials and heat dissipation. Allowances in design must be made for the development of adequate pull under conditions of low line voltage (e.g. 80% or less of nominal), and high conductor resistivity when hot.

The majority of lifting magnets, except those of small size, have a winding of flat strip, which is more adaptable than wires of circular section to the attainment of a good space factor with the large conductor areas generally necessary. Aluminium is sometimes employed in preference to copper for the advantage of weight economy: the weight of a magnet is

Figure 20.6 Single-phase actuator

**Figure 20.8** Circular lifting magnet

important as it represents a useless additional load to be moved every time its crane is operated. The winding in *Figure 20.8* is shown diagrammatically: it comprises a number of flat spirals with heat-resistant insulation.

The general dimensions are such that the diameter of the inner pole-face is about one-third of the overall diameter  $d$ . The load lifted is proportional to  $d^2$  and the power rating (in kilowatts) is of the order of  $4d^2$  (with  $d$  in metres). As regards the load, only in exceptional cases does close and uniform contact occur between magnet and load surfaces. The tendency for flux concentration over small contact regions develops local saturation and increases the effective gap.

#### 20.2.4.2 Rectangular magnets

Materials of regular shape, such as sheets, bars, pipes, etc., are well suited to lifting by rectangular magnets. The general

construction is similar to that of the circular type, the body being formed of a box-shaped steel casting with a central projection to give the inner polar surface.

The approximate lifting capacities of circular and rectangular magnets are given in *Table 20.1*.

#### 20.2.4.3 Control

Simple on/off switching is not practicable because of the high level of stored magnetic energy. The general control features needed are: (1) discharge resistors connected across the winding just prior to disconnection to reduce contact arcing and limit inductive e.m.f.; (2) auxiliary resistors introduced into the coil circuit after a predetermined time to limit coil temperature rise; and (3) reversal of polarity at a low current level to overcome remanence and so release small pieces such as turnings or scrap.

### 20.2.5 Crack detectors

Electromagnetic crack detection depends on the fact that, in magnetic material, the magnetic susceptibility of a fault is markedly inferior to that of the surrounding material. The success of the whole technique of magnetic crack detection depends largely on the care taken to ensure correct strength and direction of magnetisation. The following methods are used:

- (1) *Needle method.* The surface to be tested is explored with a small magnetic needle. This needle carries a pointer which moves over a scale, with a right and left motion as the needle turns on its pivot to align with the field distortion passing beneath it in the direction of the arrow. Thus the fault is detected. The sensitivity is increased by using a mirror and light beam.
- (2) *Powder method.* The part to be tested, previously cleaned, is laid across the arms of the machine, and the circuit-

**Table 20.1** Approximate lifting capacities

#### Circular magnets: load lifted (t)

Material	Magnet diameter (m)				
	1.6	1.4	1.2	1.0	0.6
Skull-cracker ball	18	15	10	7	3
Slabs	27	23	16	9	3
Pig-iron	1.3	1.0	0.6	0.3	0.1
Broken scrap	0.8	0.5	0.4	0.3	0.1

Steel turnings	0.5	0.3	0.2	0.1	0.005

#### Rectangular magnets: plate area lifted (m<sup>2</sup>)

Plate stack			Magnet dimensions (m)			
Plate thickness (mm)	Longest plate (m)	Maximum No. of plates in stack	0.6 × 0.4	1.0 × 0.4	1.4 × 0.4	2.0 × 0.4
0.4	1.5	80	0.9	2.3	3.5	4.6
1	2.8	20	1.8	4.3	6.5	8.7
3	4.2	10	2.4	5.5	8.3	11
6	6.7	5	2.8	6.5	9.7	13
12	9.5	3	3.2	7.5	11.3	15
25	13.5	2	3.2	7.5	11.3	15

Figure 20.9 Magnetic pulley separator

closing push-button switch depressed and released quickly. The article is then removed and sprinkled with special powder, the excess of which is blown away or shaken off; it will then be found that the defects are clearly indicated by the magnetic patterns.

- (3) *Fluid method.* This resembles the powder method but employs a fluid (e.g. paraffin) containing finely divided magnetic material in suspension.

Each of these techniques can be applied to the detection of cracks or other flaws in parts which have been magnetised. There are two methods of attaining this magnetisation in normal commercial use.

In the first method the part to be tested is placed between the poles of an electromagnet, in which case the direction of the field is from pole to pole. The second method utilises the fact that a concentric magnetic field forms round an electric current. A heavy low-voltage current is passed through the part itself, or through a current-bar adjacent to it or threaded through it.

As only those cracks or flaws will be shown up which cut across the magnetic field, it will readily be understood that the first method is most suited to the detection of transverse cracks, the second to the detection of longitudinal ones. However, apparatus designed for testing by means of the second method may be adapted to the detection of transverse cracks by encircling the part with several turns of cable through which the heavy current is passed.

## 20.2.6 Separators

The bulk handling of material, particularly where the process involves crushing or grinding, may require the use of a magnetic separator for removing unwanted or tramp iron and steel, or for quickly separating ferrous from non-ferrous scrap metals. Successful operation depends on uniformity of the feed thickness, and often an installation must include a suitable conveyor/feeder.

### 20.2.6.1 Types

*Magnetic pulley* This form of separator (Figure 20.9) comprises a number of circular cores and poles, the magnetic axis being that of the shaft. Coils encircle the cores, with d.c. (or rectified a.c.) excitation, and set up a magnetic field pattern. Iron attracted to the pulley surface is removed by aid of the conveyor belt, the material being drawn away from the magnetic field region. When the belt speed or width, or the thickness of the feed, is unsuitable for a single

pulley, two may be used, one at each end of a short auxiliary belt that receives its feed from the main conveyor.

*Drum* This has an advantage over the pulley type in respect of its more effective separation. A drum can operate in conjunction with a belt conveyor if placed below the head pulley and a suitable guide. Feed is readily arranged down a chute or directly on to the feeder tray, if one is provided. A common type of feeder has the tray oscillated by an eccentric motion, or vibrated in a straight-line motion, at about 15 Hz.

*Suspension* A structure resembling a lifting magnet is suspended over a conveyor belt. It operates successfully on feeds containing awkward shapes of tramp iron at a belt speed up to 2.5 m/s. The magnet will not automatically discharge its load, but the large gap can contain a considerable load. The power rating is large.

*Disc* Most machines utilise rotating discs with a sharp or serrated periphery, set above the conveyor belt and over the magnet. Separation of iron depends on the change of polarity of a given region of the disc as it rotates, so that ferrous particles can be released.

*Induction roll* A powerful magnet (Figure 20.10) is provided with a return path plate. Rollers set between them are

Figure 20.10 Induction roll separator

magnetised by induction. Material is fed into the top. Non-magnetic pieces fall through under gravity, while ferrous material adheres to the roller and is carried round and detached. Up to eight rollers in tandem may be used.

**Wetherill** The Wetherill separator has a single magnet unit mounted either side of a conveyor belt on which the material to be treated is passed beneath the upper magnet pole (Figure 20.11). Another belt is arranged over the upper pole of each magnet to take off the extracted ferrous material. The success of the separator depends on the shape of the magnet poles: the lower is flat and the upper is arranged with a ridge to concentrate the field. As the material passes under the magnets, each ferrous particle jumps towards the upper pole and is intercepted by the take-off belt, which in turn carries it to the side where it is discharged in a continuous operation. In practice, several magnets are used; the number of products that can be separated in a single operation is determined by the number of take-off belts, of which there are two per magnet unit.

#### 20.2.6.2 Ore separation

For dealing with material in large lumps the magnetic field must have a deep penetration. This involves widening out the poles. The flux density is inevitably weakened. Thus, while feed depths of 250 mm are usual with a drum of 1 m diameter for the removal of tramp iron, the depth must be cut to, say, 75 mm when feebly magnetic material is operated on.

An important branch of separation deals with the subdivision and concentration of ores, the constituents of which have permeabilities very much lower than that of iron. Data on this point are given in Table 20.2. The process may be performed in several ways. A single product can be removed from the bulk; several constituents may be removed, each separately, in a single operation; or the separation may be carried out by a wet process.

The general design for feebly magnetic materials differs from that for the removal of tramp iron, essentially in the necessary flux density. A material with a permeability of 1% of that of iron may require a gap density exceeding 1.6 T, and the field must be divergent. For this purpose the lower pole over which the material passes is made flat; the upper pole, whether fixed or moving, is provided with a concentrating V-edge so that particles travel to it out of the general bulk of the material treated.

Figure 20.11 Wetherill separator

#### 20.2.7 Clutches

The conventional clutch consists essentially of two members: the field member, which carries the exciting winding, and the armature member, consisting virtually of a steel ring which becomes attracted to the field member when the winding is energised. The engaging surfaces of these members have a friction lining for taking up the load when the clutch engages, and means are provided for spring disengagement of the armature when the winding is de-energised. As the clutch rotates in operation, it is necessary to employ slip-rings and brushes for the current supply.

A special type of clutch with a double friction lining is shown in section in Figure 20.12. In this case the field and armature members rotate together on the same shaft. The other shaft carries on a spring plate the lining carrier member. The two friction surfaces on this member engage between the armature and field members when the field coil is energised. General particulars for representative sizes of this type of clutch are given in Table 20.3.

#### 20.2.8 Couplings

Eddy-current couplings resemble induction motors in that they develop torque by 'slip', and the throughput efficiency falls with decrease of speed. In selecting a coupling the critical factors are the speed range and the load torque variation therein.

The essential features are shown in Figure 20.13. The outer member (the loss drum) is mounted on the shaft extension of the drive motor, and the inner member (the pole system) on the driven shaft. Operation depends on the induction of current in the loss drum by e.m.f.s resulting from the speed difference between the driving and driven shafts. The two types illustrated are:

- (1) *Interdigitate*. This is common for drives transferring up to about 100 kW. The loss drum is of plain ferromagnetic material of low resistivity, normally with forced cooling. The 'claw'-shaped pole structure gives a multipolar field by means of a single exciting coil. There is substantial interpolar leakage flux.
- (2) *Inductor*. The toothed rotor produces an alternating flux density pattern in the loss drum by the modulation of the airgap permeance. An annular exciting coil, fixed or rotary, causes the two air gaps to have opposite polarity,

the flux between them completing its path through the loss drum.

### 20.2.9 Brakes

The three basic forms of brake are: (i) solenoid-operated, (ii) tractive, and (iii) a thruster (electrohydraulic). In each case a brake-band or (more commonly) a brake-shoe is pressed against the brake-drum, either by weights or by springs operating through a lever. The use of springs is preferable, especially with large brakes, as the cushioning of the shock due to a falling weight introduces additional problems of design as well as limiting the positions in which the brake may be mounted. The brake is released by the operating force acting against the force due to the resetting spring. The brake is held in the off position for as long as the controlling circuit is energised.

The pressure used on the friction surfaces and the coefficient of friction are of the same order as for clutches. The pressure employed should be such as to give a reasonable rate of wear, and the figure chosen will determine the width of shoe required for a given operating force and wheel diameter. In general practice there are two brake-shoes, each embracing about one-quarter of the wheel circumference.

#### 20.2.9.1 Solenoid brake

The brake is held 'off' by a solenoid/plunger device acting through leverage against spring loading, the latter being adjustable to suit the brake-torque requirements. If the brake is energised only for short periods, with intervening periods of rest (with the brake on), it is usually possible to fit a coil giving more ampere-turns than are obtainable with a continuous rating and thus to use a greater resetting spring pressure, giving increased braking torque.

#### 20.2.9.2 Tractive brake

The example in *Figure 20.14* embodies a tractive electro-magnet operating on inner and outer disc armatures A when

the magnetising coil B is energised. The mechanical features are the adjusting wedge C, the brake-shoes D, the adjusting nuts E for the outer shoe-lever F, the torque spring G and its adjuster H, the tie-rod J, the terminals K, and the shoe-clamping screws L. Armatures AA rest in slots in the base and tend to remain against the slot abutments as a result of spring pressure and magnetic force. The powerful mainspring forces the armatures AA apart, causing the inner to apply pressure to the right-hand shoe and the outer to the left-hand shoe through the tie-rod J. When coil B is energised, the armatures AA mutually attract, so releasing the brake.

#### 20.2.9.3 Thruster brake

The thruster brake employs a hydraulic thruster cylinder, with a piston acting under the fluid pressure produced by a small motor-driven pump unit. The power consumption is relatively low, but there is a short time-lag in brake response.

### 20.2.10 Magnetic chucks

In cases where awkwardly shaped ferrous-metal parts have to be machined in any quantity, the electromagnetic chuck forms a valuable auxiliary to various kinds of machine tools. The chuck contains a number of distributed windings which when energised from a d.c. source produce a concentrated and uniform field at the surface of the chuck, which is ground flat so as to form a suitable base-plate for accurate machining operations. The magnetic pull on ferrous materials in contact with the chuck surface is sufficient to prevent movement under all normal machining stresses.

When the current is switched off, the residual magnetism is in some cases sufficient to prevent easy removal of the part. The usual form of control switch accordingly has a demagnetising position.

The principle can be applied to rotating chucks, in which case slip-rings are necessary to convey exciting current to the windings.

In some cases *permanent-magnet* chucks can be employed. Hold and release of the workpiece are effected by an operating

**Figure 20.13** Eddy-current couplings

lever which, in the off position, closes the flux paths of the magnets through high-permeability bridges and reduces the flux through the work. With either electro- or permanent-magnet forms, the workpiece may have to be demagnetised after machining.

### 20.2.11 Vibrators

A vibrator generator develops a vibro-motive force of adjustable magnitude and frequency for the noise, fatigue and vibration testing of small structures and for the assessment of mechanical resonance.

**Figure 20.14** Tractive electromagnetic brake

#### 20.2.11.1 Electrodynamic vibrator

Figure 20.15(a) shows the essential features of an electrodynamic vibrator, which are those of a powerful loudspeaker mechanism in which a circular coil, carrying an alternating current and lying in a constant radial magnetic field, develops vibratory force and displacement of corresponding frequency. A construction of the form shown can be adapted to develop torsional vibration by pivoting the armature centrally.

#### 20.2.11.2 Magnetostrictive vibrator

The magnetostriction effect can be employed by placing the a.c. exciting coil around a stack of magnetostrictive material (Figure 20.15(b)). Mechanical amplification of the very small displacement is provided by a truncated drive rod. Vibrators of this kind are generally fixed-frequency devices, but they are suitable for relatively high frequencies only.

Single-frequency low-power vibrators can be constructed with piezo-electric drive. As large crystals are not readily available, these vibrators are usable only in the ultrasonic frequency range.

### 20.2.12 Relays and contactors

Relays and contactors, a.c. or d.c. excited, are widely employed for low- and high-power switching. The basic features are shown in Figure 20.16.

#### 20.2.12.1 Contactors

The term 'contactor' applies to power-control devices. For d.c. operation the contactor is made single- or double-pole as required. When the coil is energised, a magnetic field is established across the air gap and the armature is attracted to the pole to close the contacts. The moving contact has a flexible conductor attached to it in order to avoid passing current through the hinge. The destructive effects of d.c. arcs are such as to make necessary an arc shield and magnetic blow-out arrangement. The blow-out winding carries the main current and its connection is so arranged that the arc is expelled from the contact region when the contacts separate.

Figure 20.15 Vibrators

Figure 20.16 Elements of a contactor

For a.c. service the contactor normally has two or three poles. The magnetic circuit is laminated and the pole-face has a shading coil to reduce 'chatter'. Blow-out coils may not be provided because the principle operates less effectively on a.c.; reliance may be placed on extinction at a current zero. A typical a.c. contactor is illustrated in Figure 20.17.

**Ratings** These have been standardised. The severity of operating conditions varies considerably according to the class of service. Although the cleaning action on the contacts due to frequent operation is desirable in removing cumulative high-resistance films which tend to increase heating, this class of service causes greater contact wear and erosion for a given loading than would occur with less frequent operation. Conversely, very infrequent operation which involves the contacts carrying current for long periods is not onerous from the viewpoint of wear and erosion but is conducive to the formation of high-resistance surface films unless a suitably low temperature is maintained so as to limit the formation of the films. The permissible temperature rise for different types of contact is given in Table 20.4. Operation must be satisfactory with the shunt windings at final rated temperature and with reduced operating voltage (80% of normal for d.c., 85% for a.c.).

Table 20.4 Temperature limits for contacts

Type of contact	Temperature rise (°C)
Solid copper in air	
Standard rating	65
Uninterrupted rating	45
Solid copper in oil	45
Laminated copper in air or in oil	40
Solid silver or silver faced in air	80
Carbon	100

### 20.2.12.2 Relays

The electromagnetic relay operates one or more sets of contacts by the attraction of a movable armature towards a magnetised core. The representative types shown in Figure 20.18 are: (a) the 'telephone' type with pivoted armature; (b) the 'commercial' version of (a); (c) a mercury switch with hinged armature; and (d) a spring-suspended armature. An important feature is the operating time.

**High-speed operation** may be obtained by one or more of the following methods: (i) lamination of the magnetic circuit to minimise eddy-current delay; (ii) reduction of the mass of moving parts; (iii) use of a large coil power; or (iv) reduction of coil inductance.

**Low-speed operation**, sometimes needed to introduce a time-lag, is obtained by: (i) use of a lag (or *slugging*) coil comprising an additional and separate short-circuited loop or winding; (ii) use of a series inductor or shunt capacitor; or (iii) addition of an external time-delay relay.

**Design features** Contact sets may be normally open or normally closed, and both types may be fitted on the same relay mechanism. The arrangement is determined by the operating sequence required: i.e. make, break, change-over, make-before-break, break-before-make. The contact size and material must be chosen in accordance with the rating and electrical characteristics of the circuits controlled.

Ideally, the contacts should operate cleanly and with no bounce. They should be of adequate size and of the most suitable material. In extremely low-voltage circuits the contact resistance is usually an important consideration and special precautions may also have to be taken to ensure reliable operation under conditions of vibration or shock.

Similarly, in cases of high-current switching it may be necessary to ensure wide separation of the contacts or even to

Figure 20.17 Triple-pole a.c. contactor

Figure 20.18 Electromagnetic relays

arrange for several gaps to operate in series. In some cases it may be necessary to use arc-suppressing circuits.

The number and type of the contacts and springs determines the switching operation to be performed by the relay; this factor also determines the work to be done by the magnetic circuit. It follows, therefore, that the choice of a suitable coil and iron circuit design is determined by the contact arrangement of any particular relay. Various configurations of magnetic circuits and materials are used in the relays under review, depending upon their particular application. For example, in the high-sensitivity relays, where the air gap has to be kept to a minimum, it is necessary to use materials having a very low residual magnetism and high permeability.

The power required to operate the relay is determined by the spring-set arrangement and the magnetic circuit. The method of construction is important, since it largely determines the safe operating temperature of the winding and this, in turn, governs the coil power and the maximum pull available at the armature. By increasing the area of the flux path while maintaining the ampere-turns and coil power constant, the total air gap flux, and therefore the armature pull, can be increased and the increased coil area will permit cooler operation of the coil. This may, however, lead to a relay that is physically larger than can be tolerated. In practice, therefore, it is more reasonable to build a relay of a

given size and to use other means to amplify the controlling power.

The continuous power input to a given relay coil is limited only by the maximum temperature that the coil insulation can withstand without breakdown. This temperature is governed by the environmental conditions as well as by the coil construction and the quality of the insulating material.

Many of the functions performed by the electromagnetic relay have been taken over by solid-state switching.

### 20.2.13 Miniature circuit-breakers

The miniature circuit-breaker (m.c.b.) is, for the control of small motors and domestic subcircuits, considered primarily as an alternative to the fused switch. The appropriate British Standard is BS 3871, which lays down specific technical requirements. The usual form of the m.c.b. embodies total enclosure in a moulded insulating material. As the operating mechanism must be fitted with an automatic release independent of the closing mechanism, the m.c.b. is such that the user cannot alter the overcurrent setting nor close the breaker under fault conditions. At the same time the m.c.b. must tolerate harmless transient overloads while clearing short circuits. For most practical conditions, a change-over from time-delay switching to 'instantaneous' tripping at currents exceeding 6–10 times full-load rating is suitable.

#### 20.2.13.1 Tripping mechanisms

Methods of achieving the required operating characteristics can be classified as (i) thermomagnetic, (ii) assisted thermal and (iii) magnetohydraulic. In the *thermomagnetic* method the time-delay is provided by a bimetal element, and the fast trip by a separate magnetically operated mechanism based on a trip coil. In the *assisted thermal* method the bimetal is itself subjected to magnetic force. The *magnetohydraulic* mechanism incorporates a sealed dashpot with a fluid and a spring restraint, the dashpot plunger being of iron and subject to the magnetic pull of the trip coil. The essential features are illustrated in Figure 20.19.

**Thermomagnetic** The bimetal element shown in Figure 20.19(a) may carry the line current or, for low current ratings, be independently heated. Its flexure operates the trip latch through a crank. On overcurrent the magnetic force acts directly on the latch bar, with or without the aid of the bimetal deflection.

Figure 20.19 M.c.b. trip mechanisms

**Assisted thermal** The time-delay characteristic is provided by a bimetal element, and instantaneous tripping is provided by magnetic deflection of the bimetal. The operation is shown in Figure 20.19(b). A bar of magnetic material is placed close to the bimetal element, and the magnetic field set up by the current develops a pull on the bimetal such as to increase its deflection and release the trip latch. The magnetic effect is proportional to the square of the current and so becomes significant on overcurrent. However, as the position of the bimetal element on the occurrence of a short circuit is arbitrary, there is no well-defined change-over point at which instantaneous tripping occurs.

The method is cheap and simple, but is difficult to design for low-current (e.g. 5 A) breakers because the operation tends to be sluggish, particularly at fault-current levels that are less than 500 A.

**Magnetohydraulic** This method, shown in Figure 20.19(c), combines in one composite magnetic system a spring-loaded dashpot with magnetic slug in a silicone fluid, and a normal magnetic trip. When the line current flows, the magnetic field produced by the trip coil moves the slug against the spring towards the fixed pole-piece, so reducing the reluctance of the flux path and increasing the magnetic pull on the trip lever. If it reaches the end of the dashpot, the pull is sufficient to operate this lever and trip the circuit-breaker. On sudden overcurrent exceeding 6–10 times full-load value, there is sufficient pull at the fixed pole-piece to attract the armature of the trip lever regardless of the position of the slug in the dashpot. The characteristic is more definite and satisfactory

for low-current ratings than that of the assisted thermal mechanism.

### 20.2.13.2 Operating features

Thermal operation by bimetal elements implies that the effective current rating is a function of the ambient temperature. It is the practice, if complete ambient compensation is not fitted, to rate m.c.b.s in such a way as to allow for the type of enclosure. With magnetohydraulic devices the tripping is independent of the ambient temperature over a specified range, the small variations due to change of viscosity of the damping fluid being minimised by use of a fluid with a nearly flat viscosity–temperature characteristic.

The combination of thermal and magnetic functions is not easily controlled for low current ratings, and for m.c.b.s with such ratings the tolerances on operation must be wider than they are for larger currents.

Normally, m.c.b.s are suitable only for a.c. circuits. As with all a.c. switchgear, the problems of breaking efficacy are associated not only with the actual short-circuit current but also with its asymmetry and power factor.

As m.c.b.s can be linked to give two- and three-pole versions, so arranged that a fault on one pole will produce complete circuit isolation, the risk of single-phasing in motor control is effectively eliminated. In other directions, however, m.c.b.s cannot necessarily replace fuses: they do not possess the high short-circuit breaking capacity of the modern h.r.c. fuse, nor do they have its inherent fault-energy limitation. If, therefore, conditions are such that back-up protection has to be provided for m.c.b.s, the 'take-over' zone should be of the order of 1.0–1.3 kA.

### 20.2.14 Particle accelerators

Modern accelerators produce high-energy beams of electrons, ions, X-rays, neutrons or mesons for nuclear research, X-ray therapy, electron irradiation and industrial radiography. If a particle of charge  $e$  is accelerated between electrodes of p.d.  $V$  it acquires a kinetic energy  $eV$  electron-volts ( $1 \text{ MeV} = 4.6 \times 10^{-13} \text{ J}$ ). Accelerators are classified as *direct*, in which the full accelerating voltage is applied between the two electrodes; *indirect*, in which the particles travel in circular orbits and cyclically traverse a region of electric or magnetic field, gaining energy in each revolution; and *linear*, in which the particles travel along a straight path, arriving in correct phase at gaps in the structure having high-frequency excitation, or move in step with a travelling electromagnetic wave.

#### 20.2.14.1 Direct accelerators

The Cockcroft–Walton multiplier circuit has two banks of series capacitors, alternately connected by rectifiers acting as change-over switches according to the output polarity of the energising transformer. The upper limit of energy, about 2 MeV, is set by insulation. A typical target current is 100  $\mu\text{A}$ .

The Van de Graaff electrostatic generator is capable of generating a direct potential of up to about 8 MV of either polarity. It has an endless insulating belt on to which charge is sprayed from 'spray-set' needle-points at about 50 kV. The charge is carried upwards to the interior of the high-voltage (h.v.) electrode, a metal sphere, to which it is transferred by means of a second spray set. H.v. insulation difficulties are overcome by operating the equipment in a tank filled with a high-pressure gas, e.g. nitrogen–freon mixture at 1500 kN/m<sup>2</sup>. In two-stage Van de Graaff generators for higher energies, negative hydrogen ions are accelerated from earth potential to

6 MeV; they are then fired into a thin beryllium foil 'stripper' which removes the electrons from the outer shells of the atom and leaves the remanent ions moving on with little change of energy but with a positive charge. The second stage brings these ions back to earth potential and the total energy gain is 12 MeV. To bring ions on to a small target the accelerating and deflecting fields must be accurately controlled, and scattering limited by evacuating the accelerator tubes to very low pressure. The energies are sufficient for the study of nuclear reactions with the heaviest elements.

#### 20.2.14.2 Indirect (orbital) accelerators

Indirect (orbital) accelerators may have orbits of approximately constant radius with a changing magnetic field (betatrons and synchrotrons) or orbits consisting of a series of arcs of circles of discrete and increasing radii in a constant magnetic field (cyclotrons and microtrons).

**Betatron** The betatron is unique in that the magnetic field not only directs particles into circular orbits but also accelerates them. The magnet has an alternating field of which only one quarter-period is used. Electrons are accelerated in an evacuated toroidal chamber between the poles of the magnet. They are injected at an energy corresponding to a low magnetic field, which bends them in circular orbits round the toroid. A cross-section of the poles and vacuum chamber is shown in *Figure 20.20*. As the magnetic flux through an electron orbit increases during the cycle of alternation, the electron experiences a tangential force, and its gain in energy per revolution is the voltage that would be induced in a loop of wire in the orbit. As the electron gains energy, the magnetic guide field intensity at the orbit increases at a suitable rate. To keep the electron on a constant radius from injection to peak energy requires the rate of change of intensity at the orbit to be half that of the mean flux per unit area within the orbit. At peak energy (or earlier) the electrons are caused to move away from their equilibrium orbit and to strike a target inside the vacuum chamber, producing X-rays or corresponding energy. The output consists of short pulses of radiation whose repetition rate is the frequency of the magnet excitation. Energy limitations are set by the size and cost of the magnet and the radiation loss when a high-energy electron has circular motion.

**Synchrotron** The synchrotron uses an annular magnetic guide field which increases as the particles gain energy, as in the betatron, so that they maintain a constant orbit radius. Electrons are initially accelerated by the action of central 'betatron bars' which saturate when the main magnetic field corresponds to an energy of 2–3 MeV when electrons travel at a velocity only 1–2% less than the velocity of light. Further

Figure 20.20 Cross-section of a 20-MeV betatron

gain of energy is produced by radio-frequency (r.f.) power at the frequency of orbital rotation (or a multiple of it) that is fed to resonators inside the vacuum chamber. The particles become bunched in their orbits so that they pass across the accelerating gap in the resonator at the correct phase of the r.f. field. The limitation on electron acceleration is now mainly set by radiation losses due to circular motion.

Protons are injected at about 500 keV, which produces a velocity of only 3% of that of light. Further acceleration changes the frequency of orbital rotation. For a proton synchrotron the magnetic guide field strength and the r.f. power frequency have to be varied accurately over large ranges.

**Cyclotron** This early form of accelerator consists of a vacuum chamber between the poles of a fixed-field magnet containing two hollow D-shaped electrodes which load the end of a quarter-wave resonant line so that a voltage of frequency 10–20 MHz appears across the accelerating gap between the 'D's. Positive ions or protons are introduced at the centre axis of the magnet and are accelerated twice per rotation as they spiral out from the centre. The relation between particle mass  $m$ , charge  $e$ , magnetic flux density  $B$  and frequency  $f$  is  $f = Be/2\pi m$ . Energy limitation is set by the relativistic increase of mass, which limits the speed of high-energy particles so that their phase retards with respect to the r.f. field.

**Synchrocyclotron** In this device the energy limitation of the cyclotron can be removed by modulating the oscillator frequency to a lower value as a bunch of particles gains energy.

**Microtron** In the microtron, or electron cyclotron, electrons are accelerated in a vacuum chamber between the poles of a fixed-field magnet. The orbits consist of a series of discrete circular arcs which have a common tangent at a resonant cavity in which the electrons gain their successive increases of energy from an r.f. electric field. The highest energy achieved with such a machine is 6 MeV, and mean currents are less than 1  $\mu$ A.

#### 20.2.14.3 Linear accelerators

Indirect accelerators of protons have so far used a resonant cavity in which drift-tube electrodes are introduced that distort the fields and enable particles to be shielded from field reversals. Particles are accelerated between gaps and move between centres of successive gaps in one complete period of oscillation (*Figure 20.21*). Oscillators operating at about 200 MHz and a pulse power of 1–2 MW are used to excite the cavity for some hundreds of microseconds. Injection is by a Cockcroft–Walton or Van de Graaff device.

An important device for electron acceleration is the travelling-wave accelerator, using megawatt pulses of r.f. power at 3000 MHz. The power is propagated along a cylindrical waveguide loaded with a series of irises. A travelling wave is set up with an axial electric-field component, and correct dimensioning of the iris hole radius  $a$  and the waveguide

Figure 20.21 Field resonant cavity for a proton accelerator

radius  $b$  (Figure 20.22) enables the propagation velocity and the field-intensity/power-flow relation to be varied. An electron injected along the axis with an energy of the order of 45 keV is accelerated by the axial field, and as its velocity changes it remains in correct phase with the travelling field, the propagation velocity of which is varied to match. A fixed axial field is required to provide for electron focusing.

High-energy machines with low beam-currents have been used in the USA, low-energy machines with high beam-currents in the UK. The 25 MeV Harwell accelerator has a length of 6 m divided into six sections, each fed by a 6 MW klystron amplifier to give a peak beam-current of 1 A and a mean output power of 30 kW.

#### 20.2.14.4 Large machines

The Harwell proton synchrotron gives the particles an energy of 7 GeV in an orbit of radius 19 m within a 7000 t magnet. The magnet takes 10 kA to raise the orbit flux density to about 1.4 T in 0.75 s, to hold this value for 0.25 s and to reduce it to zero in 0.75 s, with a repetition frequency of about two cycles per hour. The inductance of the magnet is about 1.1 H, and to produce a rate of change of current of  $10/0.75 = 43.3$  kA/s the magnet supply voltage must be about 14 kV. The peak stored energy is 40 MJ. The supply is from a pair of 3750 kW/75 MW motor/generators through rectifiers.

The new accelerator for CERN near Geneva is to use the existing 25 GeV machine to inject particles into a 300 GeV proton synchrotron with an orbit of diameter about 2.2 km. The magnet will employ superconducting exciting windings giving a flux density of 4–6 T. The design is such that it can be built initially with only alternate magnet sections, and upgraded in energy later without basic alteration of the main structure, possibly to 800 GeV.

## 20.3 Industrial rotary and linear motors

The elements discussed in Section 2.4.3.6 indicate that there are two methods of developing a mechanical force in an electromagnetic machine.

- (1) *Interaction.* The force  $f_e$  on a conductor carrying a current  $i$  and lying in a magnetic field of density  $B$  is  $f_e = Bi$  per unit length, provided that the directions of  $B$  and  $i$  are at right angles; the direction of  $f_e$  is then at right angles to both  $B$  and  $i$ . This is the most common arrangement.
- (2) *Alignment.* Use is made of the force of alignment between two ferromagnetic parts, either or both of which may be magnetically excited. The principle is less often applied, but appears in certain cases, e.g. in salient-pole synchronous machines and in reluctance motors.

Figure 20.22 Fields in a corrugated waveguide

### 20.3.1 Prototype machines

Three basic geometries (Figure 20.23) satisfy the requirement for the relative orientations of  $B$ ,  $i$  and  $f_e$ . For a rotary case the *cylindrical* form is the most common, while the *disc* with its short axial length suits particular applications. The *flat* form is employed for linear motion.

Such machines are almost exclusively *heteropolar* (i.e. have alternate north and south poles). To maintain unidirectional interaction force, the direction of the current in a given rotor conductor must reverse as it passes from a north pole to a south pole region.

#### 20.3.1.1 Heteropolar cylindrical machine

A heteropolar cylindrical machine for a two-pole magnetic circuit is shown in Figure 20.24. The active region is the air gap between stator and rotor. In Figure 20.24(a) the stator conductors are arranged (normally in slots) on the surface and are connected so as to develop the current-sheet pattern indicated, giving rise to a distributed m.m.f. of peak value  $F_1$  on the axis of the winding. A corresponding rotor current-sheet pattern sets up an m.m.f.  $F_2$ . If the m.m.f. distributions are assumed to be sinusoidal, the torque on the rotor can be shown to be

$$M_e = k F_1 F_2 \sin \lambda_c$$

where  $\lambda_c$  is the *torque angle* between the stator and rotor winding axes, and  $k$  is a function of the air gap dimensions. For  $\lambda_c = 0$  the m.m.f.s  $F_1$  and  $F_2$  are in alignment and there is no torque. Displacement of the rotor increases the torque, which reaches a maximum for  $\lambda_c = \pi/2$  rad. For further displacement the torque falls, to become zero again for  $\lambda_c = \pi$  rad.

The machine in Figure 20.24(b) has a fixed optimum torque angle  $\lambda_c = \pi/2$  rad. Here the rotor must have a closed winding and be provided with a commutator or alternative switching device so that each conductor, as it passes from a north to a south polar region, has its current automatically reversed. Then the direction of  $F_2$  is fixed for all operating conditions. As the direction of  $F_1$  is also fixed, it is usually developed by salient poles.

Figure 20.23 Basic geometries for electromagnet machines

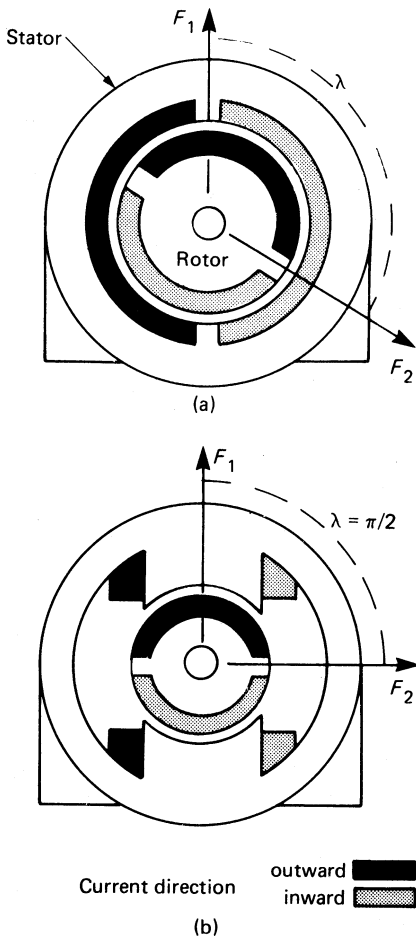

Figure 20.24 Prototype two-pole cylindrical machines

### 20.3.1.2 Types of machine

The three most common machines—synchronous, induction (asynchronous) and commutator—are all heteropolar and have at least one member cylindrical. They are distinguished by the nature of the supply (a.c. or d.c.) and that of the air gap flux (travelling wave or fixed axis).

**Travelling-wave gap flux** The stator current-sheet pattern in Figure 20.24(a) is set up by a three-phase winding ABC as in Figure 20.25 for a two-pole machine. With the phase windings excited by balanced symmetrical three-phase currents of frequency  $f_1$ , the sequential cyclic reversal of currents in the displaced windings shifts the current-sheet pattern, as shown for peak current (i) in phase A and (ii) in phase B (one-third of a period later). Thus the stator m.m.f.  $F_1$  produces a travelling wave of m.m.f. and air gap flux (often called a 'rotating field') moving at synchronous speed  $n_s = f_1/\tau$  (rev/s) or angular speed  $\omega_1 = 2\pi f_1$  for a three-phase supply of frequency  $f_1$  to a two-pole machine; in general  $n_s = f_1/p$  and  $\omega = 2\pi f_1/p$  for a machine with  $p$  pole-pairs.

Let the rotor, rotating at angular speed  $\omega_r$ , have a three-phase winding carrying currents of frequency  $f_2$ ; then it has an m.m.f.  $F_2$  rotating at angular speed  $\omega_2 = 2\pi f_2$  with respect to the rotor body, and therefore at  $\omega_r \pm \omega_2$  with respect to the stator. For a steady unidirectional torque to be developed,

Figure 20.25 Production of a travelling-wave field

$F_1$  and  $F_2$  must rotate in synchronism to preserve unchanging the torque angle  $\lambda$ . Thus  $\omega_r \pm \omega_2 = \omega_1$  is the essential running condition.

**Synchronous machine** The rotor is d.c. excited, so that  $F_2$  is 'fixed' to the rotor body; then  $\omega_2 = 0$  and  $\omega_r = \omega_1$ . The rotor must therefore rotate synchronously with the stator travelling-wave field. The torque angle accommodates to the torque demand up to a maximum for the torque angle  $\lambda \leq \pi/2$  rad. The machine can operate in both generator and motor modes by simple reversal of the torque angle.

**Induction machine** The rotor winding, isolated and closed, derives its current inductively from the stator. If the rotor spins at synchronous speed, its conductors move with the stator field and no rotor current can be induced. However, if  $\omega_r$  is less than  $\omega_1$  by a fractional 'slip'  $s = (\omega_1 - \omega_r)/\omega_1$ , the rotor conductors lie in a field changing at slip frequency  $s\omega_1$ , and currents of this frequency are induced to provide an m.m.f.  $F_2$  travelling around the rotor at this frequency. This gives  $\omega_r = \omega_2 = \omega_1$ , the required condition. Torque is developed for any slip  $s$  other than zero (synchronous speed), with  $F_1$  and  $F_2$  mutually displaced by the torque angle. By driving the machine above synchronous speed the slip and torque are reversed, and the machine generates.

**Fixed-axis gap flux** In the usual constructional form (Figure 20.24(b)), the gap flux is produced by the stator m.m.f.  $F_1$ , generally with the poles salient. The rotor m.m.f.  $F_2$  has the optimum torque angle  $\lambda \leq \pi/2$  rad. As the rotor spins, the current of an individual conductor is reversed as it passes from the outward- to the inward-directed region of the current sheet in the process of commutation. In consequence the machine can develop torque at standstill and at any practicable speed.

**D.c. commutator machine** Both stator and rotor windings are d.c. excited. The torque is smooth and continuous, with simple control of speed and both motor and generator operation. In small d.c. motors the stator may be magnetised by permanent magnets, dispensing with the exciting winding.

**Single-phase commutator machine** As simultaneous reversal of  $F_1$  and  $F_2$  does not affect the direction of the torque, the d.c. motor can be operated on a one-phase supply with the stator and rotor windings connected in series. However, the torque has a double-frequency pulsation about a unidirectional mean.

**Other forms** There are many variants, especially in small and miniature machines. Single-phase induction motors require special starting techniques ('split-phase', 'shaded-pole'). Some operate on alignment torque ('reluctance', 'hysteresis', 'brushless', 'stepper'). A few large homopolar d.c. machines have been devised.

**Disc motors** The geometry shown in Figure 20.23 has been applied with permanent-magnet multipolar field systems to machines that must have a very short axial length, e.g. for driving cooling fans for motor vehicles.

**Linear motors** These are most usually based on the three-phase induction-motor principle.

## 20.3.2 D.c. motors

In spite of the fact that a standard d.c. motor costs 1.5–2 times as much as a cage induction motor, and that alternating current is universal for general power distribution, the scope for d.c. motors is still large, particularly for drives requiring speed control or some other special feature. D.c. motors are built in all sizes from fractional-kilowatt up to about 4 MW, the upper limit being imposed by commutation problems.

In addition to the standard types of motor (shunt, series or compound) which are normally fed from a constant-voltage d.c. supply, many modern d.c. motors incorporate thyristors enabling them to operate from a standard a.c. supply. The thyristors rectify the alternating voltage and, by gate control, enable the resulting direct voltage to be varied, thereby giving a wide range of speed control.

### 20.3.2.1 Characteristics

The connections and basic torque–current and speed–torque characteristics of standard shunt, series and compound motors are given in Figure 20.26. Motors with separately excited fields are often used for control purposes.

When connected to a d.c. supply of voltage  $V$  a motor takes a current  $I = \frac{P}{V\eta_s}$  when developing a useful output power  $P$ . The efficiency  $\eta_s$  varies with the rating: typical rated currents are given in Table 20.6 for a range of operating voltages. The rotational e.m.f. in an armature of resistance  $r$  over the brushes and carrying a current  $I_a$  is  $E = \frac{4}{\pi} - I_a r_a$ . The power-conversion relation is  $E I_a = \frac{4}{\pi} \omega_r$ , where  $M$  is the torque and  $\omega_r = \frac{2}{\pi} \pi n$  is the angular speed. Then

$$E = \frac{4}{\pi} - \frac{4}{\pi} r_a = \frac{2}{\pi} (p/a) n N \Phi = \frac{4}{\pi} n \Phi \quad M = \frac{4}{\pi} \Phi I_a / 2\pi s$$

where  $\Phi$  is the flux. Here  $K = \frac{2}{\pi} (p/a) N$  involves the number of pole-pairs ( $p$ ), the total number of turns ( $N$ ) on the armature and the number of pairs of parallel paths ( $a$ ) of the winding. For simple lap and wave windings,  $a = \frac{4}{\pi}$  and  $a = \frac{2}{\pi}$  respectively. In a shunt-connected machine the total input current  $I$  is the sum of the armature and field currents,  $I = I_a + I_f$ . In a series-connected machine the same current  $I$  flows in both field and armature windings.

**Shunt excitation** The field winding has the constant terminal voltage applied to it so that the flux will be approximately constant and the torque will be proportional to the armature current. Speed is proportional to  $E$  and is approximately constant since  $I_a r_a$  is normally not more than 3–5% of  $V$  at full load. In practice, the flux will, owing to armature reaction, be distorted when the machine is loaded, the flux density under the leading pole tips being increased and that under the trailing pole tips decreased. Owing to saturation of the iron in the teeth under the leading pole tips, the increase in density there is less than the decrease in density under the trailing tips, so that there is a net reduction of flux of 2–3% at full load. The drop in speed from no load to full load is therefore less than

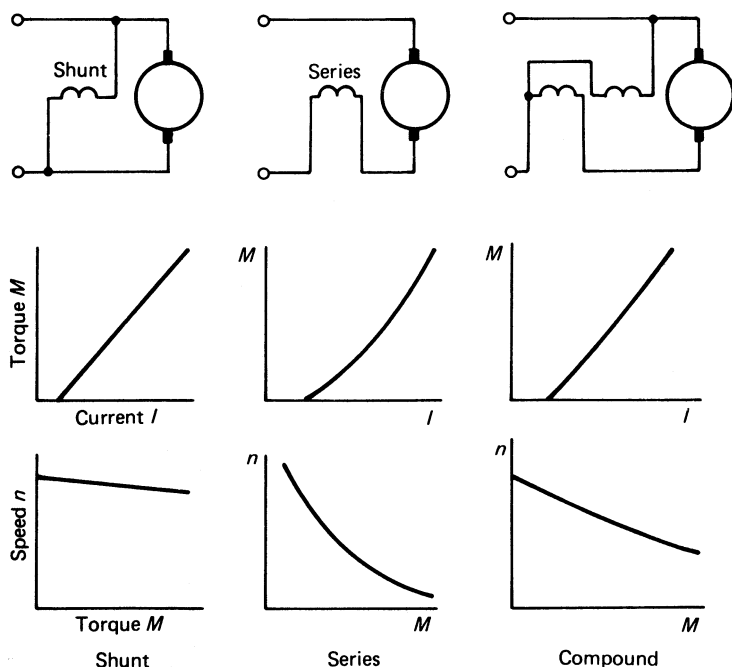

Figure 20.26 D.c. motors: basic characteristics

would be expected from the speed equation—in some cases this action even gives a rising speed characteristic, a disadvantage which can be corrected by the use of a small series field winding. Increase in temperature from cold to hot raises the resistance of the field winding and reduces the current in it, thereby reducing the flux and increasing the speed for a given load.

Motors designed to give a wide range of speed control by variation of the field or to be used in situations where sudden and heavy load fluctuations occur are often fitted with a compensating winding in the pole face to neutralise the effect of armature reaction and prevent flux distortion; such windings are connected in series with the armature so that neutralisation is correct at all loads.

The shunt motor can be used for the drive of machine tools, pumps and compressors, printing machinery and all forms of industrial drive requiring a speed which is approximately constant and independent of the load.

**Separate excitation** This is applied widely to control motors, particularly where speed variation is required over a considerable range. For a given field voltage, the characteristics resemble those of a shunt motor. Separate excitation (but without the facility of field control) applies to small motors with permanent-magnet field systems.

**Series excitation** The field m.m.f. is produced by the motor current so that at low currents where the iron is unsaturated  $\Phi$  is approximately proportional to  $I$ , but at high currents (1.5–2 times full-load current)  $\Phi$  tends to become constant as the iron saturates. The starting torque, when the current is above the full-load value, is thus greater than for a shunt motor with corresponding full-load current and flux. The speed at heavy currents drops to a low value on account of the increase of flux.

The high starting torque and falling speed–torque characteristic make the series motor suitable for driving hoists and cranes, for traction and rope haulage and for driving fans, centrifugal pumps or other apparatus where there is no danger of the motor being run light.

**Compound excitation** Where a drop in speed between no load and full load greater than that obtainable with a plain shunt motor is required, a series winding may be added to assist the shunt winding, giving a speed–torque characteristic having any desired amount of droop. Instability of a shunt motor due to the weakening of the field by armature reaction can also be cured by the addition of a series winding known as a *series stability* winding. The chief application of the compound motor arises when the motor is used in conjunction with a flywheel—a fairly steep droop to the speed–torque characteristic is then necessary in order to enable the flywheel to give up its stored energy when a sudden load comes on. Compound motors are also used for driving pumps, compressors and other heavy-duty machinery.

If the series winding is arranged to oppose the shunt winding, a motor with a flat or even a rising speed–torque characteristic can be designed, such a motor being known as a differentially compound motor. Such motors are, however, very rarely used.

### 20.3.2.2 Construction

Motor design aims at economy of materials and the reduction of loss. Further, as most industrial d.c. machines are fed from an a.c. supply through thyristors, an all-laminated magnetic circuit reduces the effect of supply harmonics. There is increasing use of square frames, either of rolled steel or of laminations.

**Poles** Constructed separately, the pole body and shoe are assembled from laminations, or a solid body is provided with a laminated shoe. The poles are bolted to the yoke and retain the field windings. Commutating poles may be solid or, more usually, laminated. Motors of rating below about 10 kW may have half as many commutating as main poles.

**Field windings** Main *shunt-field* windings are of circular- or rectangular-section wire, insulated and wound on a former. The whole is then taped, impregnated, slipped on to the pole and held by the pole-shoe. Large machines may have the turns wound on a bobbin of pressboard or of steel lined with micanite. *Series windings* to carry currents exceeding 50 A are more generally of copper strip wound on edge, and a similar construction is used for *compole* windings.

**Armature core** This is built from core-steel laminations (0.35–0.6 mm), coated on one side with an insulating varnish and bolted or clamped between thick end-plates. For diameters up to about 1 m the stampings may be made in disc form; above this size they are in sectors keyed to the shaft hub. If the core length exceeds about 20 cm, radial ducts are provided, each 5–6 cm. Axial ducts are employed with small machines. Machines of ratings up to 50 kW may have slots skewed to reduce noise.

**Commutator and brushgear** The commutator is conventionally made by assembling hard-drawn copper sectors interleaved with 0.7–2 mm sheet mica, these separators being ‘undercut’ by about 1 mm. The brushes, of a suitable carbon/graphite content, are mounted in boxes with spring loading to hold them against the commutator surface with a medium to strong pressure depending on the application. The circumferential brush width is typically 2–3 sector widths (10–20 mm) and about 30 mm axially. One brush-arm per pole is employed except for certain four-pole wave-wound machines which have two brush-arms in adjacent positions to facilitate maintenance.

**Armature winding** Almost all motors other than very large machines use a simple two-circuit wave-winding. Conductor wires of section 1 mm<sup>2</sup> or less are circular and enamel insulated, the conductors of a coil being taped half-lap before being placed in the slots. Larger machines have former-wound coils of rectangular-section conductors, insulated by half-lapped tape. The coils are assembled from the conductors and taped before insertion. The slots are lined with pressboard, and the two layers separated by a pressboard spacer. Various recent developments in epoxy resins have made possible the use of better insulants at higher temperatures. Typical slot sections are shown in *Figure 20.27*. The coils are contained in the slots by wedges or by steel or glass-cord binding.

In small wire-wound armatures the coil ends are soldered direct into grooves in the commutator sectors. For strip windings, the sectors carry ‘risers’ for connection to the ends of the coils.

**Bearings** End-shield bearings are usual for ratings up to 250 kW, above which pedestal bearings are employed. Journal bearings are fitted where ball or roller bearings are unsuitable.

**Enclosure and ventilation** Recent standards define the conditions to be met by machines for a variety of ambient conditions (e.g. drip-proof, splash-proof, hose-proof, weather-proof, and flame-proof).

Cooling air is drawn into the machine directly or through cowls, pipes or screens except in totally enclosed machines, for which there is no communication between the outside air

Figure 20.27 Typical slot sections

and the interior of the motor. As cooling must then be solely by dissipation from the outside of the carcass, the rating is limited to about 75 kW. Cooling can be improved by shaft-mounted fans, by inlet and outlet pipes or by closed-circuit ventilation. In the latter case the fan-assisted air circulating through the machine is cooled by passing it through an air/air (c.a.c.a.) heat-exchanger or an air/water (c.a.c.w.) exchanger mounted on the motor frame.

### 20.3.2.3 Commutation

Modern motors can be made to commute sparklessly up to 1.5–2 p.u. load. To secure this behaviour, commutating poles are fitted to all motors in the integral-kilowatt range.

**Compoles** Before the commutator sectors connected to a particular armature coil reach a brush, the coil will be carrying current in a certain direction; while the sectors connected to the coil are passing under the brush the coil will be short circuited by the brushes, and after leaving the brushes the coil will be carrying current in the opposite direction. The current must thus be reversed during the time for which the coil is short-circuited (the time of commutation). At normal commutator peripheral speeds of 10–30 m/s this time will usually lie between 2.5 and 0.2 ms. Owing to the inductance of the coil, the current cannot reverse in this time without some external assistance; it is necessary to induce in the short-circuited coil an e.m.f. to assist the change of current, i.e. an e.m.f. in a direction opposite to that of its e.m.f. when, after leaving the commutating zone, it enters to next pole region. Compoles are therefore fitted to influence the coil-sides undergoing commutation; the compoles have an excitation proportional to the armature current and the polarity of the successive main pole. The arrangement (i) neutralises the main armature m.m.f. in the commutating zone and (ii) produces the necessary commutation flux density there. The compole flux required is proportional to the armature current, and the compole windings are therefore connected in series with the armature.

Commutation in a machine not fitted with compoles can be effected by brush-shifting backward (against the direction of rotation) so that the commutating flux is provided by the succeeding pole. This cannot be done if the motor is required to run in both directions.

**Sparking** Sparking causes burning and pitting of the commutator surface, so intensifying the trouble. The origins of sparking, and the remedies, are as follows.

**Mechanical defects** The chief causes are: the sticking of brushes in holders; 'high' or 'low' commutator bars; flats, irregularities or dirt on the commutator surface; badly bedded brushes. The commutator can be cleaned while running with a commutator stone, but irregularities make it necessary to grind the commutator. Small sparks between sectors, starting a few centimetres away from the brush, are probably due to partial short circuits caused by dirt on the mica surfaces. Correct bedding is essential to ensure that the brushes carry current over the whole of their contact surface. It can be carried out by adjusting the brush springs to give a fairly heavy tension and passing, first coarse and finally fine, glass-paper between the brush and the commutator; care must be taken to remove all trace of dust after the operation.

**Incorrect brush position** The correct position of the brush rocker is usually marked by the manufacturer, but it may tend to move in service. If the marking is obliterated, the correct position can be found by determining the neutral position. If the machine has no compoles the brushes will have to be moved backward from the neutral position by two or three sectors, the best position being found by trial. With a compole motor the brushes should be almost exactly on the neutral position, although they may be moved forward by a small distance so that the compole flux adds to that of the preceding main pole and prevents any tendency of the speed to rise as the load comes on, the compole winding acting as a series stability winding. Incorrect spacing between adjacent brush arms may occur; this should be checked very carefully by a steel tape, not by counting the sectors.

**Winding defects** Open- and short-circuited coils in the armature will cause severe sparking. An open-circuited coil will cause sparks to go all round the commutator with severe burning at the bars connected to the open-circuited coil. A short-circuited coil will cause overheating of the faulty coil and segments and is often due to molten solder falling between the commutator risers. In either case the presence of a fault can be verified by carrying out a drop test.

**Incorrect compole excitation** The compole strength can be checked by the brush-drop or black-band tests. Incorrect strength can be remedied by inserting or removing thin steel shims between the back of the compole and the yoke: removing a shim increases the air gap and weakens the compole. Weakening can also be obtained by shunting a resistor diverter across the compole winding, but this is not fully effective in transient conditions.

**Thyristor-assisted commutation** The speed and output limitations imposed by commutation have encouraged attempts to use thyristors to perform the switching function, leaving the brush to act as a simple current collector. Success would enable the voltage per sector (30–40 V peak, 15–20 V mean) to be raised, fewer sectors could be employed and high-power high-voltage d.c. machines achieved. Promising results have been obtained with the arrangement of Figure 20.28. The armature coils are connected to two separate commutators with alternately 'live' and 'dead' sectors, the latter shown shaded. In the diagram, brush D has just come fully into contact with active sector 2, and thyristor  $T_x$  has been turned on; the e.m.f.  $E_c$  in the coil that has just been commutated must, acting through brush A, be enough to turn off thyristor  $T_y$ . Separation of the brushes into two parts, AB and CD, is

Figure 20.28 Thyristor-assisted commutation

necessary to ensure that the part-brush is fully on to an active sector before it begins to carry current; otherwise contact damage occurs. Although the switching procedure is satisfactory, current collection difficulties, causing commutator damage and arising from the transient current changes, have not yet been overcome.

### 20.3.2.4 Starting

If a d.c. motor is to be started from a constant-voltage supply, its normally low resistance must be augmented to limit the current to a safe value, e.g. 1.5–2 times full-load value. The starting rheostat is cut out as the motor speed rises and the counter-e.m.f. imposes a limit on the current.

**Shunt motor** For maximum starting torque, the field must be fully established at starting; the starting rheostat is therefore connected only in the armature circuit. The total starting resistance  $R$  is determined by the maximum starting current  $I = \mathcal{E} / (R + r_a)$ , where the armature resistance  $r_a$  has the typical values:

Motor rating (kW)	1	2	5	10	50	100
Armature resistance ( $\Omega$ )						
at 110 V	1.4	0.8	0.2	0.1	0.08	0.006
at 230 V	6.0	3.0	0.8	0.5	0.10	0.025
at 460 V	22	13	3.0	2.0	0.50	0.010

Traditional face-plate starters are obsolescent. Usually a fully automatic push-button system is employed.

**Series motor** The starting rheostat is in series with the motor, the resistance of which is about twice the value given for  $r_a$  in the table above. Industrial series motors are often used in cranes and hoists, and the starting resistance is commonly utilised also for speed control.

### 20.3.2.5 Speed control: standard motors

A prime reason for the continued use of d.c. motors is the possibility of simple and economic speed control over a wide range. Reference to the expression in Section 20.3.2.1 shows that speed can be controlled by varying the applied voltage, the flux or the armature resistance.

**Shunt motor** In a shunt machine the variation of the supply voltage does not greatly affect the speed because the result is also a comparable change in flux.

**Field control** The field current (and therefore the flux) is varied by adding resistance into the field circuit (Figure 20.29). For a given setting of the field regulator the speed is approximately independent of the load, giving a series of flat speed–torque curves. The upper limit of speed for a standard motor is about 30–50% above normal, fixed partly by mechanical considerations and partly by weak-field flux distortion. However, a 3:1 range can be obtained by suitable design, although very low speeds cannot be obtained in this way. For a given armature current, a flux reduction raises the speed but reduces the torque to yield a *constant-power* characteristic,  $P$  in Figure 20.29. The loss in the field-regulator resistance is small, so that the efficiency of the machine is not affected.

**Armature-circuit resistance control** The speed for a given value of resistance added into the armature circuit falls with the load, giving a group of speed–torque characteristics (Figure 20.29). The flux remains constant so that for a given current the torque will not vary with speed (*constant-torque* characteristic); power output therefore falls proportionately with speed. Owing to the losses in the added resistance the efficiency is low and approximately proportional to the speed: e.g. with a 60% speed drop the efficiency will be a little less than 40%. The resistance required is  $R = \mathcal{E} (V - I_a r_a) / I_a$  where  $x$  is the desired fractional speed reduction and  $I_a$  is the armature current at the reduced speed, the latter depending on the type of load.

**Diverter control** With series armature-circuit resistance control a large resistance is required to obtain low speed on small load, and the machine is unstable in that there is a large change of speed with load. This can be overcome by adding a variable resistor in parallel with the armature circuit. The efficiency is low, and the method is justified only as a temporary measure or with very small motors.

**Ward–Leonard control** The main d.c. motor  $M$  is separately excited with a constant field current, the armature being supplied with a controlled variable voltage obtained from a d.c. generator  $G$  driven by a constant-speed motor (Figure 20.30). Control of the generator field varies the main motor armature voltage and consequently the armature speed: a range of 25:1 is obtainable, and reversal is possible if the generator field excitation can be reversed. Each setting of the generator field provides for a ‘shunt’ operating characteristic in the main motor, with a torque proportional to the armature current. The method is economical in energy and is applicable to mine winding gear and machine-tool drives, but it is high in capital cost; consequently for smaller ratings the motor–generator is replaced by a thyristor bank.

**Series motor** The three basic methods of speed control are shown in Figure 20.31.

**Field control** This is obtained by a diverter rheostat in parallel with the field circuit. Only on small machines is a continuous speed variation obtainable, and the diverter must generally be varied in one or two discrete steps. An alternative, commonly used with traction motors, is to tap each field winding so that part of the winding is cut out to reduce the field m.m.f. and raise the speed. Both methods can give only a speed rise. In some cases it is possible to arrange the field windings in two groups, which can then be connected in series or parallel, the latter giving 20–30% higher speed for a given current than the former.

**Resistance control** A variable resistor in series with the motor reduces its terminal voltage and lowers the speed.

Figure 20.29 Shunt motor: speed control

Figure 20.30 Ward-Leonard control

Although the method involves  $I^2R$  loss, it is commonly employed for cranes, hoists and similar plant, the resistance steps being used also for starting.

**Series/parallel control** If two series motors are connected mechanically to ensure the same speed for each (as is usual in d.c. traction systems) series/parallel voltage control can be obtained by connecting the motors electrically in parallel or in series, the former giving full voltage and the latter one-half voltage to each motor. Intermediate speeds can be obtained by resistance or field control. The full-parallel speed is, for a given motor current, approximately twice that in full-series.

A scheme known as *parallel/series* control is sometimes applied to battery vehicles, the battery being arranged in halves that can be paralleled for starting and low speed, and in series for full speed.

### 20.3.2.6 Speed control: thyristor-fed motors

A separately excited motor may be fed from a constant-voltage a.c. supply through thyristors, which rectify the current and also (by delaying the commutation angle  $\alpha$  by controlled gate signals) furnish a variable-voltage supply to the armature. The field current is obtained from the a.c. supply through semiconductor diodes or thyristors. The main thyristor equipment thus replaces the motor-generator

set of the Ward-Leonard speed control in ratings up to about 500 kW and, being static, is more economical and commercially viable even down to fractional-kilowatt sizes.

**Connections** The choice of thyristor circuit is a compromise between cost (i.e. the fewest thyristors, which with their firing circuits are more expensive than diodes) and operational difficulties arising from harmonic production or poor commutation, both accentuated by the use of a small number of thyristors. For economy, half-controlled circuits in which half the units are thyristors and half are diodes are common, but such circuits cannot regenerate.

The thyristors may be fed direct from an a.c. supply of r.m.s. voltage  $V_a$  as in Figure 20.32. The mean direct voltage available with zero commutation delay ( $\alpha = 0$ ) is  $V_{a0} = 0.9 V_a$  for the one-phase and  $V_{d0} = 0.43 V_a$  for the three-phase arrangement. With commutation delayed by angle  $\alpha$  the mean direct voltages are

$$\text{Fully controlled } V_d = V_{d0} \cos \alpha$$

$$\text{Half-controlled } V_d = V_{d0} \frac{1}{2} (1 + \cos \alpha)$$

The one-phase half-controlled arrangement of Figure 20.32(a) is very widely used for ratings up to about 5 kW. The current tends to be discontinuous, causing bad commutation, and sufficient inductance should be included in the circuit to avoid this except at large delay angles; a separate inductor may be used or, in the smaller ratings, the motor winding may be designed to have a sufficiently high inductance.

The three-phase half-controlled circuit (b) has been used for outputs up to about 200 kW but recent practice tends towards the use of the fully controlled circuit from about 25 kW up to 1000 kW. The fully controlled circuit (c) gives rise to a 300 Hz ripple on the direct voltage but the half-controlled circuit gives 150 Hz over most of its range, rising to 300 Hz when  $\alpha$  approaches zero.

The transformer-fed networks in Figure 20.32 give the designer a free hand in choosing the operating voltage of the d.c. motor. The one-phase centre-tap connection (d) has

Figure 20.31 Series motor: speed control

the advantage over the one-phase bridge of making regeneration possible.

By connecting in series two six-pulse units, the supplies to which are obtained respectively from delta- and star-connected windings of a three-winding transformer (Figure 20.32(e)) a  $30^\circ$  phase-shift is obtained giving a 12-pulse operation and a 600 Hz ripple of small amplitude. Such an arrangement is generally desirable for outputs above 1 MW and up to 5 MW (the upper limit for a d.c. motor).

The field supply for the motor is generally obtained from the a.c. supply through a 1-phase bridge or centre-tap connection using diodes. If field control is desired in addition to armature voltage control it can be achieved by a conventional field resistor or by using thyristors instead of diodes.

Figure 20.32 Thyristor control

**Harmonics** In addition to the harmonics on the d.c. side which may interfere with commutation, harmonics also appear on the a.c. side and can cause interference with communication and control circuits and difficulties with other plant connected to the system, particularly overloading of shunt capacitors and possible resonances at the 11th and 13th harmonics. For these reasons the rating of plant connected to a single point on the supply is limited by the Supply Authority, typically from 250 kW at 0.4 kV to 3 MW at 33 kV for six-pulse units, and from 750 kW to 7 MW for 12-pulse units.

**Motor construction** As a result of harmonics on the d.c. side, a motor may have to be derated by 15–20%. To minimise commutation troubles, composites and main poles and yokes may all be laminated.

**Thyristor firing** The signals applied to the thyristor gates are usually high-frequency pulses (2–8 kHz). For large units the pulse current may be 1–2 A in amplitude with a rise-time less than 1  $\mu$ s. The electronic equipment to generate the signals comprises a power supply, timer and phase-shift units, pulse generator and amplifier, and output unit. The control of the gate pulse may be manual, or by signals from a closed-loop control system.

#### 20.3.2.7 Braking

Rheostatic, regenerative and plug braking are applicable, but they cannot hold a motor at rest: for that a mechanical brake is necessary.

**Shunt motor** The electric braking methods are shown in Figure 20.33.

**Rheostatic braking** The field connection to the supply is maintained but the armature is disconnected and then reconnected on to a resistor. The machine generates, dissipating power in the resistor. The braking effect is controlled by varying the field current. For a total armature-circuit resistance  $R$ , the armature current is  $I = \mathcal{E}/R = k_1 n \phi / R$  and the braking torque is  $M = k_2 EI / n = k_3 n \phi^2 / R$ . If the excitation is constant, then the braking torque is directly proportional to the speed  $n$  and decreases as the motor speed falls.

**Plugging** The armature connections are reversed, and the motor torque tends to retard the machine and then run it up in the opposite direction. The applied voltage and the armature e.m.f. are additive, so that a resistance of about twice starting value must be included to limit the current. For a total armature-circuit resistance  $R$ , the armature current is  $I = (V + E)/R = (V + k_1 n \phi)/R$  and the braking torque is  $M = (k_4 \phi + k_3 n \phi^2)/R$ . With constant excitation the braking torque is  $k_5 + k_6 n$ . Braking by plugging gives a greater torque and a more rapid stop, but current is drawn from the supply during the braking period, and this energy together with the stored kinetic energy has to be dissipated in resistance. A relay must be provided to open-circuit the motor at rest in order to prevent it from running up in reverse.

**Regenerative braking** If a load (such as a descending hoist) overruns the motor at a speed higher than normal, the counter-e.m.f.  $E$  exceeds the terminal voltage  $V$  and the machine generates. This is a very convenient method of 'holding' a load, but not at low speeds unless excessive field current is supplied.

With thyristor-controlled motors regeneration is possible if fully controlled connections are used. It is necessary to reverse the polarity of the motor terminals relative to those of the thyristor unit. This can be done by reversing either the armature or the field terminals at the moment of entering regeneration, the reversal being effected by conventional

reversing contactors. Armature reversal requires about 150 ms but field reversal may require up to 2000 ms. Where a very rapid reversal is required it is necessary to employ separate thyristor units for motoring and regenerating, these being connected in 'anti-parallel'. Only switching of the gate pulses is then required, a process that can be achieved in about 10 ms.

**Series motor** The electric braking methods are shown in Figure 20.34.

**Rheostatic braking** The motor acts as a series generator loaded on resistance. It is necessary to reverse the field connections at the instant of changing from motoring to braking. Further, the load resistance must be below a critical value if the machine is to self-excite. In practice the starting resistance, the value of which is well below the critical, is used for braking. The braking torque is approximately  $M = k n I^2$ .

**Plugging** The conditions are generally similar to those in the shunt machine.

**Regenerative braking** This is not practicable with series motors. In traction, regeneration is sometimes effected by separately exciting the motors.

### 20.3.2.8 Design data

Some general and typical data are given here. Small motors up to 5 kW at 1000 rev/min normally have two poles, up to 50 kW four poles and up to 200 kW six poles. Larger motors have more, the number being such that the 'speed frequency' is 20–30 Hz and the pole-pitch between 45 and 55 cm.

The rated output power  $P$  is related to the main dimensions (diameter  $D$ , length  $l$ ), the speed  $n$  and the specific magnetic and electric loadings  $B$  and  $A$  by

$$D^2 l n = P / \pi^2 \eta B A$$

where  $B$  is the mean gap flux density of value up to about 0.55 T and  $A$  varies between 5 and 35 kiloampere-conductors per metre of armature periphery.

The maximum safe peripheral speed is 30–40 m/s for the armature and 25–30 m/s for the commutator. The number of slots is about six per pole for fractional-kilowatt motors and 10–14 per pole for machines of 100 kW. The total current per

**Figure 20.33** Electric braking of a shunt motor: (a) rheostatic; (b) plugging; (c) regeneration; (d) thyristor

**Figure 20.34** Electric braking of a series motor: (a) motoring,  $E < V$ ; (b) rheostatic; (c) plugging  $E > V$

slot is about 700 A for the latter rating. The number of slots must suit the winding required. A simple wave winding is used for nearly all industrial motors except in ratings of several hundred kilowatts for which lap (parallel-circuit) windings with equalising connectors may be used. The number of conductors is  $Z = \frac{2}{\pi}(p/a)n\phi$ ; the number of coils and commutator sectors is  $2pV/e$ , where the mean voltage  $e$  between sectors is usually between 12 and 15 V.

The field m.m.f. is 1.15–1.25 times the full-load armature m.m.f., and in designing the magnetic circuit the pole leakage (about 15%) must be taken into account. The length of the air gap is governed by the requirement that the field distortion shall not be excessive.

### 20.3.2.9 Disc motors

The disc-armature machine has been developed for special applications such as small pumps, freezer-compressor drives, domestic sewing machines, computer spool drives and light battery vehicles. The basic geometry can be realised in the diagrams shown in Figure 20.35. A ring of permanent magnets of alternate polarity provides the axial field. In (i), two magnet rings M flank the armature A. In (ii), one of the magnet rings is replaced by a flux-conveying steel 'yoke' Y. In (iii), the yoke is carried by the armature, increasing its inertia but reducing the effective air gap length. The wave or lap winding (of which a single turn is shown) has an angular span equal to the angular pole-pitch. A multipolar structure, in which a front-face conductor is paired with another on the back of the armature disc, is employed to reduce the length of the 'overhang'. In small low-inertia motors the winding is punched from a copper or aluminium sheet and then placed on either side of an epoxy-resin-impregnated glass-fabric disc. The resin is then given a completion cure. Larger motors have wire-wound armatures with face or barrel commutators.

The magnets are usually of sector rather than circular shape to increase the working flux density towards the outer radius, where it is the most effective. Consider a machine in which the magnets, set between outer and inner radii  $R$  and  $r$ , produce in this annulus a uniform mean flux density  $B$ . Then for an

angular speed  $n$  and a current loading  $A$  (in A/rad) the e.m.f. in a conductor and the torque developed are respectively.

$$E_r = \frac{1}{2}\pi(R^2 - r^2)Bn \quad \text{and} \quad M_e = \frac{1}{2}\pi(R^2 - r^2)BA$$

showing the influence of the outer radius in increasing the output. However,  $R$  is limited by rotational stress, flexure of the disc and any operational constraints on the armature inertia.

**Homopolar motors** A homopolar d.c. motor is an embodiment of the Faraday disc. The voltage is inevitably low (less than 200 V) and the current high. Such machines as generators have been built to supply electromagnetic pumps and electrochemical processes requiring very large currents. Homopolar motors have also been built, notably a 2.5 MW 200 rev/min machine for a power-station pump where the motor has a superconducting field system developing a working flux density of nearly 4 T by means of an m.m.f. of  $3 \times 10^6$  A-t.

### 20.3.3 Three-phase induction motors

The great majority of industrial, commercial and agricultural electric motors above the fractional-kilowatt size are three-phase induction machines, on account of their simple, cheap and robust construction and the almost universal availability of three-phase supplies.

The induction motor has a 'shunt' speed-torque characteristic, the operating speed  $n$  falling slightly below the synchronous speed  $n_s = \frac{60}{p}f$ , where  $f$  is the supply frequency and  $p$  is the number of pole-pairs for which the three-phase stator winding is arranged. The drop in speed below  $n_s$  is the *slip*, given by  $s = (n_s - n)/n_s$ . The slip increases from nearly zero on no load to 0.03–0.05 on full load. Most industrial motors are four-pole machines with a synchronous speed of 1500 rev/min, but two-pole machines ( $n_s = 3000$  rev/min) are sometimes of use, and lower speeds obtained with six, eight or more poles may be used in large ratings.

The *cage* motor has a rotor winding internally short circuited on itself with no external access. The *slip-ring* motor has the polyphase rotor winding brought to three slip-rings so that connection can be made to it for starting or speed control; for normal operation, however, the rotor winding is short circuited. In each type the stator carries a conventional three-phase winding, fed from the main supply and generally delta-connected. Almost all induction motors are of the cage type, with slip-ring machines used normally only in ratings above about 100 kW.

#### 20.3.3.1 Operating principle

Currents in the stator windings set up an air gap travelling-wave magnetic field of almost constant magnitude and moving at synchronous speed. The field cuts the rotor conductors at slip speed, inducing a corresponding e.m.f. and causing currents to flow in the short-circuited windings. The interaction of these currents with the travelling-wave field produces torque to turn the rotor in the direction of the field. The magnitude of the rotor currents depends on the slip and on the impedance (comprising resistance, and inductive reactance proportional to slip) of the rotor windings. With the rotor running at synchronous speed, the rotor slip is zero, the rotor inductive reactive vanishes and, as the gap flux does not cut the rotor conductors, the induced e.m.f. is zero; as a consequence there is no rotor current and no torque is developed. Since there must always be a small torque to overcome mechanical loss, the motor cannot quite achieve synchronous speed. As the

Figure 20.35 Elements of a disc motor

motor is loaded, it slows so that the slip becomes a small finite quantity, rotor e.m.f. is developed and rotor current flows; the rotor circuits are mainly resistive but a small inductive reactance is introduced. The various interactions yield the torque-speed curve A in Figure 20.36. It has been taken into the region of reverse rotation (slip greater than unity), for which the machine acts as a brake. The normal working range of the machine as a motor is the region for small positive slips: here the torque-speed relation is almost linear, corresponding to that of the d.c. shunt motor.

Reversal of the direction of rotation of the motor is obtained by interchanging two of the stator terminal connections, thus reversing the direction of the travelling-wave field.

### 20.3.3.2 Equivalent circuit

The performance is most readily predicted with the aid of an equivalent circuit (Figure 20.37) assembled from the various resistances and inductances (i.e. magnetising and leakage) of the machine, taken as independent of current, frequency and saturation conditions. The essential parameters are as follows, it being assumed for convenience that the rotor and stator windings are identical; all electric-circuit quantities are *per phase*:

Figure 20.36 Three-phase induction motor: torque-speed characteristics

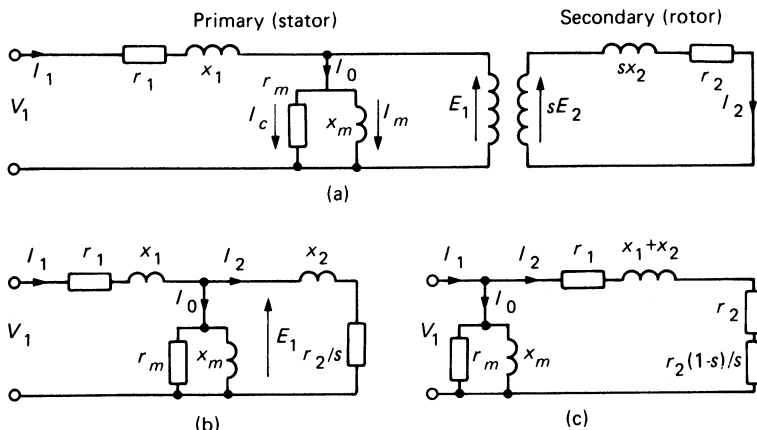

Figure 20.37 Three-phase induction motor: equivalent circuit per phase

$V_1$	stator applied voltage
$E_1, E_2$	stator e.m.f., rotor e.m.f. at standstill
$r_1, x_1$	stator resistance and leakage reactance
$r_2, x_2$	rotor resistance and leakage reactance at supply frequency (corresponding to standstill, $s = 1$ )
$r_m, x_m$	resistance representing core loss, magnetising reactance
$I_1, I_2$	stator current, rotor current
$I_0$	no-load current given by $\sqrt{(I_m^2 + I_c^2)}$ , where $I_c \Leftarrow E_1/r_m$ and $I_m = E_1/x_m$

The basic equivalent circuit is shown in Figure 20.37(a); it is similar to that of a transformer on short circuit except that the transformer ratio varies with slip (and therefore with the speed). With unity turns-ratio and a division of the rotor parameters by the slip  $s$ , equivalent circuit (b) is obtained. For easier calculation the approximate circuit (c) can be used, with an error not exceeding 2% or 3% provided that the operating conditions are not abnormal. The rotor resistance  $r_2/s$  has been split into  $r_2$  for the rotor  $I^2R$  loss, and  $r_2(1-s)/s$  in which the  $I^2R$  value represents the power conversion to the mechanical form.

**Equations** The following relations can be developed from the approximate equivalent circuit:

$$\text{Rotor current: } I_2 = V_1 / [(r_1 + r_2/s)^2 + (x_1 + x_2)^2]^{1/2}$$

$$\text{Stator current: } I_1 = I_2 + I_0$$

$$\text{Power division: rotor input : rotor } I^2R \text{ : gross output} = 1 : s : (1-s) \Leftarrow$$

$$\text{Gross torque: } M = V_1 I_2 (r_2/s) / 2\pi n_s$$

The peak torque, which is independent of the actual value of rotor resistance, is approximately

$$M_m = \frac{V_1^2}{(x_1 + x_2) 4\pi n_s} \text{ at } s = \frac{x_2}{(x_1 + x_2)} \Leftarrow$$

and its value is normally 2–2.5 times the full-load torque.

The losses in the machine comprise the core loss, stator and rotor  $I^2R$  loss, and mechanical loss in windage and friction. The no-load input current is 0.25–0.3 of the full-load current, at a lagging power factor in the range 0.15–0.2. At standstill on normal voltage the stator current is 4–6 times full-load current. Typical full-load values for conventional induction motors are:

10 kW motor: p.f., 0.87 (4-pole), 0.75 (12-pole); efficiency, 0.85

1000 kW motor: p.f., 0.94 (4-pole), 0.91 (12-pole); efficiency, 0.95

### 20.3.3.3 Construction

As the working flux is alternating, the stator and rotor cores must be laminated, using plates 1.0–1.5 mm thick.

**Stator** The core comprises annular stampings for small and segmental plates for large machines; it is mounted in a welded steel frame that does not form part of the magnetic circuit.

The voltage for which the stator is wound is normally between 380 and 440 V for motors up to 250 kW. Larger machines are wound for higher voltages, the minimum economic sizes being about 250 kW for 3.3 kV, 400 kW for 6.6 kV and 750 kW for 11 kV.

**Rotor** Slip-ring rotors may be wound to develop an e.m.f. when stationary of about 100 V for small and up to 1 kV for large machines, with insulation to correspond. The winding of a cage rotor comprises copper or aluminium bars located in slots (usually without insulation) and welded or brazed at each end to a continuous end-ring. The joints between bars and end-ring may prove to be points of weakness unless carefully made. Small cage motors generally have aluminium bars and rings cast into the rotor in one piece, with the end-rings shaped to form simple fan blades. To minimise the magnetising current the air gap is made as small as is mechanically practicable, e.g. from 0.25 mm for small motors up to about 3 mm for large motors.

**Enclosure** This follows standard practice. The *flameproof* construction is available for motors used in hazardous atmospheres classified as 'Division 1 Areas' (mines, petroleum plants, etc.): it is a total enclosure with all joints flanged so that any flame generated by an internal explosion will be cooled by its passage through the joint and will not ignite external explosive gases. Cage motors, which have no slip-rings, are well suited to such situations, and they may be used without flame-proofing in 'Division 2 Areas' where flammable gas is not present unless there is some breakdown in the plant.

### 20.3.3.4 Starting

The factors of importance are (i) the starting torque and (ii) the starting current drawn from the supply. If the motor is to be started on full load, the starting torque must be 50–100% above full-load torque to overcome static friction and to ensure that the motor runs up in a reasonably short time to avoid overheating. Lower values are acceptable if the motor is always to be started on no load, and may be desirable in order to avoid too abrupt a start. The starting current should be as low as practicable to avoid overheating. Occasionally, supply authorities limit the starting current that may be drawn from the supply in order to avoid excessive voltage drops interfering with other consumers; it must also be remembered that, since torque is proportional to (voltage)<sup>2</sup>, any voltage drop will significantly reduce the available starting torque. The torque and current may be expressed in terms of full-load values, but a more significant comparison between motors of different efficiencies and power factors is had by expressing the starting kVA in terms of the full-load output in kilowatts.

The curves A, B, C, D in Figure 20.36, drawn for different resistances, show that the rotor resistance has a major effect on the starting torque.

**Slip-ring motor** By adding external resistance to the rotor circuit any desired starting torque, up to the maximum-torque value, can be achieved; and by gradually cutting out the resistance a high torque can be maintained throughout the starting period. The added resistance also reduces the starting

current so that up to 2–2.5 times full-load torque can be obtained with 1–1.5 times full-load current.

**Cage motor** For high efficiency, the rotor resistance must necessarily be low, and the starting torque on direct starting (when the motor is switched on to full voltage) is likely to be 0.75–1 times full-load torque with a stator input of 4–6 times full-load current. The table below gives typical values of the ratio (starting kV-A)/(full-load kW) for a range of conventional motors with direct starting are:

Range, kW:					
1–6	6–40	40–250	250–500	500–1500	1500–4000
kV-A/kW:					
10	9	8	7.7	7.4	7.2

These values are acceptable to supply authorities in most cases.

From the relations already given for the division of the power input to the rotor, the starting torque  $M_s$  for a starting current  $I_s$  is, in terms of the full-load values  $M_1$  and  $I_1$  and the full-load slip  $s_1$ , given by

$$M_s/M_1 = (I_s/I_1)^2 s_1$$

If direct starting is not admissible by reason of the initial current and/or the impulsive torque, then the voltage must be reduced for starting, bearing in mind that torque is proportional to (voltage)<sup>2</sup>.

**Series resistance** A resistor in each line to the stator terminals can reduce the current to any fraction  $x$  of the direct-starting value, but the torque will be the fraction  $x^2$ . Although cheap and simple, this method is acceptable only for motors that start on no load.

**Autotransformer** Usually no more than three tapplings (50%, 70% and 80%) are provided. With a tapping giving the fraction  $x$  of normal voltage, both current and starting torque are reduced to  $x$  times the direct-start values. The cost of the transformer and contactors is high, especially if special connections are used to avoid disconnection of the supply when tap-changing.

**Star-delta switch** This starts the motor in star connection, and changes it to the normal delta connections as the speed approaches normal. Both current and torque at starting are one-third of their respective direct-start values. All six stator phase-ends must be available. The momentary disconnection can cause significant transient effects during the change-over.

**Current displacement** This relies on the change of leakage reactance with rotor frequency to give enhanced starting and run-up torque, but with some sacrifice in pull-out torque. The inner cage in (a) and the inner region of the deep bar in (b) of Figure 20.38 have a high leakage inductance, and at low speed (i.e. at higher rotor frequency) current is forced mainly into the outer cage in (a) and the upper region of the deep bar in (b). Thus most of the rotor current flows in the higher resistance outer cage or in the constricted region of the deep bar.

**Solid state** For loads with a rising torque/speed load demand, a 'soft' start can be obtained by including anti-parallel thyristors in the stator circuits, using phase control. At starting, stator voltage control can be obtained by appropriate triggering, or stator impedance control by use of a gapped-core inductor.

**Figure 20.38** High-torque rotor cages: (a) double cage; (b) deep bar

### 20.3.3.5 Speed control

The speed for an induction motor is  $n = (1 - s)f/p$ . The frequency  $f$  is normally fixed, the machine is built with  $p$  pole-pairs and, as the operating slip  $s$  lies generally between the limits 0.03 and 0.05, the motor is a substantially constant-speed machine with a working range as shown on curve A of *Figure 20.36*. Speed variation is often needed and, with some additional cost and complication, can be achieved by varying the slip, the number of poles or the frequency. For small motors a limited control can also be obtained by varying the applied voltage.

**Slip control** This, applicable only to slip-ring motors, requires connection into the rotor circuit of a device producing an adjustable volt drop or counter-e.m.f. The rotor induced e.m.f.  $sE_2$  must overcome this to enable torque-producing current to flow, so that the slip must change in accordance with the magnitude of the injected volt drop or e.m.f.

**Resistance control** A variable volt drop is set up in the rotor circuit by variable resistors in each phase, giving a series of torque-speed characteristics (A, B, C, D in *Figure 20.36*). Only the low-slip parts can give normal operation, as the lower speeds may be unstable. The starting resistors, if continuously rated, can be used for speed control. The method is cheap and simple, but results in high  $I^2R$  ('slip energy') especially for low speeds. The efficiency is a little less than  $1 - s$ , the speed varies widely with load, and low speeds are not obtainable at low loads. This form of control is used only where small or infrequent speed reductions are called for.

**Slip-energy recovery** Here the slip energy is not dissipated in resistance but is returned to the supply (constant-torque drive, as with resistance control) or added to the shaft output of the main motor (constant-power drive). Commutator machines have in the past been employed to deal with the slip energy. A modern method (*Figure 20.39*) is to rectify the slip-frequency currents in a diode bridge network; the unidirectional output current is smoothed and passed on to a three-phase line-commutated inverter at a rate depending on the supply voltage, the rectified direct voltage and the thyristor firing angle. The inverted current has a fixed waveform and a constant conduction angle of  $2\pi/3$  rad. The onset of conduction with respect to the phase-voltage zero is controlled by the firing angle. As power flow through the rectifier is unidirectional, only subsynchronous speeds are feasible.

**Pole changing** Switching the stator winding to give two (sometimes three) different numbers of pole-pairs gives two (or three) alternative running speeds. Cage rotors are normally employed, as slip-ring windings must be pole-changed to correspond always to the stator. Pole-changing motors with a 2:1 ratio have been used for many years, a typical arrangement being that in *Figure 20.40*. A more recent innovation is the pole-amplitude-modulated method.

**Figure 20.39** Thyristor slip-energy recovery

**Pole-amplitude modulation** The m.m.f. (and flux) distribution around the air gap produced by one phase of a conventional machine can be expressed as  $F(\theta) = A \sin p\theta$ , where  $\theta$  represents an instantaneous angular position. If  $F(\theta)$  is modulated by making  $A = C \sin k\theta$ , the m.m.f. becomes

$$F(\theta) = \frac{1}{2}C[\cos(p-k) - \cos(p+k)] \Leftarrow$$

which is an m.m.f. comprising two superimposed waves of pole-number  $p-k$  and  $p+k$ . One wave can be eliminated by adjusting the chording and relative position of the phase windings so that the machine has  $p$  pole-pairs (unmodulated) and either  $p-k$  or  $p+k$  pole-pairs (modulated). The modulation is effected by reversing half of each phase winding and, in some cases, isolating certain coils. Two basic forms of connection are given in *Figure 20.41*. The coils that are isolated for the unmodulated connection are in the sections A'A, B'B and C'C. For designs that do not need coil isolations the phase terminals during modulation are A'B'C'.

In general, when the distribution of coil groups per pole and per phase is not uniform, some coils are isolated for modulation; with a more uniform distribution, however, a simple reversal of the second half of each phase winding is sufficient. The latter is more suitable for power outputs that are required to be similar at the two speeds.

This simple theory led to the design of successful industrial motors with close speed ratios from, for example, 8/10 or 12/14 poles. The recent development of a more general theory has made possible wide ratios from, for example, 10/2 and 16/4 poles, and also three-speed motors. There is virtually no limit to the size and speed ratio available, even in fractional-kilowatt ratings. The pole-amplitude-modulated (p.a.m.) motor is thus superseding the two-winding change-speed motors commonly used in the past, as the starting torques, power factors and efficiencies of p.a.m. machines are comparable with those of single-speed standard machines and have optimum performance on all ranges. The rating for a given frame-size is about 90% of that of a normal single-speed motor.

**Frequency variation** Development of the static thyristor inverter has made possible the provision from a three-phase supply of an a.c. source of controllable voltage and of frequency infinitely variable from zero up to three or more times the supply frequency. Wide speed variation with such a source is possible with a cage motor. To maintain a constant motor flux, the voltage applied to the motor must be proportional to the frequency. The speed-torque characteristics (*Figure 20.42*) show that the peak torque is approximately the same at all operating frequencies.

**D.c.-link converter** A rectifier converts the a.c. of mains frequency to d.c., and a thyristor inverter converts this to a.c. of the desired frequency in the d.c.-link converter

Figure 20.40 Pole change in the ratio 2:1

**Figure 20.41** Pole-amplitude modulation. Unmodulated/modulated connections: (a) parallel-Y/series-Y; (b) parallel-Y/series-delta. Poles  $2p$ : supply to ABC with abc joined. Poles  $2(p \pm 4)$ : supply to abc with ABC isolated

Figure 20.42 Torque-speed relationships for variable frequency

losses in the motor; however, the impairment may be reduced by series inductors in the motor circuit. It must be remembered that although the motor has the usual overload capacity, the converting equipment has no such reserve and must be rated for the peak power.

An upper frequency of about 150 Hz is usual, permitting the speed range of a two-pole machine to be from zero to 9000 rev/min. For small machines and with thyristors having very fast switching characteristics, higher frequencies can be generated and speeds up to 100 000 rev/min achieved.

**Cyclo-converter** In this alternative equipment, sections of the normal mains-frequency wave are selected and used to build up an outgoing wave of lower frequency, usually not higher than about two-thirds of the mains frequency, in a single static unit. The equipment has an efficiency higher than that of the d.c.-link converter, but a considerably more complicated control network: basically 18 thyristors are required for a three-phase motor. The cyclo-converter employs natural commutation and may be more reliable than the forced commutation in the d.c.-link converter under abrupt changes of load; it can also be made reversible for regenerative braking without the additional complication that a d.c.-link converter would involve for this duty.

(Figure 20.43). The direct voltage is varied by a thyristor chopper instead of by a controlled thyristor equipment in order to mitigate harmonics in the supply. The inverter produces a waveform with about 20% of fifth and 14% of seventh harmonic, and these may cause small additional

Figure 20.43 Basic d.c.-link converter system

**Voltage variation** As the peak torque of an induction motor is proportional to the square of the voltage, a limited speed control can be effected by voltage variation. Typical speed–torque curves for a small motor operating at 100% and 70% of rated voltage are given in Figure 20.44. For a constant-torque load the speed is reduced from A to B; for a torque proportional to the square of the speed, as for a fan, the greater reduction from C to D is obtained. Greater variation occurs if the motor has a high rotor resistance/reactance ratio, so that the method is ineffective for motors of rating more than a few kilowatts; it is, in fact, used chiefly with small mass-produced motors. The voltage variation may be achieved by means of series rheostats (cheap but wasteful) or by thyristors in the supply circuit (expensive, efficient and harmonic-producing).

#### 20.3.3.6 Braking

Braking may be required to bring a motor and its load to rest rapidly in an emergency or as part of a production process, or to hold the motor at a set speed against gravity, as in a descending hoist. Mechanical brakes must be used if a motor is to be held at rest, but motional braking can be electrical and may not need much auxiliary control equipment.

**Plugging** If a motor, operating with a small slip  $s$ , has a pair of its supply leads interchanged, the direction of its travelling-wave air-gap field reverses and the slip becomes  $2-s$ . A braking torque is developed, retarding the motor towards standstill,  $s=1$ . The braking torque normally varies from about one-half the value of the starting torque initially, up to the starting torque when the machine comes to rest, and the braking current throughout is approximately equal to the starting current. Unless the motor is disconnected when it stops, it will start up again in the opposite direction.

**D.c. injection** The three-phase supply to the stator is disconnected and immediately replaced by a d.c. supply giving a stationary field in the air gap. The rotor conductors, moving in this field, develop e.m.f.s and currents that exert a braking torque, initially about equal to the starting torque but falling

Figure 20.44 Torque–speed relationships for variable voltage

with the speed and vanishing as the motor is brought to rest by friction. The direct current is fed into the stator by two terminals, leaving the third isolated if the stator winding is star-connected.

**Regeneration** When a load overdrives the motor to a speed exceeding synchronous (i.e. with negative slip) as with a descending hoist load, the machine acts as an induction generator and sets up a braking torque (see Figure 20.36). Such braking cannot bring the motor to rest but it can limit the speed to a value a little above synchronous, the power from the load being partly returned to the supply. With two-speed pole-change motors a high braking torque can be obtained if, when running at the higher speed, the motor is switched to the larger pole-number.

### 20.3.4 Three-phase commutator motors

The recovery of slip energy can be achieved in a single machine by incorporating in the rotor a commutator winding. The *Schrage* (rotor-fed) and *doubly fed* (stator-fed) motors have some commercial importance. Both have a ‘shunt’ speed–torque characteristic and can operate both above and below synchronous speed. A three-phase commutator motor with a ‘series’ characteristic is also available.

#### 20.3.4.1 Schrage motor

The Schrage motor has its primary winding on the rotor, connected to the supply through slip-rings and brushes. The rotor also carries a low-voltage commutator winding with conductors located in the same slots as, and above, those of the primary. The secondary winding is on the stator. The primary and secondary windings are similar to those of a conventional induction motor. The brushgear comprises two movable rockers, each fitted with three brush spindles per pair of poles. The two rockers are geared together, each being fitted with a toothed segment. The two segments mesh with pinions fitted to a short shaft to which either a hand-wheel or a small pilot motor is connected. The gearing is so arranged that the movement of the handwheel or pilot motor causes the brush rockers to move in opposite directions.

The brushes attached to each rocker move over separate portions of the commutator surface to enable these brushes to be placed ‘in line’ or to be moved in either direction, so that more or fewer commutator sectors are included between a brush on one rocker and the corresponding brush on the other.

The bus-rings of each rocker are connected to the secondary (stator) winding as in Figure 20.45, which represents a two-pole machine.

As the primary winding is on the rotor, e.m.f.s of slip frequency are induced in the secondary (stator) winding. The e.m.f.s at the brushes are also of this frequency. The e.m.f. induced in each coil of the commutator winding is constant at all speeds, and therefore the e.m.f.s injected, via the brushes, into the secondary winding are proportional to the number of commutator sectors included between corresponding brushes on the two rockers, i.e. between the brushes connected to a particular phase of the secondary. Thus, when these brushes are in line, the secondary winding has no e.m.f. injected into it and the motor will run with its natural slip. When the brushes are moved so that the injected e.m.f. opposes the current, the speed is reduced (slip positive); for the opposite movement the speed is increased (slip negative).

**Performance** In a machine with a synchronous speed  $n_s$  and a brush-separation electrical angle  $\theta$ , the no-load speed is

Figure 20.45 Schrage motor; stator and rotor circuits

$$n = \frac{1}{2} (1 - k \sin \frac{1}{2} \theta) \leftarrow$$

where  $k$  is a constant depending on the numbers of turns in the secondary and commutator windings. A typical relation between  $n$  and  $\theta$  is given in Figure 20.46(a) for a motor with a 4:1 speed range—about the practical limit. For a given brush position the speed is nearly constant up to 1.5–2 times full-load torque, as shown in Figure 20.46(b). The speed drop with increasing load is greater than for a plain induction motor because of the brush resistance and the impedance of the tertiary commutator winding. At synchronous speed, when  $\theta = 0$  and the secondary is short circuited through the brushes, the overall efficiency is similar to that of an induction motor. At other speeds the efficiency is perhaps 5% lower on account of the tertiary  $I^2R$  loss and the stator core loss. The power factor approaches unity at speeds above synchronous as the negative slip results in a capacitive effect. At subsynchronous speeds the power factor falls; however, it can be raised in non-reversing motors by arranging that the brush movement is asymmetric with respect to the 'in-line' position, the axis bisecting a corresponding pair of brushes being progressively displaced in a direction opposite to that of the rotor rotation.

Starting can be effected by direct switching with the brushes set in the lowest-speed position, the starting torque

Figure 20.46 Schrage motor: characteristics

being about 1.5 times full-load value with 1.5–2 times full-load current. Commutation limits the output to about 20 kW/pole and the speed range to 4:1. The maximum output for a motor is thus about 200 kW. With limited speed range, rather higher ratings, e.g. 350 kW and 1.5:1, can be achieved. As the primary winding is supplied through slip-rings the supply voltage is restricted to about 600 V.

#### 20.3.4.2 Doubly fed motor

The stator resembles that of a conventional induction motor; it is fed from the supply at any desired voltage up to 11 kV. The rotor carries a commutator winding and has six (occasionally three) brushes per pole-pair (see Figure 20.47). The rotor voltage is necessarily low (200–300 V) and the brushes are connected to the supply through a variable-ratio transformer. The gap flux travels at synchronous speed, and as a result of the commutating function the e.m.f.s at the brushes are of supply frequency at any speed. A variable e.m.f. can thus be obtained from the transformer and injected into the rotor circuits to give speed control from standstill to 1.5–2 times synchronous speed. In practice the variable-voltage transformer is an induction regulator to give smooth speed control. It must be a double regulator to avoid changing the phase angle of the injected voltage.

**Performance** At the zero-voltage position of the regulator the brushes are short circuited through the regulator winding and the machine operates as an induction motor, though with a higher rotor effective impedance. Moving the regulator in one or other direction introduces an e.m.f. into the rotor circuit, to give speed–torque relations similar to those of the Schrage motor. The overall power factor tends to be low owing to the magnetisation of the regulator, but it can be improved by special means.

With the regulator in the lowest-speed position the motor can be direct-started to give about 1.5 times full-load torque with 1.5–2 times full-load current. The regulator must carry the slip power, so that speed variation down to zero requires it to be of a physical size comparable to that of the motor. Machines of some thousands of kilowatts can be economically built for speed ranges of  $\pm 15\%$  or 20% of synchronous speed.

Unlike the Schrage motor the stator-fed commutator motor is not self-contained, but it can be made in larger ratings and for higher voltages. Again, the simpler brush arrangements makes the machine economic in ratings down to 2 or 3 kW.

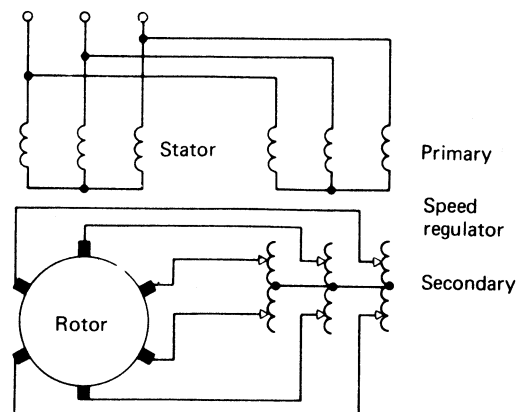

Figure 20.47 Stator-fed three-phase commutator motor

### 20.3.4.3 Three-phase series motor

It is possible to connect the rotor brushes in series with the stator winding to give a machine with a 'series' speed-torque characteristic and with speed variation by moving the brush position. To limit the rotor voltage, however, a transformer is necessary between stator and rotor. If the transformer is that of the induction-regulator type the brushes can be fixed and the speed adjusted by means of the regulator. The series commutator motor is uncommon, but if a steeper characteristic than that furnished by the stator-fed machine is desirable or acceptable, as for fan drives, there is some economy because of the smaller losses and the simpler regulator.

### 20.3.5 Synchronous motors

Any synchronous generator will operate as a motor and run at precisely synchronous speed up to its pull-out torque of 2–2.5 times full-load torque. Other significant features of the motor are the controllability of its power factor up to unity or leading values, the necessity of a d.c. excitation circuit and the fact that the motor is not inherently self-starting. In ratings above 300–500 kW, however, the synchronous motor, although more expensive than the induction motor, has a higher efficiency and lower running cost and, therefore, often gives a more economic drive. Except for 3000 rev/min motors the salient-pole construction is generally adopted.

#### 20.3.5.1 Starting

If the motor is always to be started on no load it can be run up to speed by a small pony motor, usually an induction motor, and then allowed to pull into synchronism when the excitation is switched on. If the motor has solid poles and pole-shoes it may be possible to start it by induction-motor action resulting from eddy currents induced in them when the supply is switched on.

**Induction start** Most synchronous motors are started by use of a cage winding embedded in the pole-faces to give an induction-motor torque when the stator is energised, by direct switching on through an autotransformer. When the speed approaches synchronous the d.c. excitation is applied and the motor synchronises. During starting, high voltages may be induced in the field winding, and it is usual to short-circuit this winding during the start through a resistor which is disconnected after the machine has pulled into step. The current in the field winding adds significantly to the starting torque.

To ensure that the motor closely approaches synchronous speed at the end of an induction start, the resistance of the cage winding should be low; however, for good torque production at low speeds the cage resistance should be high, so some compromise is required.

With direct switching the starting torque is about one-half of full-load torque with 2–3 times full-load current. For machines rated above 200 kW an autotransformer is needed for starting.

#### 20.3.5.2 Excitation

The conventional method of excitation is by a shunt-connected d.c. exciter mounted on the motor shaft, control being effected by variation of the exciter field current; the exciter should, however, be disconnected from the motor field winding during starting on account of the alternating currents that would otherwise be induced in it and which could destroy residual magnetism and prevent the build-up of the excitation.

An a.c. mains-fed rectifier with d.c. output fed to the rotor through the slip-rings could replace the d.c. exciter,

but modern practice favours *brushless excitation*, in which an a.c. exciter feeds the rotor field winding through rectifiers, the whole arrangement being incorporated in the rotor. The a.c. exciter field is energised by means of a small permanent-magnet generator to ensure build-up of the excitation under all conditions.

Excitation control can be made automatic, but it is more usually pre-set to give unity or leading power factor at full load. The increased reactive leading power at lighter loads helps to raise the overall system power factor and to improve the transient stability of the motor when it is subject to disturbances.

#### 20.3.5.3 Synchronous-induction motor

Where high starting torques (e.g. 2–2.5 times full-load) are required, the synchronous-induction motor is suitable. It resembles a slip-ring induction motor and is started on resistance when it is up to nearly synchronous speed, d.c. excitation is switched on to the rotor through the slip-rings and the machine synchronises.

The air gap of the synchronous-induction motor is longer than that of the normal induction motor in order to achieve synchronous stability, and the rotor winding resistance is lower in order to ensure pulling into step. An exciter must also, of course, be provided. Another difficulty is the adaptation of the rotor for the dual purpose of starting and excitation; the direct current is normally fed into two of the slip-rings, the third being isolated so that the winding is not all usefully employed during running. Moreover, the relatively few turns and the large current for which the winding is usually designed necessitate an abnormal design for the exciter, i.e. a low-voltage, high-current machine. The starting performance is similar to that of a slip-ring induction motor, but the running performance is better in that the efficiency is 1–2% higher and the power factor may be made unity or leading. The pull-out torque in the synchronous mode is about 1.5 times full-load torque, but if the machine pulls out it can continue to run as an induction motor with a peak torque up to 2.5 times full-load value.

Where the compromise characteristics of the synchronous-induction motor are inadequate, large salient-pole synchronous motors may be built with a slip-ring pole-face winding, so that the starting and synchronous functions may each be optimised.

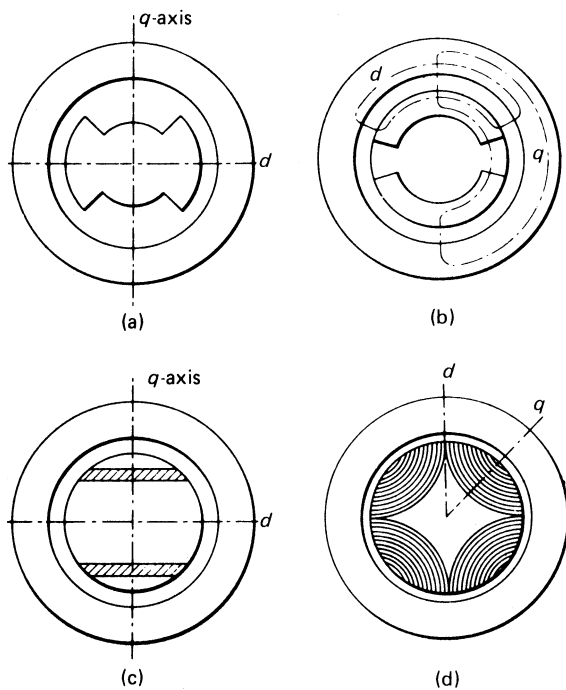

### 20.3.6 Reluctance motors

The reluctance motor is a cheap and reliable synchronous motor that requires no d.c. excitation. Commercial motors are available in ratings of 20 kW or more. The machine has a three-phase stator winding similar to that of an induction motor, and a rotor without windings. For a given frame the output is about 60% of that of an induction machine, and the motor has a slightly lower efficiency. It has, however, advantages for drives such as the accurate positioning of nuclear-reactor rods, the operation of rotating stores in computers, and in synchronised multi-motor drives.

The essential feature of the rotor is a strong 'saliency' effect obtained in ways such as those illustrated in *Figure 20.48*. The obvious saliency in (a) is, in modern machines, replaced by designs based on studies of flux patterns to give the greatest difference in the reluctance offered respectively in the direct and quadrature axes—a condition of good saliency effect. The rotor iron may be solid but is more usually laminated.

Reluctance torque is maintained only at synchronous speed, so that some form of cage winding must be incorporated for starting. Direct switching is employed, giving starting currents

**Figure 20.48** Reluctance motors: (a) salient two-pole; (b) segmental two-pole; (c) flux-barrier two-pole; (d) axially laminated four-pole

up to 4–6 times full-load current. The effective rotor resistance has an important influence on the starting and pull-in torques.

The requirements for a satisfactory motor are good synchronous performance (efficiency, power factor and pull-out torque), good pull-in torque (especially for high-inertia loads) and stability. Some of these conflict: increasing the ratio of  $d$ - and  $q$ -axis reluctances gives higher output and pull-out torque, but lower pull-in torque and impaired stability. The design is influenced particularly by the load inertia. For a motor of 5 kW rating typical data are: reluctance ratio, 3–6; efficiency, 70–80%; power factor, 0.6–0.75 lagging; pull-out torque, 2–2.5 p.u.; pull-in torque, 0.9–1.2 p.u.

Motors with change-speed windings are possible, and motors can be built for variable frequency (20–200 Hz) but these are liable to instability at the lower end of the range.

### 20.3.7 Single-phase motors

Single-phase motors are rarely rated above 5 kW. Fractional-kilowatt motors, most of which are one-phase, account for 80–90% of the total number of motors manufactured and for 20–30% of the total commercial value. A typical modern home may have 10 or more one-phase motors in its domestic electrical equipment.

#### 20.3.7.1 Series motor

As the direction of rotation and of torque in a d.c. series motor are independent of the polarity of the supply, such a motor can operate on a.c. provided that all ferromagnetic parts of the magnetic circuit are laminated to minimise core loss.

**Universal motor** In the fractional-kilowatt sizes the series motor has the advantage, since it is non-synchronous, of

being able to run at speeds up to 10 000 rev/min. It is very well adapted to driving suction cleaners, drills, sewing machines and similar small-power rotary devices. Its facility of operating on d.c. and a.c. is not now important, but is the origin of the term ‘universal’. The machine has a ‘series’ speed–torque characteristic, the no-load speed being limited by mechanical losses. The power factor is between 0.7 and 0.9 (mainly the result of armature inductance), but this is of no significance in small ratings. Typical characteristics for a motor for d.c. and 50 Hz supplies of the same nominal voltage are shown in Figure 20.49.

In all a.c. commutator motors the commutation conditions are more onerous than on d.c. because the coils undergoing commutation link the main alternating flux and have e.m.f.s induced of supply frequency. The e.m.f.s are offered a short-circuited path through the brushes and contribute to sparking at the commutator. As the e.m.f.s are proportional to the main flux, the frequency and the number of turns per armature coil, these must be limited; a further limit on the current in a short-circuited coil is provided by high-resistance carbon brushes.

**Compensated motor** Series a.c. commutator motors up to 700–800 kW rating are used in several European railway traction systems. For satisfactory commutation the frequency must be low, usually  $16\frac{2}{3}$  Hz, and the voltage must also be low (400–500 V), this being provided by a transformer mounted on the locomotive. The inductance of the armature winding is necessarily rather high, so that a compensating winding must be fitted to neutralise armature reaction in order to ensure a reasonable power factor.

Motors of this type have been built, of limited output, for operation on modern 50 Hz traction systems but have now been superseded by rectifier- or thyristor-fed d.c. motors.

#### 20.3.7.2 Repulsion motor

The repulsion motor is a form of series motor, with the rotor energised inductively instead of conductively. The commutator rotor winding is designed for a low working voltage. The brushes are joined by a short circuit and the brush axis is displaced from the axis of the one-phase stator winding

**Figure 20.49** Characteristics of a 75 W universal motor

(Figure 20.50). With non-reversing motors (Figure 20.50(a)) a single stator winding suffices; however, for reversing motors the stator has an additional winding, connected in one or other sense in series with the first winding to secure the required angle between the rotor and effective stator axes for the two directions of rotation, as in Figure 20.50(b).

A stator winding of  $N_1$  turns as in (a) can be resolved into two component windings respectively coaxial with and in quadrature with the axis of the rotor winding, and having respectively turns  $N_1 \sin \alpha$  and  $N_1 \cos \alpha$ . Windings (b) give the two axis windings directly, although here the turns can be designed for optimum effect. The coaxial winding induces e.m.f.s and currents in the rotor, and these currents lying in the field of the other stator winding develop torque; since both stator and rotor currents are related, the motor has a 'series' characteristic.

When the motor is running, the direct and quadrature axis fluxes have a phase displacement approaching  $90^\circ$ , so producing a travelling-wave field of elliptical form which becomes nearly a uniform synchronously rotating field at speeds near the synchronous. Near synchronous speed, therefore, the rotor core losses are small and the commutation conditions are good.

Figure 20.50 Repulsion motor: alternative forms and starting characteristics

Small motors can readily be direct-switched for starting, with 2.5–3 times full-load current and 3–4 times full-load torque. The normal full-load operating speed is chosen near, or slightly below, synchronous speed in order to avoid excessive sparking at light load. Repulsion motors are used where a high starting torque is required and where a three-phase supply is not available. For small lifts, hoists and compressors their rating rarely exceeds about 5 kW.

### 20.3.7.3 Induction motors

The one-phase induction motor is occasionally built for outputs up to 5 kW, but is normally made in ratings between 0.1 and 0.5 kW for domestic refrigerators, fans and small machine tools where a substantially constant speed is called for. The behavior of the motor may be studied by the rotating-field or the cross-field theory. The former is simpler and gives a clearer physical concept.

**Rotating-field theory** The pulsating m.m.f. of the stator winding is resolved into two 'rotating' m.m.f.s of constant and equal magnitude revolving in opposite directions. These m.m.f.s are assumed to set up corresponding gap fluxes which, with the rotor at rest, are of equal magnitude and each equal to one-half the peak pulsating flux. When the machine is running, the forward field component  $f$ , i.e. that moving in the same direction as the rotor, behaves as does the field of a polyphase machine and gives the component torque-speed curve marked 'forward' in Figure 20.51; the backward component  $b$  gives the other torque component, and the net torque is the algebraic sum. At zero speed the component torques cancel so that the motor has no inherent starting torque, but if it is given a start in either direction a small torque in the same direction results and the machine runs up to near synchronous speed provided that the load torque can be overcome.

The component torques in Figure 20.51 are, in fact, modified by the rotor current. Compared with the three-phase induction motor, the one-phase version has a torque falling to zero at a speed slightly below synchronous, and the slip tends to be greater. There is also a core loss in the rotor produced by the backward field, reducing the efficiency. Moreover, there is a double-frequency torque pulsation generated by the backward field that can give rise to noise. The efficiency lies between about 40% for a 60 W motor and about 70% for a 750 W motor, the corresponding power factors being 0.45 and 0.65, approximately.

The equivalent circuit of Figure 20.52 is based on the rotating-field theory, using parameters generally similar to

Figure 20.51 Torque components in a single one-phase induction motor

**Figure 20.52** Simple one-phase induction motor: equivalent circuit

those for the three-phase machine. The e.m.f.s  $E_f$  and  $E_b$  are generated respectively by the forward and backward field components and are proportional thereto. The respective component torques are proportional to  $I_{2f}^2 r_2 / 2s$  and  $I_{2b}^2 r_2 / [2(2-s)]$ , the next torque being their difference.

**Starting** To start a one-phase induction motor, means are provided to develop initially some form of travelling-wave field. The arrangements commonly adopted give rise to the terms 'shaded-pole' and 'split-phase'.

**Shaded-pole motor** The stator has salient poles, with about one-third of each pole-shoe embraced by a shading coil. That flux which passes through the shading coil is delayed with respect to the flux in the main part of the pole, so that a crude shifting flux results. The starting torque is limited, the efficiency is low (as there is a loss in the shading coil), the power factor is 0.5–0.6 and the pull-out torque is only 1–1.5 times full-load torque. Applications include small fans of output not greatly exceeding 100 W.

**Resistance split-phase motor** The additional flux is provided by an auxiliary starting winding arranged spatially at  $90^\circ$  (electrical) to the main (running) winding. If the respective winding currents are  $I_m$  and  $I_s$  with a relative phase angle  $\alpha$ , the torque is approximately proportional to  $I_m I_s \sin \alpha$ . At starting, the main-winding current lags the applied voltage by  $70^\circ$ – $80^\circ$ . The starting winding, connected in parallel with the main winding, is designed with a high resistance or has a resistor in series so that  $I_s$  lags by  $30^\circ$ – $40^\circ$ . The effect of this resistance on the starting characteristic is shown in Figure 20.53(a). With given numbers of turns per winding and a given main-winding resistance, then for a specified supply voltage and frequency there is a particular value of starting-winding resistance for maximum starting torque. The relation can be obtained from the phasor diagram. Figure 20.53(b), in which  $V_1$  is the supply voltage and  $I_m$  at phase angle  $\phi_m$  is the main-winding current. The locus of the starting-current phase  $I_s$  with change in resistance is the semicircle of diameter OD (which corresponds to zero resistance). The torque is proportional to  $I_m I_s \sin(\phi_m - \phi_s)$  and is a maximum for the greatest length of the line AC. From the geometry of the diagram it can be shown that for this condition  $\phi_s = \frac{1}{2}\phi_m$ .

Direct switching is usual. To reduce loss, the auxiliary winding is open-circuited as soon as the motor reaches running speed. The starting torque for small motors up to 250 W is 1.5–2 times full-load torque, and that for larger motors rather less, in each case with 4–6 times full-load current. The operating efficiency is 55–65% and the power factor 0.6–0.7.

(a)

(b)

**Figure 20.53** Single-phase induction motor: split-phase resistance start

**Capacitor split-phase motor** A greater phase difference ( $\phi_m - \phi_s$ ) can be obtained if a series capacitor is substituted for the series resistor of the auxiliary winding. Maximum torque occurs for a capacitance such that the auxiliary current leads the main current by  $(\frac{1}{2}\pi - \phi_m)/2$ . The capacitor size is from 20–30  $\mu\text{F}$  for a 100 W motor to 60–100  $\mu\text{F}$  for a 750 W motor. For economic reasons the capacitor is as small as is consistent with producing adequate starting torque, and some manufacturers quote alternative sizes for various levels of starting torque.

If the capacitor is left in circuit continuously (*capacitor-run*) the power factor is improved and the motor runs with

less noise. Ideally, however, the value of capacitance for running should be about one-third of that for the best starting. If a single capacitor is used for both starting and running, the starting torque is 0.5–1 times full-load value and the power factor in running is near unity.

**Repulsion-induction motor** Machines have been designed to combine the high starting torque capability of the repulsion motor with the constant-speed running characteristic of the induction motor.

**Repulsion-start motor** This motor has a stator winding like that of a repulsion motor and a lap commutator winding, with the addition of a device to short circuit the commutator sectors together by centrifugal action when the speed reaches about 75% of normal. The device may also release the brushes immediately thereafter. Thus the commutator rotor winding becomes, in effect, a short-circuited 'induction'-type winding for running. Small motors direct-switched give 3–4 times full-load torque with about three times full-load current. A lower starting current is obtained by connecting a graded resistor in series with the stator winding.

**Repulsion-induction motor** The machine has a repulsion-type stator winding but the change from the repulsion-mode to the induction-mode operation is gradual as the machine runs up to speed. The rotor has two windings in slots resembling those of a double-cage induction motor. The outer slots carry a commutator winding with brushgear, the inner slots contain a low-resistance cage with cast aluminium bars and end-rings, and its deep setting endows it with a high inductance. During acceleration the reactance of the cage falls and its torque increases, tending to counterbalance the falling torque of the commutator winding. At speeds above synchronous the cage torque reverses, giving a braking action which holds the no-load speed to a value only slightly above synchronous speed. The commutation is better than that of a plain repulsion motor, and the motor is characterised by a good full-load power factor (e.g. 0.85–0.9 lagging). With direct switching the starting torque is 2.5–3 times and the current 3–3.5 times full-load value.

### 20.3.8 Motor ratings and dimensions

Motors of small and medium rating are built to the standards of IEC 72, which list a coherent range of main structural dimensions with centre heights between 56 and 1000 mm. BS 3939 gives the standard ratings for the UK. Table 20.5 lists data for rotating machines up to 1 MW. Approximate values of rated current for three-phase, one-phase and d.c. machines are set out in Table 20.6 for machines up to 150 kW and for a range of supply voltages. Voltages for d.c. machines correspond to nominal values obtained from rectified a.c. supplies.

**Table 20.5** Rotating machines: recommended ratings and shaft heights

<b>Rating (kW)</b>
0.06, 0.09, 0.12, 0.18, 0.25, 0.37, 0.55, 0.75, 1.1, 1.5, 2.2, 3.7, 5.5, 7.5, 11, 15, 18.5, 22, 30, 37, 45, 55, 75, 90, 110, 132, 150, 160, 185, 200, 220, 250, 280, 300, 315, 335, 355, 375, 400, 425, 450, 475, 500, 530, 560, 600, 630, 670, 710, 750, 800, 850, 900, 950, 1000
<b>Shaft-centre height (mm)</b>

### 20.3.9 Testing

Tests on machines after manufacture or after erection on site are made in accordance with standard Specifications. They cover (i) insulation resistances, (ii) winding resistances, (iii) temperature rise, and (iv) losses. Further tests on particular types of machine (e.g. commutation, starting) are required to meet customers' requirements or to obtain design data. Where a batch of similar machines is concerned, a 'type test' on one for detailed performance is usually acceptable.

#### 20.3.9.1 Insulation

'Megger' testing of the insulation resistance between windings, and from windings to frame, must be performed before any live connections are made. The insulation resistance (in mega-ohms) should not be less than 1, or less than  $V/(1+S)$  for a machine of rating  $S$  (in kilovolt-amperes), where  $V$  is the rated voltage. It may be necessary, if the insulation resistance is low, to 'dry out' the machine. The winding continuity having been checked, an insulation test should immediately precede a h.v. test and also be made prior to energising the machine for the first time.

#### 20.3.9.2 Resistance

Measured resistances of the windings check the design figures and are required for calculating losses: winding temperatures must be noted. An ammeter/voltmeter method is usual; alternatively a bridge method may be used if there are no brush contacts in the circuit. For a commutator winding, the volt drop is taken between the commutator sectors under the brushes, the brush drop being taken separately.

#### 20.3.9.3 Temperature rise

The permissible temperature rise of a machine on rated load depends on the insulation class. Temperatures are measured at a number of points (particularly at or near likely 'hot spots') and, where possible, during a heat run with the machine operating at rated load, until a steady temperature has been reached. The rated load may be a *maximum continuous rating*, or a *short-time rating*, or some special rating based on a duty cycle. The duration of the heat run varies from 2 h for small machines to 8 h or more for large ones. Temperature readings are taken (where feasible) every 15 or 30 min. The following three methods of temperature measurement are in use.

**Thermometer** Mercury or alcohol thermometers may be used, the latter being preferable especially on large machines, as eddy currents in the mercury caused by stray fluxes may cause high readings; also mercury from a broken thermometer can cause damage to certain alloys. Good contact must be made between the thermometer bulb and the surface concerned, and the bulb should be well covered by a non-heat-conducting material such as felt or putty.

The thermometers should be located on the stator core and windings and read at intervals throughout the run, and then affixed to the rotor core and windings and to the commutator, if any, as quickly as possible after shut-down. They should be placed where temperatures are likely to be highest; however, only the surface temperature is measured, and not the true hot-spot temperature.

**Resistance** The resistance-temperature coefficient of the winding material can give an average winding temperature.

**Table 20.6** Approximate rated motor currents (A)

Rating (kW)	Induction motors					D.c. motors			
	Three-phase			One-phase					
	350 V	415 V	500 V	240 V	415 V	170 V	290 V	440 V	570 V

30	68	56	48	—	—	—	114	76	58
37	85	72	60	—	—	—	138	92	71
45	100	85	71	—	—	—	169	112	86
55	125	105	88	—	—	—	206	137	106
75	165	137	113	—	—	—	280	187	144
90	185	150	125	—	—	—	337	225	173
110	210	175	145	—	—	—	408	270	210
130	245	215	180	—	—	—	480	320	247
150	320	250	210	—	—	—	555	370	285

For copper, the temperature  $\theta_2$  corresponding to a measured resistance  $R_2$  is related to the resistance  $R_1$  at  $\theta_1$  by

$$\theta_2 = (R_2/R_1)(\theta_1 - 235) + 235$$

**Embedded detector** Thermocouples or resistance thermometers can be embedded in the core and windings during manufacture, a site between the coil-sides of a double-layer winding being common. At least six detectors, suitably distributed, should be installed. When well sited, detectors can give a closer estimate of hot-spot temperatures than other methods.

**Temperature limits** The three techniques above do not measure the same quantities, nor do they measure actual hot-spot temperatures. The values must therefore be in most cases significantly lower than the limits appropriate to the insulation class. Typical values for various locations as laid down in BS 2613 are given in Table 20.7.

#### 20.3.9.4 Losses and efficiency

Efficiency may be determined by direct output/input ratio, by the total loss and either input or output, or by loss summation. As the efficiency of a large machine may have to be guaranteed within 0.01%, accurate determination is essential.

**Output/input** Electric power is readily measured, but mechanical power measurement requires some form of dynamometer, often of limited accuracy. Test rigs with instrumentation are used for small motors, but for large machines an adequate estimation of efficiency by this method may be impossible.

**Back-to-back** If two similar machines are available, one as a motor can drive the other as a generator. The net input is then the total loss, which can be accurately measured. This method can be applied for heat runs with comparative economy.

**Loss summation** A separate determination of each separable loss is made; the items are then summed to give the total loss, and thence the efficiency. The losses to be determined are:

core,  
 stator  $I^2R$ ,  
 rotor  $I^2R$ ,  
 load (stray),  
 brush-contact,  
 excitation, and  
 friction and windage.

Apart from the stray loss, each of these can be determined without loading the machine (although it must be run at normal speed). For uniformity the current losses are

**Table 20.7** Temperature limits (°C)

Part of machine	Method*	Insulation class				
		A	E	B	F	H
A.c. windings						
5000 kVA or core length over 1 m	T, D	60	70	80	100	125
5000 kVA	T	60	75	80	100	125
Commutator windings	R	50	65	70	85	105
	T	60	75	80	100	125
Field windings						
Low-resistance	R, T	60	75	80	100	125
Other windings	R	50	65	70	85	105
	T	60	75	80	100	125
Single-layer windings with bare or varnished metal	R, T	65	80	90	110	135
Permanently short-circuited windings	T	60	75	80	100	125
Iron core in contact with insulated windings	T	60	75	80	100	125
Commutators and slip-rings	T	60	70	80	90	100

Temperature measurement: T, thermometer; R, resistance, D, embedded detector.

found from the measured resistances referred to a standard temperature of 75°C.

**Stray losses** These are, in practice, largely proportional to (current)<sup>2</sup> and, although insignificant in small machines up to a few kilowatts, they become very important in large machines. It is possible to estimate the stray loss from certain tests, as described later for particular machines; in other cases, however, they must be estimated from experience.

#### 20.3.9.5 H.v. tests

The final test carried out before shipping a machine is the h.v. test in which a specified voltage at a frequency between 25 and 100 Hz is applied for 1 min between windings and earth and between windings. The specified voltage is usually (twice rated voltage + 1000) volts, although certain exceptions to this are given in BS 2613.

The purpose of the test is to ensure that the insulation has a sufficient factor of safety to guard against fortuitous voltage transients which may occur in practice. The test should, however, only be carried out once as repeated applications may damage the insulation. It may be desirable in some cases to repeat the test after the machine has been assembled on site, in which case a voltage of not more than 80% of the original test voltage should be applied.

#### 20.3.9.6 D.c. motors

The following tests are related specifically to d.c. machines.

**Armature volt-drop test** This is carried out on the armature winding before assembly or if it has developed a fault. Current is fed into the armature by clamped connectors and the voltage between sectors is measured around the commutator. A placing of the connectors a *pole-pitch* apart is suitable for most industrial two- or four-pole wave-connected armatures: the direction of the volt drop changes at each pole-pitch. A *diametral* connection is suitable for small lap-connected rotors and for six-pole wave-connected rotors: the direction

of the drop reverses at the lead-in points. With the *bar-to-bar* connection the current is led into adjacent sectors and repeated all round the commutator, and all measured drops should be the same. An alternative test for wave windings is to lead the current into the commutator at sectors separated by the *commutator pitch* of the winding. This is repeated all round the commutator and all readings of volt drop should be the same: this checks each individual coil.

**Neutral setting** Adjustment of the brush rocker so that the brushes are in the correct neutral position can most conveniently be done by applying about half normal voltage to the field winding with a low-reading voltmeter connected between the positive and negative brushes. The position of the rocker should be adjusted until there is no kick on the voltmeter when making or breaking the field circuit. It is desirable to remove all brushes except the two being used, and these should be bevelled so that they do not cover more than one segment.

If the exact position of a coil on the armature can be observed, the armature can be moved until this coil is symmetrically placed with its centre line opposite the centre line of a pole; the brush rocker should then be moved until a set of brushes stands on the commutator segment connected to this coil and it will then be in the neutral position. Occasionally one of the armature coils is specially marked by the manufacturers to facilitate this method of setting the neutral.

**No-load test** The power input to the motor running on no load with normal field current and at normal speed gives the sum of the core, friction and windage losses, together with a small armature  $I^2R$  loss which can be calculated and deducted. A *shunt* motor is run at normal field current, the speed being adjusted to normal full-load value by varying the applied armature voltage. The core and mechanical loss so determined is the *fixed* or *constant* loss, so called because it changes only slightly with load. A *series* motor is run with separate excitation to the field, and an armature voltage that will give (for a specified field current) the speed corresponding to load conditions at rated voltage. The voltage to be applied is equal to the counter-e.m.f. under load conditions, i.e. rated voltage less the volt drop in field and armature resistances.

The mechanical loss alone can be estimated by running the motor on no load in normal connection but with a low applied voltage that is adjusted to give the speed required. Then the power input corrected for  $I^2R$  loss is substantially the mechanical loss alone.

**Loss summation** The core, friction and windage losses from the no-load test are added to calculated armature and field  $I^2R$  losses (corrected to  $75^\circ\text{C}$ ) and to the brush loss taken generally as that due to a total brush volt drop of 2 V. The stray loss is allowed for by a deduction of 1% from the efficiency calculated from the losses mentioned above. If the machine has a compensating winding to counteract the distorting effect of armature reaction, the deduction is 0.5%.

### Back-to-back

**Shunt motors** Figure 20.54 shows the connections for a back-to-back test for similar machines. The motor M drives the generator G, the excitation of which is adjusted until there is no voltage across switch S; this is then closed. Raising the excitation of G causes it to generate and supply most of the power required for driving M. The two machines operate with both field and armature currents slightly differing in magnitude, but except for small machines the differences are minor.

**Series motors** Back-to-back tests are more common for series motors, which are not easily loaded with safety. Many series motors are, however, operated in pairs as in traction. The four most common methods are set out in Figure 20.55. Method (a) is not strictly a back-to-back test as the generator output is dissipated in resistance. Putting the generator field in series with the motor ensures that the generator will always excite. In method (b) a variable-voltage booster B is included in the circuit of G to raise its voltage and enable power to be returned to the supply. In both (a) and (b) it is desirable to boost the supply so that the voltage applied to M can be held at a correct value. Method (c) requires an auxiliary drive motor to supply the core and mechanical losses, and a low-voltage booster to supply the  $I^2R$  loss. Method (d) requires a separate source of excitation, although for small machines the field winding can be connected in series with G and controlled by a diverter.

**Commutation** The compole setting can be checked by measuring the *volt drop* between the brush and the commutator at three points along the brush width with the machine running on load (Figure 20.56(a)). The drop should be approximately the same at all points, as in Figure 20.56(b);

if it is greater at the trailing edge, commutation is being delayed and the compoles are too weak. If it is higher at the leading edge the opposite is the case.

The *black-band* test is an alternative method. The compole current is varied independently of the armature current, and at each constant armature current the compole excitation is raised and lowered until sparking occurs. In the zone between these limits (Figure 20.56(c)), commutation is 'black', i.e. spark-free. The black band should be symmetrical about the axis of armature current.

### 20.3.9.7 Induction motors

The following are related specifically to three-phase induction motors. Most of the necessary data are obtained from the no-load and short-circuit tests.

**No load** The motor is run on no load at rated voltage and frequency, and the current and power input are measured. The input power supplies core and mechanical losses plus the stator  $I^2R$  loss; the rotor  $I^2R$  loss on no load can be neglected. If required, the motor may be operated at voltages above and below normal (Figure 20.57) and the power input and current plotted. Extrapolation of the power curve to zero voltage gives the friction and windage loss.

**Short circuit (locked rotor)** The short-circuit current and power are measured by holding the rotor stationary and applying a low voltage to the stator, it being usual to adjust the voltage to obtain full-load current. In the case of a cage motor the starting torque may also be measured. If the motor is connected for star-delta starting, the actual starting current and torque may be measured direct. The short-circuit current at full voltage is calculated by assuming the current to be proportional to voltage, although on some machines the short-circuit current is actually higher because the leakage reactance is reduced by saturation. This is more noticeable on two- and four-pole motors designed for a high flux density. The starting torque is approximately proportional to (phase voltage)<sup>2</sup>.

The short-circuit current is 4–8 times full-load current, depending on the speed and type of motor. A multipolar motor works on a lower flux density to allow a reasonably good power factor. To this end some overload capacity may be sacrificed and the short-circuit current is therefore low.

**Parameters** The parameters of the equivalent circuit (Figure 20.37) can be evaluated from test results. The no-load test gives  $r_m$  and  $x_m$  if the stator leakage impedance drop is neglected (which is usually justifiable). Neglecting  $r_m$  and  $x_m$  in the short-circuit test gives the total motor effective resistance

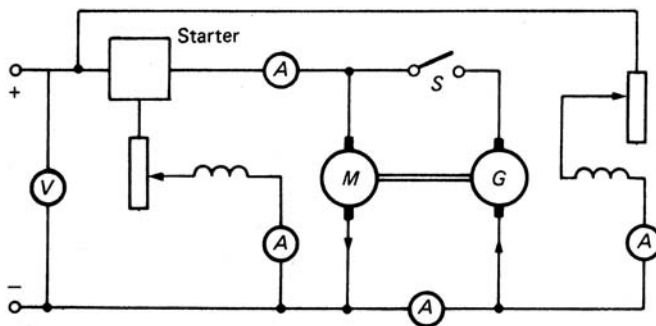

Figure 20.54 D.C. shunt motors: back-to-back test

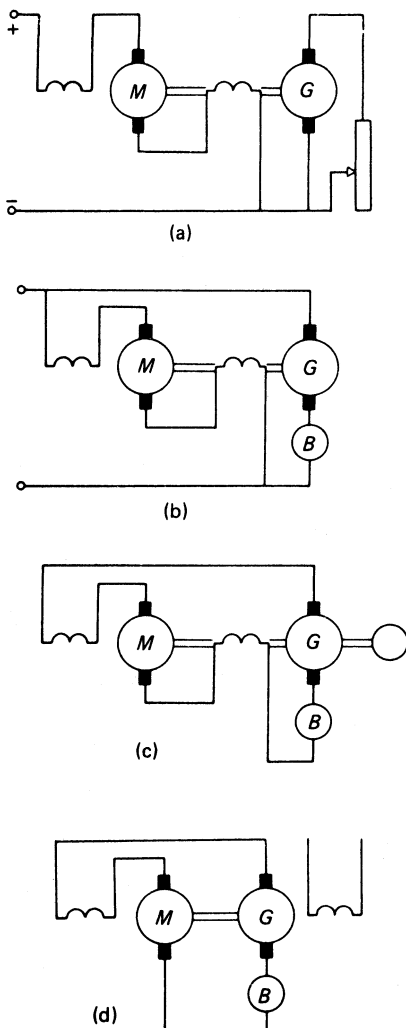

Figure 20.55 D.c. series motors: back-to-back tests

and leakage reactance,  $r_1 + r_2$  and  $x_1 + x_2$ . The stator resistance  $r_1$  can be measured directly and  $r_2$  found; however, it is not possible to separate the two leakage reactances and it is usual to assume that they are equal.

**Stray loss** Stray loss is included in the short-circuit power. If, as in a slip-ring machine, both  $r_1$  and  $r_2$  (actual and referred) are measurable, the 'true'  $I^2R$  loss can be calculated and the stray loss found by subtraction. Where efficiency is calculated by loss summation, a deduction from the calculated efficiency is made (e.g. 0.0625 p.u. at rated load).

**Back-to-back** For large machines this test is essential. There must be provision for accommodating the speed difference resulting from the positive and negative slips of the motor and generator machines. Methods available are: (i) a close-ratio gearbox where at least one of the machines has a slip-ring rotor for slip control; (ii) a fluid coupling where both are cage machines; and (iii) an adaptation of the automobile differential.

Figure 20.56 Commutation tests

Figure 20.57 Induction motor: no-load characteristics

In (iii), the test machines are coupled to the 'road-wheel' shafts. The torque shaft, driven slowly by a geared auxiliary motor, depresses the speed of the motoring machine and raises that of the generator. The main supply of rated voltage and frequency to the two stators provides the mechanical, core and stator  $I^2R$  loss and magnetising currents. The torque shaft controls the drive-power exchange between the two test machines.

### 20.3.9.8 Synchronous motors

Relevant procedures are given below. Again use is made of the open- and short-circuit tests, for which the machine is driven at rated speed by an auxiliary motor, preferably calibrated.

**Open circuit** The stator is on open circuit and the field current is varied. The stator e.m.f. gives the *magnetisation characteristic* or open-circuit characteristic (o.c.c.) (Figure 20.58). The power input to the test machine comprises core and mechanical losses, which can be separated.

**Short circuit** The stator windings are short circuited. The field current is increased to give stator current up to slightly above full-load value. The power input to the test machine comprises the stator  $I^2R$ , mechanical and stray losses, the core loss usually being negligible. An approximation to the stray loss is obtained by subtracting from the input power to the calculated  $I^2R$  loss and the mechanical loss (from the o.c.c. test).

**Excitation** The excitation for given load conditions is derived as for a generator, with reversed current and load angle. The appropriate phasor diagrams are given in Figure 20.58. Typical V-curves, relating the stator and field currents for specified output powers, are plotted in Figure 20.59.

**Loss summation** The friction and windage and the core losses can be obtained from the open-circuit tests, and the stray loss from the short-circuit test, as already described. For any given load the field current can be determined and the field power obtained therefrom. To the summation must be added the loss in the exciter or excitation circuit, and the efficiency can then be calculated.

**Figure 20.58** Synchronous motor: open- and short-circuit characteristics, equivalent circuit and phasor diagrams

**Figure 20.59** Synchronous motor: V-curves

**Back to back** If two similar machines are mechanically coupled so that their e.m.f.s are in phase, and they are driven mechanically at normal speed then, if they are connected in parallel electrically, a reactive current can be made to circulate between them by suitable adjustment of the field currents or by a booster transformer fed from an external source. The total electrical and mechanical input represents the total loss, but as the machines are not operating at their rated power factors the results are not valid for calculating full-load efficiencies. The test is, however, convenient for carrying out heat runs.

With the machines coupled so that their e.m.f.s are phase-displaced by an angle equal to twice the full-load load-angle, then full-load active and reactive powers can be circulated under conditions closely simulating normal load operation.

**Zero power factor** A pseudo full-load test can be carried out by loading the machine on inductors so that it operates at normal voltage and current but at a power factor near zero. The air-gap flux will be 4–5% above its normal full-load value and the field current will be up by 20–30%. If the machine is used for a heat run, temperatures will be higher than those that would obtain at rated load; however, appropriate adjustments can be made to simulate rated conditions more closely. Results from the zero-power-factor test can be used as described in BS 4296 to predetermine the field current on load.

### 20.3.10 Linear motors

Linear machines have translational instead of rotary motion. They can be applied to the drive of a conveyor belt, of a traversing crane on a limited track, of liquid metal in the heat-exchanger of a nuclear reactor plant, or of trains on a high-speed railway system. Short-stroke linear machines are suitable for powerful thrusting action.

#### 20.3.10.1 Forms

A linear machine can be regarded initially as resembling a normal rotating machine that has been cut and opened out flat. Of the two elements derived respectively from the stator

and rotor, either may move. The member connected to the supply is called the *primary*, the other the *secondary*. In use, either member is fixed as the *stator*, while the other becomes the movable *runner*.

Two forms of linear machine (Figure 20.60) are the *flat* machine (geometrically an 'unrolled' rotary structure) and the *tubular* machine, which is equivalent to a flat machine 'rerolled' around the longitudinal axis. For electromagnetic force to be developed, it is necessary to ensure that interaction between the working flux and the working currents should be achieved: the directions of the two components in and around the air gap must be at right angles. In the flat machine (Figure 20.60(a)) the secondary interaction currents are arranged to flow across the element from front to back, with suitable end-connectors to complete the secondary circuits. In the tubular machine the flux enters the pencil-shaped secondary in a radial direction, so that the secondary interaction currents must flow circumferentially.

In both of the shapes in Figure 20.60 there are certain practical difficulties: (i) how to deal with a linear movement which, if continued, must eventually cause a runner of finite length to part company with its stator; (ii) how to support a very strong magnetic pull tending to cause runner and stator to adhere; (iii) how to supply electrical energy to a linear-moving runner. In the flat machine, and in the tubular machine if it is not precisely centred, the otherwise unbalanced attraction force must be sustained by some suitable mechanical arrangement. The linear machine is inherently a device lacking some of the symmetry and balance of the normal rotary form.

### 20.3.10.2 D.c. and a.c. machines

Any arrangement possible in a rotary machine can be realised in the flat form. The outlines in Figure 20.60 show that the most convenient type is likely to be that corresponding to the cage induction motor, for then the stator can often be made the primary because of the convenience of its supply, while the moving secondary member will correspond to the cage rotor and will require a very simple winding with no supply connections. However, this arrangement is by no means the rule, and much depends on the particular conditions of a given application.

The d.c. and induction forms are the most common. Because of the essential secondary current supply, the d.c. linear motor is usually found as an electromagnetic pump for liquid metal. There is more freedom of shape in the induction machine, as indicated in Figure 20.61. The short-primary

Figure 20.61 Polyphase linear-induction motors

arrangement (a) suits cases in which the total distance to be travelled is great, for it would be uneconomic to wind a long three-phase primary, with only that part in the neighbourhood of the secondary being effective at any one time. The short-secondary form (b) is useful if the total excursion is limited and the moving secondary must be comparatively light. In both (a) and (b) the secondary is shown as a flattened 'cage'. A conducting sheet or plate (c) is often as effective, and it obviates magnetic attraction. The now

Figure 20.60 Linear motors: (a) flat; (b) tubular

indefinite 'gap', which increases the non-useful leakage flux, can be shortened by the use of a double primary (*d*).

Long-established methods for the design of orthodox rotary machines are not applicable to the radically changed geometry of linear flat or tubular machines. Lacking cylindrical symmetry, the magnetic flux is heavily distorted near the ends of the short element, and as the primary and secondary move relatively to one another, 'dead' regions of the secondary abruptly enter a magnetised gap, and 'live' regions abruptly leave it at the other side. As a result there are important transient effects, the elimination or mitigation of which will impose quite unusual restrictions on the design, affecting not only the length and number of poles of the primary, but also its optimum working frequency.

### 20.3.10.3 Duty

There are, in general, three operating duties, which influence the design and construction.

**Power (drive)** This is concerned with the transport of loads in conveyors, haulers, electromagnetic pumps, travelling cranes and railway traction with acceptable overall power efficiency.

**Energy (accelerator)** Here the duty is to accelerate a mass from rest within a specified time and distance, as in rope-break and car-crash test rigs and the launching of aircraft. The criterion is the *energy* efficiency, i.e. the ratio of the energy imparted to the load and the total primary electrical energy input, a figure that cannot exceed 0.5.

**Force (actuator)** This develops a thrust at rest, or over a short stroke, as in the operation of stop-valves, impact metal-forming, door closers and small thrusters. The criterion is the *force* per unit electrical power.

### 20.3.10.4 General principles

The following analysis, applying to power (drive) types of linear motor, outlines in simplified terms the basic principles.

**Speed** The speed of a d.c. linear machine is associated with the secondary applied voltage and the flux per pole in a way comparable to the relationship between these variables in a rotary machine.

The speed of an induction-type linear machine is associated with the synchronous speed  $u$ , which is given by  $u = f\lambda$  for a supply frequency  $f$ , where  $\lambda$  is the wavelength (i.e. the length of a double pole-pitch). The actual speed  $u$  differs from  $u_1$  because of the slip. If  $\lambda = 4\text{ m}$  and the supply frequency is 50 Hz, then  $u_1 = 200\text{ m/s} = 480\text{ km/h}$ . For lower translational speeds on a 50 Hz supply it is necessary to shorten the wavelength. However, if  $\lambda$  is less than about 0.2 m, corresponding to  $u_1 = 40\text{ m/s} = 36\text{ km/h}$ , the performance is impaired because the pole-pitch is short compared with the gap length. The effect is most significant in machines with an 'open' magnetic circuit (Figure 20.61(c)). Much better low-speed performance can be achieved if a low-frequency supply is available. In some cases in which starting from rest at high translational force is sought, a primary with a graded pole-pitch may be of advantage; alternatively the frequency can be raised during the starting period if the method can be economically justified.

**Power** If in a secondary member the surface current density is  $J$  and the gap flux density is  $B$ , the force developed per unit area of gap surface is  $BJ$ , and the motional e.m.f.

developed at a translational speed  $u$  is  $Bu$  per unit width. The working voltage to be supplied to maintain motion is  $v = Bu + J\rho s$  per unit width, where  $\rho s$  is the resistivity of the secondary surface current conducting path. Where the secondary is a conducting sheet (solid or liquid) the secondary current paths are ill-defined, so that estimation of performance is not straightforward.

In an induction linear machine with a two- or three-phase winding fed at frequency  $f$  and providing a travelling wave of gap flux at synchronous speed  $u_1 = f\lambda$ , the runner moves in the same direction at a lower speed  $u$ , i.e. with a slip given by  $s = (u_1 - u)/u_1$ . At a point in the gap where the instantaneous gap flux density is  $B_x$ , the e.m.f. induced in the secondary is  $e_x = B_x u_1$  per unit width, producing a secondary current of linear density  $J_x = e_x / \rho s$  (ignoring inductive effects in the current path). The interaction force per unit width is therefore  $B_x J_x = B_x^2 s u_1 / \rho$ . Summed over a wavelength (one double pole-pitch of length  $\lambda$ ) the force is  $\frac{1}{2} \lambda s u_1 B_m^2 / \rho$ , where  $B_m$  is the peak density of the travelling wave of magnetic field. As the runner moves at speed  $u_1(1 - s)$ , the mechanical power produced per wavelength and per unit width is

$$P_m = \frac{1}{2} \lambda s (1 - s) u_1^2 B_m^2 / \rho s$$

This is a maximum for  $s = 0.5$ . The simple analysis applies only to wavelengths remote from the ends of the shorter member of the machine. In general, the precise current circuit of the secondary is somewhat indefinite, there are effects of leakage inductance, and near the ends of the primary block the 'dead' regions of the secondary abruptly enter the magnetised gap while 'live' regions as abruptly leave it. As a result there are transient 'entry and exit' effects, the mitigation of which imposes restrictions on the design that are absent in rotary types.

### 20.3.10.5 Applications

Some typical applications are described.

**Electromagnetic pump** The electromagnetic pump utilises the good electrical conductivity of the liquid metal being pumped to establish electromagnetic forces directly within the liquid itself. The liquid is contained in a simple pipe, which can be welded to the rest of the circuit, so that valves, seals and glands are avoided; this is desirable since the low-melting-point metals are highly reactive chemically. Because of the absence of glands and moving parts, the pump reliability should be high and maintenance costs low. In addition, the pump itself is often smaller and the amount of liquid contained sometimes less, which is important when expensive liquids are being handled. Moreover, in favourable cases, particularly with high-conductivity liquid metals, the pump is likely to be cheaper.

The most important applications for circulating liquid metal are in nuclear energy projects where the metal is used as a coolant: sodium, sodium-potassium and lithium are the metals chiefly concerned. Most other industrial applications are restricted to low-melting-point metals, as in the die-casting industry or in chlorine plants for pumping mercury, but a form of liquid-metal pump has been found useful for stirring molten steel in arc furnaces.

The liquids mentioned divide into two distinct classes: (1) sodium, sodium-potassium and lithium; and (2) bismuth, mercury, lead and lead-bismuth, which have much poorer pumping properties. For example, the resistivity of bismuth is nearly eight times that of sodium, its viscosity is five times higher and its density is 11 times higher. A high resistivity lowers the efficiency, while high viscosity and density make the pump appreciably larger, for, to reduce hydraulic losses,

the liquid velocity must be low, and this increases the size of the pump duct.

The wide difference in liquid pumping properties influences the type of pump and the efficiency obtainable. Liquids like bismuth usually necessitate conduction pumps, in which current is supplied directly to the liquid through the tube walls. In contrast, sodium can be pumped by conduction or induction.

**D.c. conduction pump** The general arrangement is shown in Figure 20.62. The magnetic field can be produced by a permanent-magnet system or by an electromagnet. A series-excited electromagnet is preferred for large pumps as it is usually smaller and cheaper and involves only the provision of a few turns around the pole, as close as possible to the gap, to carry the main operating current. The supply requirements vary from 5 kA at 0.5 V for a pump of 0.05–0.1 m<sup>3</sup>/min capacity at a pressure differential of 350 kN/m<sup>2</sup>, up to 250 kA at 3–4 V for a nuclear reactor pump delivering 25 m<sup>3</sup>/min at 500 kN/m<sup>2</sup>. These inconvenient requirements form the major disadvantage of the d.c. pump; the compensating advantages are the minimal insulation levels (desirable if the liquid is hot or radioactive), the accommodating performance which can deal with a wide range of flow rates and pressures with good efficiency, and the adaptability to a variety of metals, including bismuth.

In d.c. pump design it is important to assess the field distortion due to the current in the liquid metal and to apply compensation if necessary, by returning the current to the electrode between the pole and the pump duct, usually as a pole face winding. It is also important for good efficiency to restrict the useless components of electrode current, which flows in the tube wall and in the liquid outside the pole region. The tube-wall current can usually be limited only by choosing a thin-walled tube of high intrinsic resistivity. The useless current can be substantially reduced by fringing the field to match the natural fringing of the current density between the electrodes. It is also important in design to limit magnetic leakage by appropriately positioning the magnetising turns and by shaping the iron.

The operation can be approximately described in terms of the flow of a quantity  $q$  of liquid at velocity  $u$  in a tube of width  $b$  in the current direction and effective length  $c$  in the direction of the liquid movement, the liquid having a resistivity  $\rho$ :

Electrodes: voltage  $V_0 = (Bu + J\rho)b$ ;  
current  $I_0 = I = I_t = I_s$

Figure 20.62 D.c. conduction pump

Pump: gross pressure  $p = (B_m J)c$ ;  
gross power  $P_0 = pq$

Here  $B$  is the flux density, of mean value  $B_m$ , and  $J$  is the current density. The electrode current  $I_0$  includes the useful current  $I$ , and non-useful shunt currents  $I_t$  in the tube walls and  $I_s$  in the liquid outside the magnetised region. The gross pressure  $p$  includes the hydraulic pressure, drop in skin friction, etc.

**A.c. induction pump** The two basic forms are the flat and the annular. The flat type (Figure 20.63) has a straight duct 10–25 mm wide and up to 1 m across. Copper bars are attached to each side of the channel to form the equivalent of the 'end-rings' of a normal cage winding. A flat poly-phase winding is placed on each side of the duct. A heat-insulating blanket is usually necessary between duct and winding, which is force cooled. The annular form is similar except that the cross-section of the duct is an annulus and embraces a radially laminated magnetic core. The poly-phase winding comprises a number of pancake coils surrounding the duct and set in comb-like stacks of radial punchings. If the duct is made re-entrant, with inlet and outlet at the same end, it is possible to remove the primary windings for repair and maintenance, should this become necessary, without disturbing the pipe-work.

**Cranes** Two linear induction motors can be applied to the traversing of an overhead crane, replacing the conventional rotary cage motor, gearing, drive shaft and control equipment. Maintenance is simplified and, as the linear motors are unaffected by atmospheric conditions, the likelihood of breakdown is reduced. The arrangement for one of the motors is shown schematically in Figure 20.64. Each motor comprises a horizontal pack of laminations carrying a three-phase winding. Motors are located at each end of the crane gantry and directly below the tracks from which the crane is suspended. The track functions as the secondary, the arrangement being basically that of Figure 20.61(c).

**Traction** Several schemes have been proposed for railway traction. One uses a short-primary form of motor on the locomotive and a fixed 'plate' secondary secured to the track. The moving primary demands either that power be supplied to the moving train or that a prime mover and three-phase generator be carried on board. Some recent

Figure 20.63 A.c. induction pump

developments exploit magnetic levitation and the elimination of running wheels.

**Stirring** The stirring of molten metal in furnaces can be done by external application of short linear induction motors. The process has considerable metallurgical advantage in improving the casting properties of aluminium and copper, and in accelerating the deoxidation processes in steel. The primary of the motor does not come into contact with the melt, is readily controlled and can be arranged for vertical, rotary or horizontal stirring.

**Short-stroke devices** The linear induction motor offers a compact and readily controllable means for the automation of punching, stamping and impact extrusion. With the wavelength graded on the fixed primaries to raise the 'synchronous' speed as the short secondary runner approaches the workpiece, end speeds of 30 m/s and considerable kinetic energy can be attained. Other industrial applications include the following:

**Sliding doors:** here an advantage is that, should the supply fail, the motor does not impede movement of the door by hand.

**Figure 20.64** Linear traversing crane motor

**Goods lifts:** the arrangement is that of *Figure 20.64* turned vertically, the linear motor stator providing some of the counterweight.

**Tensioning machines:** the linear motor gives readily controllable tension for testing ropes, aluminium strip, etc.

## 21.1 Light and vision

*Light* is electromagnetic radiation, i.e., it has electric and magnetic fields, mutually at right angles and varying sinusoidally as shown in *Figure 21.1*. It is capable of causing a visual sensation in the eye of an observer. It is measured in terms of its ability to produce such a sensation.

The *spectral range* of visible radiation is not well defined, and can vary with the observer and with conditions. The lower limit is generally taken to be 380–400 nm (deep-blue radiation) and the upper limit 760–780 nm (deep-red radiation).

The human eye is not equally sensitive to all wavelengths, as shown in *Figure 21.2*. For normal daylight vision, referred to as *photopic vision*, the eye has a peak sensitivity at 555 nanometres (nm). The eye contains two distinct types of light-sensitive receptors referred to as *rods* and *cones*. The cones are responsible for colour vision whilst the rods operate in dark conditions.

At low levels of illumination the more sensitive rods begin to take over, and the resultant image appears less brightly coloured. Furthermore, the peak sensitivity shifts towards the blue/green region of the spectrum. This condition is known as *mesopic vision*.

At still lower levels vision is almost entirely by rod receptors and the eye is said to be dark-adapted. In this state, known as *scotopic vision*, the sensation is entirely in black and white and the peak sensitivity has moved to 505 nm.

The Commission Internationale de l'Eclairage (CIE) has defined an agreed response curve for the photopically adapted eye, known as the *spectral luminous efficacy* or  $V(\lambda)$  function. Luminous flux, which is the rate of flow of light, is radiant power weighted according to its ability to produce a visual sensation by the  $V(\lambda)$  function.

The luminous flux emitted by a source of light will vary with direction of emission. The rate of change of luminous flux with solid angle is termed the *luminous intensity*.

*Illumination* is the process whereby luminous flux is incident upon a solid surface and the corresponding quantity (flux density per unit area) is the *illuminance*.

Light striking a surface can be reflected, transmitted or absorbed according to the nature of the surface, and the fractions of the incident luminous flux thus affected are termed the reflectance, transmittance or absorptance, respectively.

**Figure 21.1** Electric field and magnetic field mutually at right angles. Electric field and magnetic field have same axis  $x-x'$  but are shown separately for clarity only

## 21.2 Quantities and units

Each quantity has a quantity symbol (e.g.  $I$  for luminous intensity) and a unit symbol (e.g. cd for candela) to indicate its unit of measurement.

*Luminous flux*,  $\Phi$ ; lumen (lm) The rate of flow of luminous energy. A quantity derived from radiant flux by evaluating it according to its ability to produce visual sensation. Unless otherwise stated, luminous flux relates to photopic vision as defined by the  $V(\lambda)$  function of spectral luminous efficacy.

If  $K_m$  is the maximum spectral luminous efficacy (about  $680 \text{ lm} \cdot \text{W}^{-1}$  at a wavelength of 555 nm), then the luminous flux  $\Phi$  (in lm) is related to the spectral power distribution  $P(\lambda)$  at wavelength  $\lambda$  by

$$\Phi = K_m \int P(\lambda) \cdot V(\lambda) \cdot d\lambda$$

*Luminous efficacy (of a source)*,  $\eta$ ; lumens per watt ( $\text{lm} \cdot \text{W}^{-1}$ ) The quotient of the luminous flux emitted by a source to the input power. It should be noted that for discharge lamps the luminous efficacy may be quoted either for the lamp itself or for the lamp with appropriate control gear. The latter figure will be lower.

*Luminous intensity*,  $I$ ; candela (cd) The quotient of the luminous flux  $\delta\Phi$  leaving the source, propagated in an element of solid angle containing the given direction, by the element of solid angle  $\delta\omega$  (see *Figure 21.3*).

$$I = \delta\Phi / \delta\omega$$

*Illuminance*,  $E$ ; lux (lx) or lumens per metre<sup>2</sup> ( $\text{lm} \cdot \text{m}^{-2}$ ) The incident luminous flux density at a point on a surface. The quotient of the luminous flux incident on an element of surface, by the area of that element. Referring to *Figure 21.3*,

$$E = \delta\Phi / \delta A$$

Figure 21.2 The relative spectral sensitivity of the human eye

Figure 21.3 Luminous intensity and illumination

Note: the term *illuminance* is used for the quantity, while the term *illumination* describes the physical process.

**Luminance,  $L$ ;** candela per metre<sup>2</sup> ( $\text{cd} \cdot \text{m}^{-2}$ ) The luminous intensity in a given direction of a surface element, per unit projected area of that element.

Luminance is a physical measure of brightness, but it should be noted that an observer's assessment of the brightness of an object is subjective, unlike luminance which is the objective physical measure. It will depend upon the level of adaptation and other factors. For example, the luminance of a car headlight during the day and at night would be approximately the same, but the apparent brightness during the day would be significantly less.

### 21.3 Photometric concepts

**Inverse square law** The illuminance  $E$  at a point on a surface produced by light from a *point* source varies inversely with the square of the distance  $d$  from the source, and is proportional to the luminous intensity  $I$  towards that point. Referring to Figure 21.3, the illuminance is given by

$$E = I/d^2.$$

**Cosine law** The illuminance on a surface is proportional to the cosine of the angle  $\theta$  between the directions of the incident light and the normal to the surface. This is due to the reduction of projected area as the angle of incidence increases from zero (normal incidence) to  $90^\circ$ . For a point source at distance  $d$ , the illuminance for angle  $\theta$  is

$$E = E_0 \cos \theta = I \cos \theta / d^2$$

where  $E_0$  is the illuminance for normal incidence,  $\theta = 0$ . With the working surface horizontal and the source mounted a distance  $h$  above the surface, the illuminance on the working surface is

$$E = I \cos^3 \theta / h^2$$

involving  $\theta$  as the only variable.

**Reflection** Light falling on a surface may undergo *direct* or *diffuse* reflection. Direct reflection is specular, as by a mirror. Diffuse reflection may be *uniform* or *preferential*: in the former the luminance is the same in all available directions; in the latter there are maxima in certain directions (see Figure 21.4). Direct and diffuse reflection may occur together as *mixed* or *spread* reflection.

Examples of reflecting surfaces are: direct (mirror glass, chromium plate); uniform diffuse (blotting paper); preferential diffuse (anodised aluminium, metallic paint).

**Reflectance,  $R$**  The ratio between the reflected luminous flux and the incident luminous flux.

**Transmission** Light falling on a translucent surface undergoes partial transmission (Figure 21.5). The transmission may be *direct*, as through clear plate glass; *diffuse*, as through flashed opal glass; or *preferential*, as through frosted glass.

**Transmittance,  $T$**  The ratio between the transmitted luminous flux and the incident luminous flux.

**Absorption** That proportion of light flux falling on a surface which is neither reflected nor transmitted is *absorbed* and, normally, converted into heat.

**Refraction** While a light ray is travelling through air, its path is a straight line. When the ray passes from air to glass (or any transparent material, e.g. clear plastics, diamonds, etc.), the ray is, in general, bent at the surface of separation. The path of the ray after bending or refraction from air to glass is always more nearly perpendicular to the bounding surface than is that of the incident ray. The degree to which the ray is bent depends on the type of glass or transparent material, the angle of incidence of the ray and also the colour of the light.

Should the ray, while in the glass, strike another bounding surface, it may again be refracted. In this case the

Figure 21.4 Reflection

Figure 21.5 Transmission with partial reflection

refracted ray may be more nearly parallel to the bounding surface than is the incident ray. If the light ray strikes the bounding surface at any angle above a certain limit (the *critical angle*), it will not be refracted but will be totally reflected.

Both refraction and total internal reflection are used in the design of lighting units, the prismatic types of reflector being typical examples.

*Polar intensity distributions* Utilising the inverse-square and cosine laws, it is possible to calculate the direct illuminance

at a point from a single luminaire, or an installation, using the 'point-by-point' method. The effect of inter-reflected light is not included, as the calculations are too complex to warrant it.

Figure 21.6 shows the intensity distributions for two different interior luminaires: (a) is for a luminaire with a luminous intensity distribution symmetrical about a vertical axis, and (b) is for a non-symmetrical luminaire with a luminous intensity distribution symmetrical about two orthogonal vertical planes. These are typical of discharge and fluorescent luminaires, respectively.

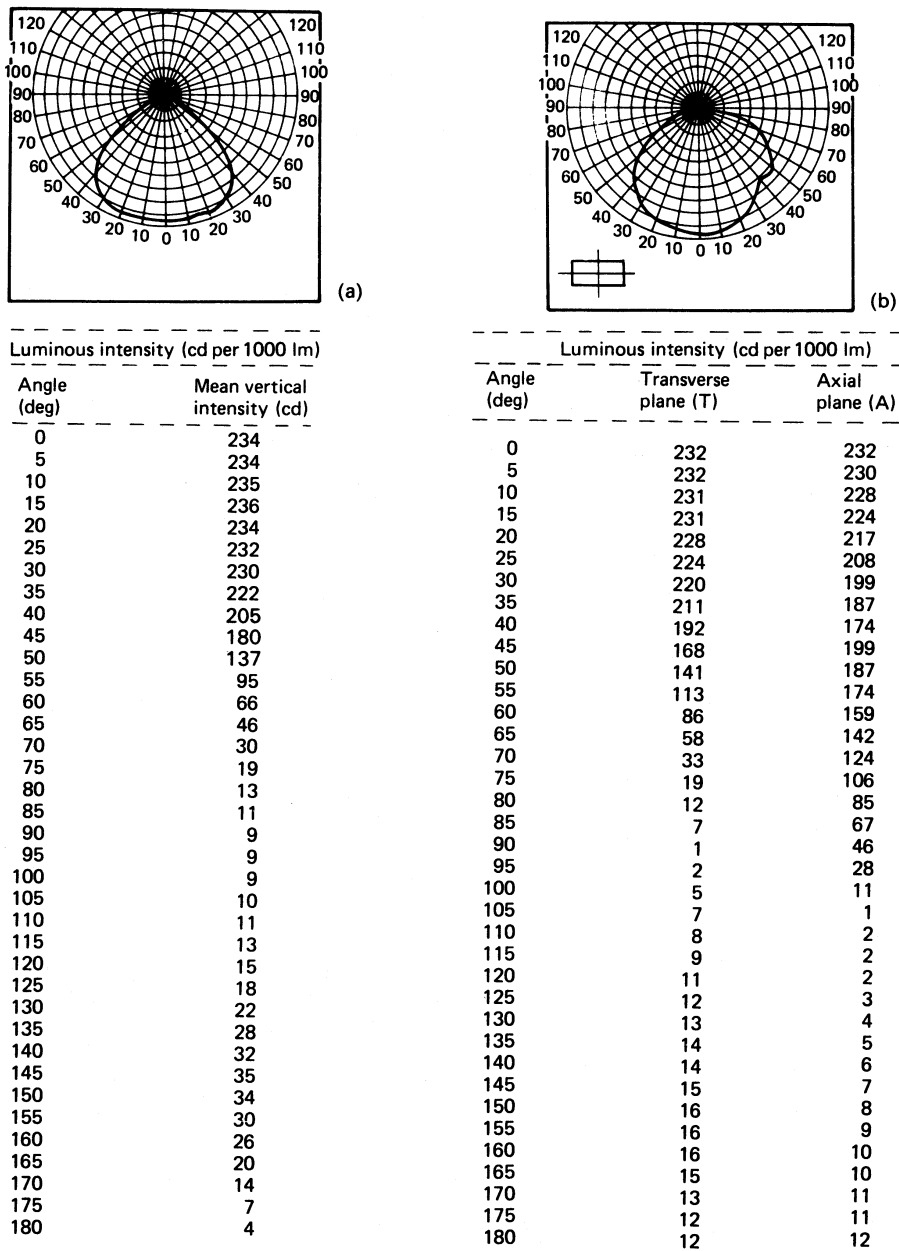

Figure 21.6 Luminous intensity distributions for: (a) symmetric luminaires and (b) non-symmetric luminaires

**Figure 21.7** The transverse and axial planes in which the transverse and axial polar curves are measured

For symmetric luminaires, only one average intensity distribution is normally given, and this can be presented graphically on polar co-ordinates or in tabular form (which is easier to use). For non-symmetrical luminaires two or more distributions are given. The principal ones are the *axial* and *transverse* distributions, which lie in vertical planes down the axis of the luminaire, and at right angles thereto, respectively (Figure 21.7).

Many luminaires can accommodate various lamp types without affecting the shape of the intensity distribution. For this reason it is a common practice to quote intensities in candelas per 1000 lamp lumens ( $\text{cd} \cdot \text{klm}^{-1}$ ) rather than in candelas. This permits easy scaling of the data according to the luminous output of the lamps.

For streetlighting and floodlighting luminaires, the main distributions are usually insufficient, and contours of equal intensity (isocandela) are normally published on a convenient Cartesian grid system, as shown in Figure 21.8.

**Isolux diagrams** A convenient way of plotting the illuminance produced by single luminaires or complete installations is by contours of equal illuminance, or isolux contours. Isolux diagrams are frequently used to depict the performance of non-symmetrical luminaires such as 'wall-washers', and are now often used when the calculations are done by computer. Figure 21.9 shows a typical isolux diagram for a reflector luminaire at a particular mounting height.

## 21.4 Lighting design terminology

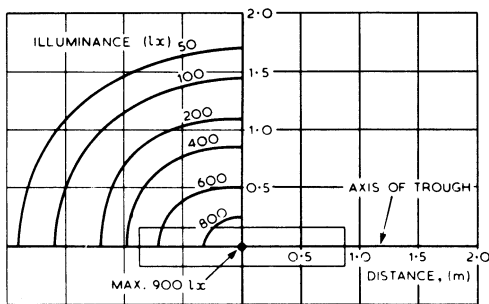

**Light output ratio (LOR)** The ratio between the light output of the luminaire measured under specified practical conditions and the sum of the light outputs of individual lamps operating outside the luminaire under reference conditions.

**Photometric centre** The point in a luminaire or lamp from which the inverse square law operates most closely in the direction of maximum intensity.

**Upward (downward) flux fraction (UFF (DFF))** The fraction of the total luminous flux of a luminaire emitted above (below) the horizontal plane containing the

**Figure 21.8** Typical isocandela diagram. Figures on contour lines represent luminous intensities in candela per 1000 lamp lumens

**Figure 21.9** Isolux diagram for a 1.8 m long trough reflector luminaire

photometric centre of the luminaire. Also known as upper (lower) flux fraction.

*Upward (downward) light output ratio (ULOR (DLOR))* The product of the light output ratio of a luminaire and the upward (downward) flux fraction.

*Symmetric luminaire* A luminaire with a light distribution nominally rotationally symmetrical about the vertical axis passing through the photometric centre.

*Non-symmetric luminaire* A luminaire with a light distribution nominally symmetrical only about two mutually perpendicular planes passing through the photometric centre. Where such a luminaire is linear, the vertical plane of symmetry normal to the long axis is designated the *transverse plane*, and the vertical plane passing through the long axis is designated the *axial plane* (see Figure 21.7). The vertical distributions taken in these planes are the transverse and axial distributions, respectively.

*Working plane* The horizontal, vertical or inclined plane in which the visual task lies.

*Reference surface* The surface of interest over which the illuminance is to be calculated. A reference surface need not contain the visual task.

*Horizontal reference plane* A horizontal reference surface. This is usually assumed to be 0.85 m above the floor and to correspond with the horizontal working plane. The horizontal reference plane is also the mouth of the floor cavity.

*Plane of luminaires* The horizontal plane which passes through the photometric centres of the luminaires in an installation. This is also the mouth of the ceiling cavity.

*Floor cavity* The cavity below the horizontal reference plane in a room (see Figure 21.10). The horizontal reference plane and the floor cavity may be designated by the reference letter F.

*Walls* The vertical surfaces of a room between the plane of the luminaires and the horizontal reference plane (see Figure 21.10). The walls may be designated by the reference letter W.

*Ceiling cavity* The cavity above the plane of the luminaires in a room (see Figure 21.10). The luminaire plane and the ceiling cavity may be designated by the reference letter C.

*Distribution factor, DF(S)* The distribution factor for a surface S is the ratio between the direct flux received by the

**Figure 21.10** Ceiling cavity, walls and floor cavity

surface S and the total lamp flux of the installation. DF(F), DF(W) and DF(C) are the distribution factors for the floor cavity, walls and ceiling cavity, respectively, treated as notional surfaces.

*Utilisation factor, UF(S)* The utilisation factor for a surface S is the ratio between the total flux received by the surface S (directly and by inter-reflection) and the total lamp flux of the installation. UF(F), UF(W) and UF(C) are the utilisation factors for the floor cavity, walls and ceiling cavity, respectively, treated as notional surfaces.

*Direct ratio, DR* The proportion of the total downward flux from a conventional installation of luminaires that is directly incident on the horizontal reference plane. The direct ratio is equal to DF(F) divided by the DLOR of the luminaires.

*Zone factor* The solid angle subtended at the photometric centre of a lamp or luminaire by the boundary of a zone. The zonal flux is obtained by multiplying the intensity of the lamp or luminaire, averaged over the zone, by the zone factor.

*Room index, RI* Twice the plan area of a room divided by the wall area (as defined above). The room is taken to have parallel floor and ceiling, and walls at right angles to these surfaces. From any point in the room all of the surfaces in the room should be visible.

*Spacing/height ratio, SHR* The ratio between the spacing in a stated direction between photometric centres of adjacent luminaires and their height above the horizontal reference plane. It is assumed that the luminaires are in a regular square array unless stated otherwise.

*Maximum spacing/height ratio, SHR MAX* The SHR for a square array of luminaires that gives a ratio between minimum and maximum direct illuminance of 0.7 over the central region between the four innermost luminaires.

*Maximum transverse spacing/height ratio, SHR MAX TR* The SHR in the transverse plane for continuous lines of luminaires that gives a ratio between minimum and maximum direct illuminance of 0.7 over the central region between the two inner rows.

*Nominal spacing/height ratio, SHR NOM* The highest value of SHR in the series 0.5, 0.75, 1.0, etc., that is not

greater than SHR MAX. Utilisation factor tables are normally calculated at a spacing/height ratio of SHR NOM.

**Maintenance factor, MF** The ratio between the illuminance provided by an installation in the average condition of dirtiness expected in service and the illuminance from the same installation when clean. It is always less than unity.

**Uniformity** The ratio between the minimum and average illuminance over a given area. For interior lighting it should be not less than 0.8 over the task area. This requirement can be satisfied by ensuring that the spacing/height ratio of an installation does not exceed SHR MAX.

**Daylight factor, DF** The ratio between the illumination measured on a horizontal plane at a given point inside a building and that due to an unobstructed hemisphere of sky. Light reflected from interior and exterior surfaces is included in the illumination at the point, but direct sunlight is excluded.

## 21.5 Lamps

Light can be produced from electrical energy in a number of ways, of which the following are the most important.

- (1) **Thermoluminescence**, or the production of light from heat. This is the way light is produced from a filament lamp, in which the filament is incandescent.
- (2) **Electric discharge**, or the production of light from the passage of electricity through a gas or vapour. The atoms of the gas are excited by the passage of an electric current to produce light and/or ultraviolet energy.
- (3) **Fluorescence**, a two-step production of light which starts with ultraviolet radiation emitted from a discharge; the energy is then converted to visible light by a phosphor coating within the lamp.

### 21.5.1 Incandescent filament lamps

Thermoluminescence is the emission of light by means of a heated filament. The term is normally synonymous with the tungsten filament lamp in its various forms. The most general form is the general lighting service (GLS) lamp (Figure 21.11). Light produced from a hot wire increases as the temperature of the wire is raised. It also changes from a predominantly red colour at low temperature to a white which approaches daylight as the temperature is increased.

Of the electrical energy supplied to an incandescent lamp filament, by far the greatest proportion is dissipated as heat, and only a small quantity as visible light (about 95% heat and 5% light) (see Figure 21.12). Because the quantity of visible light emitted depends upon the filament temperature, the higher the filament temperature the greater will be the visible light output in lumens per watt of electric power input. Thus, for an incandescent filament, a material is needed that not only has a high melting point, but is also strong and ductile so that it can be formed into wire. At present, tungsten metal is the material nearest to this ideal.

The colour temperature of a normal GLS filament lamp is typically between 2800 K and 3000 K. At the extremely high temperature of the filament, tungsten tends to evaporate. This leads to the familiar blackening of an incandescent lamp envelope. The evaporation of the tungsten filament can be reduced by filling the lamp envelope with a suitable gas that does not chemically attack the filament.

Figure 21.11 Construction of a GLS lamp

Figure 21.12 Spectral power distribution of daylight and a GLS lamp

Suitable gases are hydrogen, nitrogen, and the inert gases argon, neon, helium, krypton and xenon. However, gases also cool the filament by conducting heat away from it, and they decrease lamp efficiency. The gas used must therefore be carefully chosen. It should adequately suppress tungsten evaporation without overcooling the filament. In addition, it should not readily pass an electric current, for otherwise arcing may occur which would destroy the lamp.

Argon and nitrogen are the gases most commonly used. Nitrogen will minimise the risk of arcing, but will absorb more heat than argon. Argon is used by itself in general service lamps. A mixture of the two gases is used in incandescent lamps where the tendency for arcing is more likely, such as in projector lamps. In this case the amount of nitrogen present is kept very small—as little as 5%—in order to obtain optimum lamp efficiency.

Not all incandescent lamps benefit from gas filling. Mains voltage 15 W and 25 W lamps are mainly of the vacuum type, whereas lamps of 40 W and above are normally gas filled.

In general service lamps at least one lead is fused to prevent the envelope shattering should an arc occur. Modern fuses are encapsulated in a glass sleeve filled with small glass balls.

#### 21.5.1.1 Coiled and coiled-coil filaments

If a filament is in the form of an isolated straight wire, gas can circulate freely round it. Filament temperature is thus decreased by convection currents, and has to be raised by increasing the electrical power input.

Coiling the wire reduces the cooling effect, the outer surface of the helix alone being cooled by the gas. Further

coiling (coiled-coil filament) again reduces the effect of the gas cooling and results in further increase in lamp efficiency of up to 15%.

### 21.5.1.2 Glass envelopes

Clear-glass lamp envelopes have smooth surfaces and absorb the smallest possible amount of the light passing through them. The high temperature of the filament results in a high brightness which the envelope does not modify.

Early attempts to reduce glare from an unobscured filament used envelopes externally frosted. These were difficult to keep clean. The drawback is obviated in the modern *pearl* envelope by etching the inside surface instead. The light source appears to be increased in size and to have a larger surface area. The loss of light is negligible.

With the greatly increased illumination levels of modern lighting techniques, a further degree of diffusion is called for. This has been achieved by coating the inside of the envelope with a very finely divided white powder, such as silica or titania. In such lamps the lighted filament is not apparent. The luminous efficiency of the silica coated lamp is about 90% of that of a corresponding clear lamp of equal power rating. Silica coated lamps have a more attractive unlit appearance than either clear or pearl lamps.

In a coloured incandescent lamp the envelope is coated either internally or externally with a filter. All coloured incandescent lamps operate at reduced efficiency. In view of the low proportion of blue light in the spectrum, the efficiency of lamps of this colour is particularly low, as more than 90% of the light is filtered out. It is not possible to obtain a bright saturated blue colour.

### 21.5.1.3 Decorative and special-purpose lamps

The incandescent filament lamp in its simplest form is purely a functional light source, but the fact that an integral part of the lamp has a glass envelope enables the manufacturer to adapt this envelope to give some aesthetic appeal. The commonest form is the candle lamp, with glass clear, white or frosted. Other lamps have been marketed which combine the role of light source and decorative luminaire by virtue of their envelope shape. They are usually of larger dimensions than conventional lamps. Apart from their attractive shapes, they are made with silica coatings, coloured lacquer coatings and crown silvered tops, and are therefore rather more efficient as light-producing units than a combination of lamp and separate diffuser.

To cater for locations where vibration and shock are unavoidable, special *rough service* lamps are produced which combine filament wire modifications with the inclusion of an increased number of intermediate filament supports.

To provide directional beam control a further range of special-purpose lamps is made with blown or pressed paraboloidal envelope shapes coated with an aluminium reflector film. The filament is accurately placed at the focus of the reflector to provide the directional beam. More accurate beam control is provided by the pressed glass versions (PAR lamps).

In some lamps dichroic reflectors are employed. These reflect visible light but transmit infrared radiation. This permits the lamp to have a cooler beam, since the heat radiation is not focused. However, these lamps can be used only in luminaires able to dissipate the extra heat transmitted by the reflector. Dichroic coatings are widely used in film projector lamps with integral reflectors, to prevent

excessive temperature at the film gate. *Figure 21.13* shows the concept of the dichroic lamp

The efficacy of an incandescent lamp is related to the quantity of visible light emitted per unit of electrical power input. Thus, a 100 W incandescent lamp having a total light output of 1200 lm has an efficacy of  $1200/100 = 42 \text{ lm} \cdot \text{W}^{-1}$ .

A higher filament temperature increases lamp efficacy, but the temperature of a tungsten filament cannot be increased indefinitely, as it will melt catastrophically if the lamp efficacy approaches  $40 \text{ lm} \cdot \text{W}^{-1}$ .

At high filament temperatures tungsten evaporation—even though it is reduced by gas filling—is more rapid and leads to a shorter lamp life. Thus, the more efficient an incandescent lamp is the shorter is its life.

Variations in supply voltage vary filament temperature, which, in turn, increases or decreases lamp life. *Figure 21.14* shows how the lamp efficiency, life, light output and input power vary with supply voltage. For example, if a lamp is under-run by 5% below its rated voltage, its life will be nearly doubled (190% of rated 1000-h life) but the lamp power would be reduced to around 92% of the rating and the light output to less than 85% of the normal lumen output.

### 21.5.1.4 Tungsten halogen lamps

If the envelope of a tungsten lamp is made of quartz instead of glass, it can be much smaller, because quartz can operate safely at a higher temperature. As with a glass lamp, tungsten evaporated from the filament will deposit on the quartz envelope, causing it to blacken. However, if a small quantity of one of the halogen elements e.g. iodine is introduced into the lamp, and if the temperature of the quartz envelope is above  $250^\circ\text{C}$ , the iodine combines with the tungsten on the inner face of the quartz to form tungsten iodide, a vapour.

When the tungsten iodide approaches the much hotter filament, it decomposes; the tungsten is deposited on the filament and the iodine is released, to perform its cleaning cycle again (see *Figure 21.15*).

Unfortunately, the tungsten is not necessarily redeposited on those parts of the filament from which it originally

**Figure 21.13** Dichroic reflector lamp

**Figure 21.14** Typical effect of voltage on incandescent filament lamps

evaporated. Even so, substantial improvements in life and/or higher filament operating temperatures can be achieved, giving higher lumen outputs compared with the equivalent GLS lamp.

The increase in life is mainly due to the increased gas pressure, which can be employed in a tungsten halogen lamp to reduce filament evaporation. This, in turn, is only possible because a small outer envelope can be used without risk of lamp envelope blackening.

Tungsten halogen lamps give greater life and greater efficiency than their incandescent counterparts. For this reason they are widely used in floodlighting, photographic lighting, display lighting and automobile lighting. A typical tungsten halogen lamp will provide about 50% greater light output and about twice the life of a conventional tungsten lamp of an equivalent wattage.

Tungsten halogen lamps come in several common forms. Small capsule lamps with bi-pin lamp holders are used in spotlights and for similar applications needing good optical control and a small optical light source. The same type of lamp, but optimised to give shorter life and much higher light output, is used in photographic projectors and similar applications.

Small capsule lamps can also be built into glass or metal reflectors which form part of the lamp. These small

diameter, high performance lamps are now widely used for display lighting. With such lamps the wattage, lamp diameter (typically 20 mm or 50 mm) and beam angle are normally specified. One advantage of this type of mirror lamp is that the reflector can be manufactured from glass with dichroic coatings. Such reflectors are designed to reflect light into the beam but not the heat. Lamps of this type are popular for display lighting because they direct very little heat onto the merchandise being displayed.

The third type of tungsten halogen lamp is the linear lamp. These are used for applications where a wide beam angle is required together with a high wattage. Such lamps are used for floodlights where low capital cost or instant white light is required. The lamps have an electrical contact at each end and vary in length according to wattage.

Tungsten halogen lamps are designed to operate with an envelope temperature of 250°C to 350°C. The design of the luminaire and the location of the equipment should ensure that people cannot touch the lamp and burn themselves. Similarly, flammable objects should be kept away from the lamp.

In a conventional tungsten lamp, although some ultraviolet radiation is produced, most of it is severely attenuated by the glass outer envelope. In a tungsten halogen lamp, the higher operating temperature and quartz envelope produces a greater ultraviolet content. Although ultraviolet radiation is present in sunlight and daylight, steps should be taken to limit human exposure where high lighting levels are involved.

Both of the above problems can be eliminated if either the lamp or the luminaire is fitted with an ultraviolet radiation absorbing front glass.

The quartz envelope of a tungsten halogen lamp should not come into contact with the human skin e.g. fingers. The greases and acids, which are present on the surface of the skin, will attack the quartz. This will subsequently produce blistering of the envelope leading to premature lamp failure.

## 21.5.2 Discharge lamps

### 21.5.2.1 Principle

A discharge lamp consists essentially of a tube of glass, quartz or other suitable material, containing a gas and, in most cases, a metal vapour. The passage of an electric current through this gas/vapour produces light or ultraviolet radiation. Most practical discharge lamps (excluding those used for coloured signs) rely upon discharges in metallic vapours of either sodium or mercury, with an inert gas filling. The nature of the filling, the pressure developed and the current density determine the characteristic radiation produced by the arc. In most lamps the arc tube is enclosed within an outer glass or quartz jacket. This affords protection, can be used for phosphor or diffusing coatings, control of ultraviolet radiation emission and, by suitable gas filling, can control the thermal characteristics of the lamp.

All discharge lamps include some mechanism for the production of electrons from the electrodes within the lamp. The commonly used methods are thermionic emission and field emission, and in both cases emissive material such as barium oxide is often contained within the electrode to lower its work function and, hence, reduce energy loss.

When the lamp is put into circuit and an electric field is applied, the electrons begin to accelerate towards the positive electrode, and may collide with gas or metal atoms.

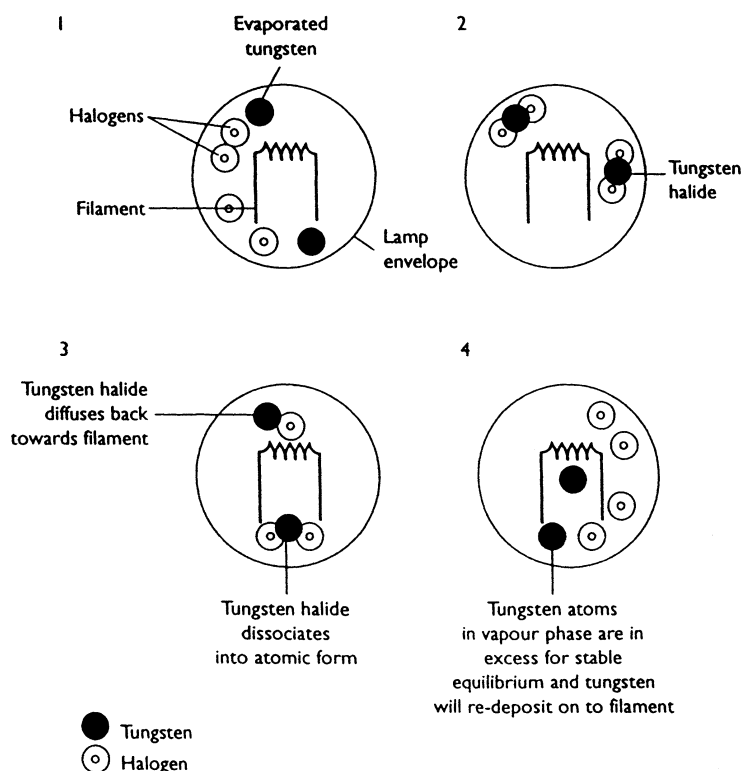

Figure 21.15 Tungsten halogen cycle

These collisions may be elastic, in which case the atom and electron only change their velocities, or inelastic, in which case the atom changes its state. In the latter case, if the kinetic energy of the electron is sufficient, the atom may become excited or ionised. Ionisation produces a second electron and a positive ion, which contribute to the lamp current and which may cause further collisions. Left unchecked, this process would avalanche, destroying the lamp. To prevent this catastrophe some form of electrical control device (such as an inductor) is used to limit the current. Excitation occurs when the electrons within the atom are raised to an energy state higher than normal (but not high enough to cause ionisation). This is not a stable condition, and the electrons fall back to their previous energy level, with a corresponding emission of electromagnetic radiation (which may be visible, ultraviolet or infrared).

In some lamp types, an inert gas is used to maintain the ionisation process, while it is the metal vapour which becomes excited. The vapour pressure in the lamp affects the starting and running characteristics, and the spectral composition of the emitted radiation.

In most lamps there is a run-up period, during which the metal is vaporised and the pressure increases to its operating condition. In some lamp types this may take 10–15 min. If, once the lamp is run-up, the supply is interrupted, then it will extinguish; and unless special circuits and suitable lamp construction are used, the pressure will be too high for the arc to restrike until the lamp has cooled.

Broadly, practical discharge lamps for lighting are either mercury vapour or sodium vapour lamps, at either high or low pressure.

### 21.5.2.2 Run-up efficiency

Smith devised a method of calculating the 'Run-up efficiency' of a discharge lamp (see *Lighting for Health and Safety*, Butterworth-Heinemann, ISBN 0-7506-4566-0).

Figure 21.16 shows the concept of 'run-up efficiency', which describes the efficiency with which a discharge lamp attains steady-state luminous output from a cold start. The diagram shows a typical locus of the instantaneous values of light output of a discharge lamp, with increasing time from switch-on from a cold start. Area 'A' represents the mathematical product of light output and elapsed time during the lamp 'run-up' period (measured in percentage-minutes). Area 'B' represents the mathematical product of the steady-state light output and time (also measured in percentage-minutes) over the same time duration as that taken for the lamp to run-up, i.e. the same time duration as that applying for area 'A'.

The run-up efficiency is then calculated from:

$$\text{Run-up efficiency} = \frac{\text{Area A}}{\text{Area B}} \times 100\%$$

### 21.5.2.3 Discharge lamp types

Discharge lamp types include low pressure mercury (fluorescent), induction, high pressure mercury vapour, mercury-blended, metal halide, low pressure sodium and high pressure sodium.

Figure 21.16 Concept of run-up efficiency

### 21.5.3 Mercury lamps

#### 21.5.3.1 Low pressure mercury vapour fluorescent lamps

**Construction** A typical mercury fluorescent tube consists of a glass tube, and up to 2400 mm long, filled with argon or krypton gas and containing a drop of liquid mercury. A diagram of the tube is shown in Figure 21.17. The interior surface of the tube is coated with a fluorescent powder, the phosphor, which converts the ultraviolet light produced by the discharge into visible light. At each end of the tube are electrodes which serve the dual purpose of cathode and anode, for generally these tubes are used on a.c. circuits.

The cathodes of a hot cathode fluorescent lamp consist of coiled-coil, triple-coiled or braided tungsten filaments, coated with a barium oxide thermionic emitter and held by nickel support wires. Cathode shields in the form of metal strips bent into an oval shape surround the cathodes in certain sizes of tube and are supported on a separate wire lead. These shields trap material given off by the cathodes during life and prevent black marks forming at the ends of the tube. The shields also reduce flicker which is sometimes noticeable at the ends of the tubes, and protect the more delicate cathodes by acting as anodes on alternate half periods. The bases of the electrode support wires are gripped in a glass pinch through which the lead wires pass, forming a vacuum-tight glass-to-metal seal.

The lead-in wires are welded to the pins of the bi-pin cap, which is itself sealed to the ends of the glass tube. Some tubes are still available with a BC cap, but the bi-pin cap is now British standard.

**Principle** An external control circuit is required, which causes a preheating current to flow through the electrodes.

Figure 21.17 Low pressure mercury vapour fluorescent tube

This causes electrons to be emitted by the emitter coating. Once these have been produced, the control circuit must apply an electric field across the length of the lamp to accelerate the electrons and strike the arc. Once struck, the arc must be stabilised by the control circuit.

Colliding electrons excite mercury atoms, and produce ultraviolet and visible radiation (about 60% of the energy consumed is converted to ultraviolet radiation). This radiation, when absorbed by the phosphor on the inside of the glass wall, is converted to visible light.

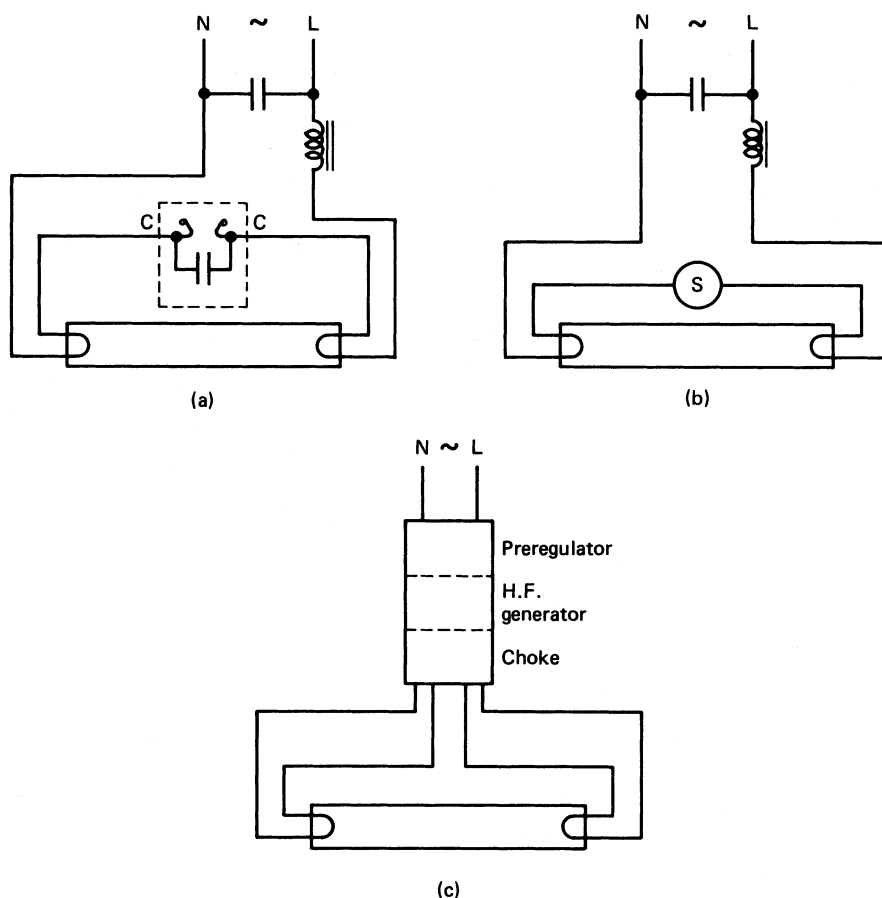

The colour and spectral composition of radiated light will depend upon the phosphors used. Lamps can be made with a 'white' appearance but with widely different efficacies or colour rendering properties.

**Basic starter-switch circuit** The basic starter-switch circuit is shown in Figure 21.18(a). The principle of operation is as follows:

- When the mains voltage is applied, a glow discharge is created across the bi-metal contacts inside the glow starter (enclosed in a small plastic canister). The contacts warm up and close, completing the starting circuit and allowing a current to flow from the 'L' terminal, through the current limiting inductor through the two tube cathode filaments and back to the 'N' mains terminal.
- Within a second or two, the cathode filaments are warm enough to emit electrons; a glow is seen from each end of the tube. At this stage, the starter-switch bi-metal contacts open (because the glow discharge, which caused them to heat and close, ceases when they touch, and they cool and open), and interrupt the pre-heat current flow. If an inductor (*choke*) ballast (coils of copper wire around a laminated iron core) is used the magnetic energy stored in the core collapses to produce a high-voltage pulse (600–1000 V) across the fluorescent tube sufficient to strike the arc and set up the electric discharge through the tube.
- Once the tube arc has been struck, the current through the tube gradually builds up. This means that the current through the inductor also increases. As this happens, the voltage across the inductor increases and the tube voltage falls. The inductor is so designed that when the tube and inductor current rise to a value determined by the inductor design setting, the circuit stabilises.

**Electronic start circuit** An improvement of the basic starter-switch circuit (Figure 21.18(b)) is the electronic start circuit. It is identical with the starter-switch circuits in all respects but one; the glow starter is replaced by an all electronic starter. In some cases it may be fitted into a conventional glow start canister, as a direct replacement, and in other more sophisticated luminaires it is a small encapsulated box.

The main advantages of this circuit are that it affords reliable starting, does not shorten tube life (a problem with

**Figure 21.18** Starting methods: (a) glow starter; (b) electronic starter; (c) electronic control gear

glow switches at the end of their life) and will last the life of the luminaire without replacement. Some circuits also inhibit the start of faulty lamps after a number of unsuccessful attempts.

**Low loss control gear** The main power losses in the control gear are the result of heating and eddy current losses. In order to improve energy efficiency, thicker wire with lower resistance can be used in the ballast and the ballast can be made more cubic in shape. When this happens the power losses in the ballast are reduced but the ballast is more costly. Such ballasts are commonly referred to as 'low loss' and 'super low loss' according to their power dissipation. There is no definition of standard, low loss or super low loss; therefore comparisons must be based on measured losses.

It should be noted that, although they improve efficiency, such ballasts are more expensive, heavier and occupy a much larger and more awkward volume than conventional ballasts. This may cause problems by increasing the weight and bulk of the luminaires.

**Electronic ballast** Electronic ballasts offer several major advantages. They are lighter and replace several discrete

components by one unit. They dramatically reduce the losses in the control gear, saving energy. Most designs provide a near-unity power factor, reducing the current drawn from the supply. The ballast also operates the lamp more efficiently, reducing the power losses within the lamp itself. Better starting will normally prolong lamp life. Better designs will operate over a wide range of supply voltage fluctuation.

Some designs can only be used with special lamps, but most will work with any standard lamp type from any manufacturer.

Electronic ballasts generate a high-frequency supply to the lamp (typically 30 kHz). At this frequency the normally bulky wire wound ballast can be made small and light. The ballast can be very efficient, but the generation of high frequency can give rise to conducted and radiated interference. Therefore, most circuits are in three parts. The first part of the circuit is designed to ensure that the supply form is not corrupted and that interference is not radiated. The second part of the circuit generates a high-frequency supply. The third part of the circuit uses the high-frequency supply through very small chokes to control the current and voltage to the lamp (Figure 21.18(c)).

Older 'hybrid' designs of electronic ballast use large iron core chokes in order to filter the supply waveform and

prevent supply corruption. Such ballasts are normally heavier and bulkier than their conventional counterparts and do not offer the advantages of the fully electronic designs.

Not all ballasts generate true high frequency. Some simply chop the mains waveform at high frequency. Those which generate true high frequency have two other advantages. Firstly, at 30 kHz fluorescent lamps operate more efficiently. Typically the lamp efficiency improves by 5–10% according to type. Secondly, it has been discovered recently that the light fluctuation at 100 Hz which occurs with conventional mains operation of fluorescent lamps, although not visible, is detectable in the human visual system. It is suggested that some individuals suffer a higher incidence of reported headaches and eyestrain as a result of this invisible fluctuation. Higher frequency lighting has been shown to minimise this problem and, as a result, improve productivity.

**Variable light output electronic ballasts** Now that electronic ballasts are widely used it has become possible to build in extra circuitry at modest cost in order to permit the light output of the lamp to be controlled. These controllable ballasts will respond to simple control signals and vary the light output of the lamp.

A good design should be able to vary the light output from 1% to 100% of full output. This is normally achieved by an extra-low-voltage control circuit connected to a simple variable resistor. Several ballasts would normally be connected to one resistor to control the lighting in a room. Such a set up is less expensive than conventional dimming circuits.

In some designs an interface can be provided which will link the ballasts to the output of a conventional dimmer without adding load. In this way a conventional tungsten load can be controlled along with the fluorescent lighting. The dimming range is normally restricted to 10–100% because of the dimmer circuit.

Not all ballasts can provide full control. Some will only operate reliably with special lamps. Some ballasts can only control the light output from 25% to 100%. Although this may seem a large variation (4:1), because of the way in which we see, it is only perceived to be about a 2:1 change in brightness at full light output. This degree of control is of little use except for minor energy management where the lighting levels can be raised and lowered to top up daylight over a limited range.

Controllable electronic ballasts can be linked together and controlled in a number of different ways. The ballasts can be linked to a full lighting management system connected to local controls, programmable clocks, occupancy sensors and daylight photocells.

**Fluorescent tube replacement** It is not easy to determine the end of the useful life of a fluorescent tube. Although failure to start will eventually occur due to exhaustion of the oxide coating on the electrode filaments, it is normally possible to justify replacement of the tube before this stage. As most installations of fluorescent luminaires are designed to give a planned illuminance, random replacement of tubes at end of life will result in a non-uniform illuminance, which is uneconomic when related to energy costs and labour costs for replacement.

Figure 21.19 indicates typically the inherent deterioration of the illuminance from the luminaires of a fluorescent tube installation, and the gains that result from regular cleaning and lamp replacement.

**Figure 21.19** Effects of deterioration, cleaning and lamp replacement on the illuminance of a fluorescent-tube installation

**Tube colours** Table 21.1 shows how the tube colours are graded in terms of lumen output efficacy and colour rendering quality. In choosing a tube colour a choice must be made between light output and colour, since tubes with high lumen output have only modest amounts of blue and red energy, whereas good colour rendering lamps have reduced yellow/green content and the tube lumen output is subsequently reduced.

A development in fluorescent tube phosphors is the multi-phosphor. Based on the principle that a mixture of red, green and blue light produces a white light, efficient red, green and blue phosphors are mixed in appropriate proportions to produce a white light when irradiated by ultraviolet light in a fluorescent tube. This produces a high-efficiency tube with good colour rendering for general applications. As the phosphors are costly, the tubes using them are more expensive and are frequently made in a diameter of 25 mm instead of 38 mm.

The characteristics of different fluorescent tubes are described and shown in Table 21.1.

**Standard halophosphate lamps** At one time these lamps were the best choice for general lighting because they combined acceptable colour with high efficiency. They have now been replaced by the superior multiphosphor lamps which give higher output, better colour and superior economy through life.

**Special lamps** These lamps have specific colour rendering characteristics.

**Multiphosphor/triphosphor lamps** These lamps are superior in colour quality and efficiency to standard halophosphate lamps. They therefore reduce installation costs because fewer luminaires are needed and also improve lighting quality. They are the primary choice for general lighting.

**Deluxe multiphosphor lamps** These lamps are superior in colour quality to normal multiphosphor/triphosphor lamps and are designed to replace the special lamps referred to previously, but with significantly better efficiency.

#### 21.5.3.2 Compact fluorescent lamps

In recent years compact fluorescent lamps have been developed. For a given light output, compact fluorescent

**Table 21.1** Fluorescent tube colours

<i>Tube colour</i>	<i>Light output relative to white (%)</i>	<i>Luminous efficacy* (lm . W<sup>-1</sup>)</i>	<i>Colour rendering</i>	<i>Colour appearance</i>	<i>Application and remarks</i>
<i>Standard halophosphate lamps</i>					
White	100	45–65	Fair	Intermediate	A general-purpose tube which combines good lumen output with a white appearance. Warmer than daylight, but cooler than incandescence
Warm white	98	45–65	Fair	Warm	For general lighting where a warmer appearance than white is required. Incandescence effect, but without good red
Daylight cool white	94	45–65	Fair	Cool	For general lighting where a cooler appearance than white is required. Daylight effect, but lacking in red
<i>Special lamps</i>					
Northlight, colour matching	59	2–40	Excellent	Cool	For displays in lighting where a cool north skylight (winter light) effect is required, with normal red rendering. For colour matching
Artificial daylight	41	20–40	Excellent	Cool	Special tube with added ultraviolet to give a very close match to natural daylight. For colour matching cubicles
Natural	70	30–50	Good	Intermediate	For office and shop lighting to give a cool effect. Close to natural daylight but with a flattering red content
De luxe natural	49	15–25	Very good	Intermediate	For food and supermarket displays with meat or highly coloured merchandise. Combination of good blue and red rendering

\*Based on total circuit power.

lamps have small dimensions compared with linear fluorescent lamps. This reduction in size is normally achieved by folding the discharge path.

These lamps have two major application advantages. Firstly, because they are available in similar sizes and light outputs to conventional filament lamps they can be used as replacements, either in existing luminaires or in new designs. They will use about 25% of the power of the tungsten lamp equivalent of similar light output and will typically last 10 times longer. Secondly, compact fluorescent lamps can be made smaller than their linear fluorescent counterparts. This means that smaller more attractive luminaires can be designed with similar light output to conventional fluorescent lamps, but without the need to be long and awkward in shape.

Therefore compact fluorescent lamps are widely used either for applications where, previously, tungsten lamps would have been used, such as decorative lighting in hotels, or for applications where fluorescent lamps would have been used but a more acceptable luminaire style or shape can be designed (e.g. a 500 mm luminaire can replace a 1200 mm × 300 mm luminaire).

Theoretically, there are many good reasons why tungsten lighting in the home should be replaced by compact fluorescent lighting. Despite the superior life and economy (the major cost of a lamp is the electricity it consumes), these lamps have not been widely used in the home. However, they are extensively used in industrial and commercial situations.

Compact fluorescent lamps can be divided into two broad categories: replacements for GLS lamps and light sources for new luminaires.

*Replacements for GLS lamps* Some lamps have integral control gear. They can be used as direct plug-in energy saving replacements for conventional lamps. The only factor to note is that some types are much heavier and rather more bulky than the lamps that they replace. Some lamps have integral electronic control gear. The main disadvantage of this type of approach is that when the lamp is thrown away then the expensive integral control gear is thrown away with it. An alternative approach is to provide adapters

which can be plugged in to lamp sockets and convert them to compact fluorescent use.

**Light sources for new luminaires** Some lamps were developed to make possible the design of compact luminaires with all the advantages of fluorescent lamps. The use of these lamps permits plastic and other materials to be used close to the lamps. This increases the scope for attractive designs using novel materials. There is a wide range of lamps with light output suitable as substitutes for conventional lamps of 100 W and below. However, in commercial and industrial lighting, greater light outputs are required.

#### 21.5.3.3 Cold cathode lamps

By comparison with conventional hot-cathode fluorescent lamps, cold-cathode lamps, which are often used in advertising signs, rely upon a relatively high lamp voltage for establishment of the arc. Electrical isolation of such lamps is typically achieved by means of a 'fireman's switch' usually located on the frontage of premises.

The electrodes used for cold-cathode lamps are typically plain nickel or iron cylinders whose size is substantial in order to limit the current density at their surface to an acceptably low value.

Lamp life values for such lamps are much higher than for hot-cathode fluorescent lamps.

#### 21.5.3.4 Induction lamps

The induction lamp is also referred to as the 'electrodeless lamp'. It relies upon both magnetic and fluorescent principles for its operation. The constructional features of the lamp are shown in *Figure 21.20*.

Energy transfer using magnetism (following the electrical transformer principle) is employed with the low pressure mercury filling in the lamp acting as a secondary coil of the transformer. A high frequency alternating electrical current in the primary winding is supplied from an external source. The current induced in the mercury vapour gives rise to emission of ultraviolet radiation in a similar manner to that in a conventional fluorescent lamp and the phosphor coating on the inside of the lamp envelope converts this UV radiation into visible light. The lamp life is typically

60 000 h, which makes the use of such lamps in relatively inaccessible areas particularly beneficial.

#### 21.5.3.5 High-pressure mercury lamps

**Construction** The lamp consists of a quartz glass (pure fused silica) arc tube, enclosed within a borosilicate outer envelope. The envelope can be tubular, but is normally ellipsoidal to ensure an even outer-envelope temperature. (Ellipsoidal outer envelopes operate at about 550 K, compared with 800 K for the hottest parts of tubular envelopes.)

The arc tube contains a controlled quantity of mercury sufficient to produce the desired pressure at operating temperature.

Electrodes, in the form of helices of tungsten wire, about a tungsten or molybdenum shank, are fitted at opposite ends of the arc tube. Emissive material is coated onto the electrodes (or may be held inside in pellet form). To assist in starting the lamp, an auxiliary electrode is mounted in close proximity to one of the main electrodes and is connected to the other electrode via a high resistance (10–30 kΩ). The electrodes are sealed into the quartz glass arc tube by means of molybdenum foil (as with tungsten halogen lamps).

The outer envelope (*Figure 21.21*) is filled to a pressure of 0.25–0.65 atm with either nitrogen or a nitrogen–argon mixture.

**High-pressure mercury fluorescent lamp** The quartz glass arc tube transmits ultraviolet light and enables a phosphor coating to be used on the inside of the outer envelope. The phosphor improves the colour rendering properties and luminous efficacy. Phosphors have upper limits of operating temperature and the use of ellipsoidal bulbs ensures the minimum size of envelopes. Improvements in phosphors to give operation at higher temperatures have resulted in smaller envelope sizes.

High pressure mercury vapour lamps (see *Figure 21.22*) have efficacies of about  $58 \text{ lm} \cdot \text{W}^{-1}$  with acceptable colour rendering for factories, storage areas, offices, etc.

**High-pressure mercury fluorescent reflector lamp** This lamp (*Figure 21.23*) is identical with the high pressure mercury vapour lamp, except that the outer envelope is shaped to form a reflector. Titanium dioxide is deposited inside the conical surface of the outer envelope: this reflects about 95%

**Figure 21.20** Induction lamp

Figure 21.21 Arc tube construction of a high pressure mercury lamp

Figure 21.22 A high pressure mercury lamp with phosphor coating

of all the light in a diffuse manner. The phosphor is applied over this coating. The front face is left uncoated (although it may be etched or have a diffusing coating of silicon dioxide) and about 90% of the light is emitted through this opening. The lamp is less efficient but has a directional light output, suitable for installations where the luminaires have to be mounted high up (as in storage areas, hangars, etc.), and where dirty conditions obtain.

**High-pressure mercury-blended lamp** By including a filament within the outer envelope the need for special control gear can be eliminated, as the filament can act as a ballast. The efficacy of the lamp ( $12\text{--}25 \text{ lm} \cdot \text{W}^{-1}$ ) is poor compared to a high pressure mercury vapour lamp and inductor, but the lamp has two important advantages: (1) it can be fitted into any standard lampholder as a direct replacement for a tungsten lamp of the same rating, and will produce more ultraviolet and visible light; and (2) unlike other mercury lamps, it will emit some light from the filament immediately upon switching on.

**High-pressure mercury-metal halide lamps** The efficacy of high pressure mercury lamps is lowered because regions of the lamp are at potentials too low for the excitation of mercury. By adding suitable metals with lower excitation potentials to the arc tube, it is possible to increase the light output and improve colour rendering. The only suitable metals are highly reactive. These would damage the quartz glass arc tube and seals. By adding the metals (sodium, thallium, gallium, scandium and others) in the form of halides (usually iodides), these problems can be eliminated.

Figure 21.23 A high pressure mercury lamp with phosphor coating and integral reflector

The halides dissociate in the arc itself, but recombine at the arc tube wall.

The metal halide lamps are better than their counterparts, in both colour rendering and efficacy ( $85 \text{ lm} \cdot \text{W}^{-1}$ ). Figure 21.24 shows a high pressure mercury-metal halide lamp.

## 21.5.4 Sodium Lamps

### 21.5.4.1 Low-pressure sodium lamps

The low-pressure sodium lamp is characterised by its monochromatic yellow light, which consists of two radiation lines (resonant doublet) at 589.0 and 589.6 nm. The lines are close to the maximum spectral sensitivity of the eye (555 nm) and the lamp is therefore efficient. Efficacies of over  $150 \text{ lm} \cdot \text{W}^{-1}$  are typical.

The lamp has poor colour rendering properties. Because the light is monochromatic, it is restricted to applications where the colour of the source and colour discrimination can be sacrificed for high efficacy. For example, the lamp is used for floodlighting and street lighting.

**Construction and operation** The lamp consists of a long arc tube of glass construction, known as 'ply tubing', filled with low-pressure gas (usually neon +1% argon). The lamp also contains a small quantity of metallic sodium (solid at room temperature), which provides a pressure of about 0.66 Pa in the lamp when operating. Precautions must be taken to prevent the sodium from attacking the lamp seals. At each end of the arc tube is a tungsten electrode of coiled-coil,

Figure 21.24 A high pressure metal halide lamp

triple-coil or braided construction (similar to those in tubular fluorescent lamps) with an emissive coating (barium oxide or similar material).

The temperature of the arc tube must be maintained at about  $270^{\circ}\text{C}$  in order to successfully vaporise the correct amount of sodium to give a vapour pressure of about 0.66 Pa. It is therefore essential to avoid excessive heat loss if this temperature is to be maintained. In early lamp designs a Dewar flask was placed around the arc tube.

Modern lamps have an outer glass envelope enclosing the arc tube, and the space between the two is fully evacuated. In addition, the outer envelope is coated with an infrared reflecting film (bismuth oxide, tin oxide or gold) which transmits light but reflects heat back onto the lamp.

The requirements for efficient operation of a sodium lamp are: (1) the arc voltage gradient must be low (long arc tubes for a given power), and (2) the current density must be low (arc tubes must have a large diameter). Sodium vapour readily absorbs light at the resonant doublet wavelengths, and therefore light generated in the centre of the arc is reabsorbed by the vapour; thus, only the outer surface of the arc emits light. This conflicts with the need for a large-diameter arc tube, and demands a compromise.

Sodium, especially hot sodium vapour, is highly reactive and attacks any glass with more than a small proportion of silica in it (i.e. almost all normal glasses and quartz glass). Special glasses have been developed with low silica content which resist the attack of sodium vapour, but they are expensive, are difficult to work and are attacked by moisture. Hence, ordinary soda-lime glass tubing has a coating of this resistant glass flashed onto its inside surface, and the resultant cheap, easily worked material is known as ply tubing.

Unless checked, sodium vapour readily migrates along the lamp to the cooler parts. To prevent this, small protrusions are moulded into the arc tube. They project out from the arc tube and are therefore slightly cooler than the surrounding wall. They act as reservoirs for the sodium metal and help to maintain the correct vapour pressure at all points along the lamp.

A long arc tube is folded into a tight U shape (*Figure 21.25*). Mutual heating is provided by the two arms of the arc tube, but also each arm absorbs any light from the other arm which may strike it. The two effects are almost self-cancelling, but do produce a slight improvement in efficacy. The resultant lamp is fairly compact, with the advantage that all of the lamp connections are at one end. A single-bayonet lamp cap can therefore be used. The lamp efficacy is around  $100\text{ lm} \cdot \text{W}^{-1}$ .

When a sodium lamp is first switched on, the sodium is all present as solid metal. An arc discharge cannot therefore occur unless the sodium is first vaporised. For this reason a mixture of neon and argon is used in the lamp. The initial discharge occurs through this gas; the sodium metal is vaporised by the heat from this discharge, and slowly takes over.

The mixture of neon and argon (1%), known as a 'Penning mixture', reduces the starting voltage required. The energy required to excite neon is slightly higher than that to ionise argon. Electrons passing through the gas collide with the main gas (neon) and excite the atoms, which may collide with argon atoms giving up their energy by ionising the argon and producing an extra electron. This mixture reduces the starting voltage by typically 30–50%.

All low pressure sodium lamps when first switched on produce a distinctive red neon glow. Should sodium migrate from any part of the lamp, that part will also exhibit the red neon glow.

**Figure 21.25** A low pressure sodium lamp

The effect of the Penning mixture is to make the starting voltage almost independent of ambient temperature. A low pressure sodium lamp can therefore be restruck when hot within about 1 min.

Although electrodes are fitted at each end of the arc tube, it is not normal to provide them with a heating current; and the two ends of an electrode are connected together.

#### 21.5.4.2 High pressure sodium lamps

If the sodium vapour pressure in a low pressure discharge tube is raised by a factor of  $10^5$ , the characteristic radiation is absorbed and broadened, greatly improving the colour rendering. However, hot sodium vapour is highly reactive, destroying or discolouring conventional arc tube materials; further, to achieve a high vapour pressure the coolest region of the arc tube must have a temperature of  $750^{\circ}\text{C}$ . These phenomena, known in the 1950s, were not exploited until the development of a translucent ceramic material—*isostatically pressed doped alumina*—capable of operating at temperatures up to  $1500^{\circ}\text{C}$  and of withstanding hot sodium vapour. The difficult process of sealing electrodes into the ends of the arc tube has also been solved. Typical methods are (a) brazing a niobium cap to the alumina tube, and (b) using hermetically sealed sintered ceramic plugs holding the electrodes.

Most high pressure sodium lamps have an arc tube containing metallic sodium doped with mercury and argon or xenon. Radiation of light is predominantly from the sodium. The mercury vapour adjusts the electrical characteristics, and acts to reduce thermal conductivity and power loss from the arc. Argon or xenon aids starting. The arc tube is sealed into an evacuated outer jacket to minimise power loss and to inhibit oxidation of the end caps, lead wires and sealing medium. Typical arc tube operating temperatures are  $700\text{--}1500^{\circ}\text{C}$ , and efficacies of  $100\text{--}200\text{ lm} \cdot \text{W}^{-1}$  are achieved.

Starting is effected by high-voltage pulses ( $2\text{--}4.5\text{ kV}$ ) to ionise the xenon or argon gas. The ionisation heats the lamp and the sodium vapour discharge takes over. The mercury vapour does not ionise, as its ionisation potential is higher than that of sodium, but its effect is to increase the lamp impedance, raising the arc voltage from about  $55\text{ V}$  to  $150\text{--}200\text{ V}$ . Electrodes are not heated during lamp operation. A hot lamp, after extinction, will not restart until

cooled, unless 'hot-restart' ignitors (giving, e.g. 9 kV pulses) are provided.

The conventional high pressure sodium lamp (*Figure 21.26(a)*) has an outer envelope, which is elliptical and coated with a diffusing material. Tubular and double-ended versions are available as shown in *Figure 21.26(b)* and *Figure 21.26(c)*.

It is interesting to note that, although the low pressure sodium lamp is more efficient than the high-pressure version, the large dimensions of the former make accurate optical control difficult. Furthermore, the luminaires are large, cumbersome and expensive. High pressure sodium lamp luminaires are therefore the better choice for many applications, and only in street lighting does low pressure sodium find a major application. High pressure sodium lamps are employed for street lighting, floodlighting and industrial and commercial interiors.

By increasing the xenon pressure in a high pressure sodium lamp and making some other changes, the output of the lamp can be improved without any loss of life or colour. The lamp efficacy improves by about 10–20% and the light output depreciation of the lamp is improved. The only penalty is that the lamp needs a much higher starting voltage (i.e. a different ignitor is needed).

If the internal pressure of a high pressure sodium lamp is increased then the colour quality and colour temperature of the light is improved at the expense of life and efficiency (life reduced by about 50% and efficacy by about 25%). These lamps are known as 'deluxe high pressure sodium lamps'. The colour rendering index is normally improved from 21 (class 4) to about 65–70 (class 2). This makes the lamp acceptable for merchandising applications and other areas where good colour is an important consideration. The lamps are widely used for lighting offices (via up-lighters) and for commercial lighting. The lamp is warm in appearance and for some applications this may be unacceptable. A recent development is the low wattage 'White' high pressure sodium lamp with very high colour rendering which has been designed for display lighting purposes. These lamps need special electronic control gear.

### 21.5.5 Control gear

The term is used affectionately to describe the equipment that is necessary for the safe and efficient operation of discharge lamps. The function of the control gear is essentially twofold: it assists in providing a high voltage pulse to enable the arc to be established within the discharge tube in the lamp and once the arc has been established the control gear takes on the role of a current limiting device in order

to limit the current flowing through the lamp. Discharge lamps exhibit a negative resistance characteristic.

It has to be appreciated that heat is produced during normal operation of lamps and control gear. Nevertheless many items of control gear have recommended maximum temperatures and it is essential that such values be not exceeded.

Individual items of electrical and/or electronic equipment used include ballasts, transformers, ignitors and power factor correction capacitors. Some items of control gear will consume power from the supply and the resulting electrical energy costs will have to be borne by the consumer. It is therefore beneficial to be aware of the power ratings of control gear when considering the economics of lighting.

### 21.5.6 Electroluminescent devices

Electroluminescence is the emission of light from a semiconductor under the action of an electric field. The process involves heat only as a by-product of the mechanism, which is essentially a 'cold' one. The phenomenon is of commercial interest because of its relatively highly efficient production of visible light.

**Characteristics** Luminescence decays with time exponentially, so that is convenient to quote the half-life of an electroluminescent source. The half-life varies from hundreds to millions of hours, depending on the type and purity of the semiconductor materials used. The sources emit light in comparatively narrow spectral bands, producing colour without the use of filters. Sources can be of almost any size, down to areas of less than  $0.05 \text{ mm}^2$ . The surface brightness is, however, comparatively low.

In an electroluminescent material two processes must take place. First, an adequate supply of electrons must be available in the conduction band, made possible by using an electric field to raise the energy level of electrons in the valence band. Second, the electrons must give up their energy in the form of photons and so return to the valence band. The recombination process is dependent on the 'forbidden gap', the wavelength  $\lambda_{\text{of}}$  of the emitted radiation being defined by the energy jump  $E$  through the relation  $\lambda = hc/E$ , where  $h$  is Planck's constant and  $c$  is the free-space velocity of electromagnetic waves. Consequently, materials with a bandgap  $E$  of 1.65–3.2 eV are capable of producing visible light by electroluminescence, provided that the electron return from the conduction to the valence band is not made in two or more stages by reason of the presence of lattice impurities; but if this is the case, luminescence can be obtained with materials having an intermediate gap energy.

**Materials** The requirements for an electroluminescent material emitting in the visible spectrum are, generally, that it should have a bandgap of at least 2 eV, be susceptible to both p- and n-type 'doping', and should have either a direct bandgap or an activator system permitting 'steps'. Typical semiconductor materials are ZnS, GaP, GaAs and SiC.

The preparation of luminescent panels based on ZnS involves baking pure zinc sulphide with various dopants such as manganese, copper and chlorine. The sintered mass is ground to a particle size of the order of  $10 \mu\text{m}$ , washed and dried, and mixed with a suitable resin. The suspension is coated on to a glass substrate supporting a very thin layer of gold or SnO, to form one electrode. The other electrode, an evaporated layer of aluminium on the rear surface of the

**Figure 21.26** High pressure sodium lamps: (a) SON lamp; (b) SON/T tubular lamp; (c) SON/TD double-ended linear lamp

**Table 21.2** Lamp characteristics

<i>Lamp type</i>	<i>ILCOS lamp coding</i>	<i>Typical lamp life (hours)</i>
Tungsten filament	I	1000–2000
Tungsten halogen	HS	2000–4000
Low pressure	FD (tubular)	6000–15 000
Mercury (fluorescent)	FS (compact)	8000–10 000
High pressure mercury	QE	14 000–25 000
Metal halide	M	6000–13 000
Low pressure sodium	LS	11 000–22 000
High pressure sodium	S	12 000–26 000
Induction	XF	60 000

cell, also acts as a reflector. The small cells are produced from GaP crystals, with areas selected for fabricating electroluminescent diodes. They are cut into 0.5 mm squares, and a p–n junction is formed by alloying a tin sphere into the GaP, which is doped with zinc to produce the junction. The diode structure is completed by alloying a Au–Zn wire into the GaP to make an ohmic contact, and then connecting a wire to the tin sphere.

**21.5.7 Lamp life**

*Table 21.2* gives details of lamp life values.

**21.6 Lighting design**

**21.6.1 Objectives and Criteria**

To design a lighting scheme the basic objectives must be first established. What sort of tasks will be carried out in the area to be lit? What mood needs to be created? What type of lighting will create a comfortable, pleasant environment? The objectives having been established, they have to be expressed as a series of lighting criteria. For example, what level of illuminance is required? How much glare is acceptable?

The designer then plans a scheme that will best meet the criteria by selecting the appropriate luminaires and considering the practical problems.

*21.6.1.1 CIBSE code for Interior Lighting*

The Chartered Institution of Building Services Engineers publishes a code of recommendations for the lighting of buildings. It puts forward ideas and methods representing good modern practice and is concerned with both quantity and quality of light.

The CIBSE code for Interior Lighting deals with: how building design affects lighting; lighting criteria; lighting and energy consumption; design methods; lighting equipment; and methods of maintenance. In addition, there is a schedule giving specific recommendations for a wide variety of areas such as assembly areas, factories, foundries, schools, hospitals, shops and offices.

For each entry a maintained illuminance and position of measurement is quoted. The amount of discomfort glare that can be tolerated is given by a limiting glare index. A list of suitable lamp types and their colour appearance

is given together with notes on special problems that may be encountered.

The recommended maintained illuminance—in other words, the recommended illuminance that should be provided for a particular application—is a useful guide for the designer. But it is only a recommendation: in some circumstances it should be increased. For example, if errors could have serious consequences in terms of cost or danger, or if unusually low reflectances or contrast are present in the particular task, or if tasks are carried out in windowless interiors where the recommended standard service illuminance is less than 50 lx, the illuminance level should be increased. On the other hand, there are circumstances (e.g. when the duration of the task is unusually short) when the designer would use his judgement to reduce the standard service illuminance. *Table 21.3* gives typical recommended maintained illuminance values.

*21.6.1.2 Uniformity*

In addition to providing the correct illuminance, the uniformity of the lighting level is also important. The uniformity is expressed as the ratio between the minimum and the average illuminance over the working area. It should not be less than 0.8 in areas where the tasks are performed.

*21.6.1.3 Reflectance*

Reflectances should also be considered. The effective reflectances of walls in a room should be between 0.3 and 0.7; the ceiling should have a reflectance of 0.6 or greater; and the floor should have a reflectance of between 0.2 and 0.3 (see *Figure 21.27*).

*21.6.1.4 Illuminance ratio*

The ratio between the illuminance on the wall and that on the task, and between the ceiling and that on the task, is also important. The wall illuminance should be between 0.5 and 0.8, and the ceiling illuminance should be between 0.3 and 0.9, of the task illuminance (see *Figure 21.27*).

For normal working environments, if the reflectances and the ratios between wall illuminance and the task, and between ceiling illuminance and the task, are outside the recommended levels, they will be unacceptable. However, there are exceptions if a particular mood or atmosphere is being created.

*21.6.1.5 Modelling and shadow*

The direction of light and the size of the luminaires in an interior affect highlights and shadows, influencing the appreciation of shape and texture. The term ‘modelling’ is used to describe how light reveals solid forms. It may be harsh (the contrast may be excessive and produce deep shadows) or flat (the light provides low contrast with little shadowing). Either extreme occurring in the lighting of a general working area makes vision difficult or unpleasant. Therefore, the aim of good lighting design must be to produce a suitable compromise between the two, although it may not be the same for different applications. Texture and surface details are best revealed by light with fairly strong directional characteristics. Reflections of lamps on polished surfaces may veil what one needs to see, reducing contrast and handicapping one’s vision.

**Table 21.3** Typical recommended maintained illuminance values

<i>Workplace</i>	<i>Typical recommended maintained illuminance values (lux)</i>	
Engineering workshops	rough e.g. bench work	300–400
	detailed work	700–800
	inspection	500–2000
Clothing and textile	preparation	300–400
	cutting	750–850
	inspection	1500
Construction sites	site roadways	5–15
	general areas	20–25
	crane loading	100–150
Electronics equipment manufacture	component assembly	300–1500
	printed circuit board work	500–750
	inspection	1000–1500
Food and drink	abattoirs	500–750
	bakeries	300–500
	breweries	300–750
	dairies	300–500
	flour mills	300–500
Metal working	iron and steel mills	300–500
	foundries	300–500
	inspection	500–1500
Furniture and timber	sawmills	300–750
	workshops	300–750
	furniture manufacture	300–750
	upholstery	500–1500
Glass production	general production	300–750
	inspection	1000
Health care premises	general wards	150–250 (day) 3–5 (night)
	maternity wards	200–1000
	laboratories	300–750
	operating theatres	500–50 000
Paper and printing	paper mills	300–750
	printing works	300–750
	inspection	1000

**Figure 21.27** Typical room surface illuminance ratios. Illuminance values quoted are relative to a task illuminance of 100 per cent

### 21.6.1.6 Glare

The visibility of a working task is influenced to a large extent by any sources of glare within the visual field. One definition of glare is that it is any excessive variation in luminance within the visual field. Glare can be conveniently divided into two main groups i.e. disability glare and discomfort glare.

Glare can be thought of as 'direct' when it occurs as a consequence of bright sources directly in the line of vision, or alternatively as 'reflected' when light is reflected onto surfaces that have high reflectance values. Factors involved in the production of direct glare include the luminance of the light source and the location of the light source.

A form of glare that will disable an individual from carrying out a particular visual task is referred to as disability glare. An everyday example of disability glare occurs when an individual looks at the headlights of a stationary vehicle during darkness. Under these circumstances it is impossible to discern the scene at the sides of the vehicle immediately behind the headlights. The glare disables the individual from carrying out the visual task. The magnitude of the disabling effect experienced with disability glare is unlikely to occur with discomfort glare. An individual will experience a feeling of discomfort when the exposure time is prolonged. Disability glare and discomfort glare are the major forms of glare. Discomfort glare is more prevalent in interiors and often occurs as a consequence of either a badly designed lighting installation or a change of use of the interior from that which it was originally intended. In addition it is possible to assign numerical values to the degree of discomfort glare prevailing in a given interior. It is therefore possible, at the design stage, to eliminate any such adverse effects.

A method used for calculating the 'limiting glare index' (LGI) is shown in detail in the CIBSE Code for Interior Lighting. The method is a 'step-by-step' process where an initial and uncorrected glare index value is obtained from published tables. In these tables the major dimensions of the room interior (length and width) are given in multiples of the mounting height  $H$  which is taken as the distance between the horizontal lines passing through the eye level of a seated observer and the centre line through the luminaire(s). The eye level of a seated observer is taken, initially, as 1.2 m above floor level.

A second stage to the calculation involves applying two correction factors to the initial glare index value obtained. These factors involve variations in (a) the luminous flux of the luminaire and (b) any variation in mounting height from the normal seated eye level of 1.2 m.

Once the 'final glare index' value is calculated it is compared with reference values of limiting glare index (LGI), which are published in references e.g. CIBSE Code for Interior Lighting. Should the final glare index value calculated be lower than the LGI value the development of discomfort glare is unlikely.

It is also possible to categorise glare as either 'direct' or 'reflected'. Direct glare occurs when the origin is bright sources. Reflected glare occurs when light is reflected from specular or mirror-like surfaces. When considering glare it is essential to consider the luminance of the source, the position of the source, the luminance distribution and the time duration of exposure. The maximum value of luminance, which is tolerable by the eye as a result of direct viewing, is approximately  $7500 \text{ cd} \cdot \text{m}^{-2}$ .

The visual comfort of an individual is influenced by the distribution of luminance across the immediate field of vision and furthermore by the luminance of the environment when seen by individuals who glance away from their work.

Ideally the work surrounds should be less bright than the work itself. Optimum visual comfort occurs when the work is slightly brighter than the near surround. This in turn should be slightly brighter than the far surround.

The ideal ratio for distribution of luminance across a task is usually taken as 10:3:1. It is possible to obtain a 'trade-off' in luminance values, away from a visual target by using different materials. *Figure 21.28* shows the ideal luminance distribution across a visual task.

The luminance contrast of a visual task will be influenced by, inter alia, the reflectance values of the task and furthermore upon the manner in which the task is lit. Task materials with matt finishes will reflect the incident light equally in all directions and it follows that the direction of the incident light falling on the task material is unimportant. Conversely if the task material has a specular finish then the direction of the incident light is important.

When the image of a source of high luminance, e.g. a luminaire or the sun, is reflected from a surface being viewed by an individual then veiling reflections will be created. An example of this is experienced when looking at a display screen. If the geometry of the individual, screen and luminaire is not controlled, an out-of-focus image of the luminaire will be seen in the screen. This will throw a veil of light on the front of the screen, hence the term veiling reflections, and some of the text on the screen will become illegible, see *Figure 21.29*.

Downlighters with a strong downward component of light distribution will produce a significant loss of task visibility due to veiling reflections. A lighting installation should ideally provide a minimum directional component immediately above the task itself. Light should preferably reach the task from wider angles, which will reduce glossy reflections seen by the individual in the visual task.

### 21.6.1.7 Colour rendering of lamps

Generally the apparent colour of objects seen under an artificial lighting installation is of some importance, sometimes it is vital, as for instance in the buying and selling of food-stuffs, the preparation of paints and dyes and the matching of silks, cottons, etc., to fabrics and to one another.

A red article looks red because it reflects red light more strongly than other colours of light, but it can only do so if there is some red light present for it to reflect. Similarly, a green article can only look green if there is some green light present, and so on. It follows that if all colours are to be seen well, the light must contain a mixture of all possible colours of light of roughly equal strength. Such a light will look white, or nearly so. Unfortunately, it is possible for a

**Figure 21.28** Ideal luminance distribution across a visual task

**Figure 21.29** Veiling reflections

light to look white even though lacking some of the possible colours (e.g. the light of an ordinary mercury lamp can in certain circumstances look fairly white, though it lacks more colours than it contains, and the poor colour rendering of this type of lamp is well known).

Filament lamps of all types emit all possible colours of light, but in far greater strength at the red end of the spectrum than at the blue end. Thus, red and yellow objects appear in stronger colour than in natural daylight, whereas blues are weak and somewhat muddy in appearance. This, however, is a distortion familiar to most people, who have learned to make allowance for it in choosing decoration materials, etc. The light of a 'deluxe warm white' fluorescent lamp is very similar to that of a filament lamp.

For accurate colour judgement a light similar to north-sky daylight is necessary. An 'artificial daylight' fluorescent lamp has been developed which meets the requirements of BS 950:1967. The 'colour-matching' or 'north-light' type of fluorescent lamp gives a close approximation to north-sky light and is found entirely satisfactory in many industries critically concerned with colour, but this very white light is perhaps too 'cool' in appearance to be used alone in interiors of a more domestic nature, where a 'warm' light is traditional. The other colours of fluorescent lamps are mainly of higher efficiency than the previously-named two types, and the choice will lie between them according to the relative importance of their efficiency and their particular colour rendering properties.

#### 21.6.1.8 Display screens

When a display screen equipment operator is viewing a screen, other parts of the interior will be within their visual field and this will lead to problems with adaptation. Light scattered in the eye will reduce the contrast of the image subsequently formed on the retina. The effect of this is to produce impaired vision. In addition if the display screen operator momentarily glances away from the screen, transient changes in adaptation will occur and again vision can be impaired.

There are several options available to the designer in an attempt to produce optimum lighting conditions. The most simple involves a repositioning of one or more of the light sources, the screen and the operator.

It will be evident that any re-positioning of the light source is the least practical since in many cases luminaires are ceiling-mounted in fixed locations. There are however much simpler remedies, for example the ergonomics of the operator is highly significant.

In interiors where the installation of uplighters is inappropriate then downlighters can be used. In such situations restrictions are placed upon the luminous output characteristics of the luminaires. In an attempt to avoid high-luminance reflections appearing on display screens it is important to use luminaires with an appropriate luminous intensity distribution, which subsequently limits the luminance seen by screen operators.

If the relationship between the terminal and operator could be established then it would be possible to determine the appropriate geometry, which in turn would allow calculation of luminaire characteristics necessary to prevent direct vision of the light sources. However such information is seldom available due to the wide range of tasks and screen types in use.

The work activities of those who use display screen equipment are covered by both EC and UK legislation, which specifies minimum standards for the visual environment, including the lighting conditions. In order to satisfy the legislation, display screen equipment tasks must be classified in accordance with the conditions specified therein. The tasks can influence the magnitude and severity of reflections likely to be encountered on the screen. The three categories relative to areas where display screen equipment is used are designated Category 1, Category 2 and Category 3. Luminaires for use in each of the three areas specified are known as Category 1, Category 2 and Category 3 luminaires. For each of these luminaire categories the luminance above a predetermined angle, referred to as the critical angle, is limited to 200 candelas per metre<sup>2</sup>. The values of critical angles referred to, for categories 1, 2 and 3 luminaires, are 55°, 65° and 75° respectively. *Figure 21.30* shows the geometry of the critical angles described.

Category 1 luminaires are used typically where there is a high number of screens, in an area where extensive use is likely and where errors occurring as a consequence of misreading the data on the screen are unacceptable. Category 1 luminaires are typically used in air traffic control rooms and emergency services control rooms. Category 2 luminaires tend to be used far more than other Category

**Figure 21.30** Critical angles for downlighter luminaires used in VDU areas

luminaires and their use is typically in areas where display screen equipment is located at each workstation. Category 3 luminaires are usually used where screen usage is random and where the number of screens is relatively low.

The Health & Safety (Display Screen Equipment) Regulations 1992, under the Health & Safety at Work Act 1974, refers to minimum health requirements in relation to work with display screen equipment. Employers must take steps to ensure that all workstations under their control comply with the regulations. In general terms the regulations require lighting conditions which are satisfactory and which ensure that an appropriate contrast between display screen equipment and the background environment be provided. Any glare or distracting screen reflections must be prevented.

### 21.6.2 Luminaires

The luminaire formerly referred to as the 'light fitting' provides support, protection and means of electrical connection to the lamp, which is contained within the luminaire. Additionally the luminaire has to be able to operate safely and to withstand the environmental conditions in which it is likely to be installed.

Luminaires may also be classified according to the following categories: type of protection provided against electric shock, the degree of protection provided against the ingress of dust or moisture, type protection provided against electrical explosions and according to the characteristics of the material of the surface to which the luminaire can be fixed.

Those luminaires that are designed for use internally, and those for use in some external applications, will normally operate efficiently in dry and well-ventilated atmospheres.

Some luminaires are installed in atmospheres that are far less acceptable. In order to be able to perform within the environments likely to be encountered, the equipment must therefore be manufactured so as to comply with strict specifications. Such environments are referred to as hostile or hazardous. Examples of hostile areas include: high humidity conditions (requiring drip-proof equipment), dusty and

corrosive atmospheres, and food factories (where the interior walls, floors and ceilings are required to be hosed down).

Hazardous atmospheres are usually created by the presence of flammable or explosive dusts and gases in the atmosphere.

#### 21.6.2.1 Optical control of light output from luminaires

When a bare lamp is used, i.e. one without any form of control of the directional qualities of the light emitted, then the distribution of light is likely to be completely unacceptable. Furthermore the bare lamp is also likely to create a source of disability glare to the occupants of the interior. It is likely that the lighting installation will be uneconomical and whilst some fraction of the light output from the bare lamp will reach the working plane either directly or indirectly, the efficiency of the installation will be relatively low.

It will be clear that some means of control of the light output from the bare lamp is essential and four of the most widely used methods are detailed:

**Obstruction** When a bare lamp is installed within an opaque enclosure, which has only one aperture from which the light can escape, then the light distribution from the basic luminaire will be severely limited (*Figure 21.31*).

**Reflection** This method of light control uses reflective surfaces, which may range from matt to specular. By comparison with the 'obstruction' method of light control, reflection is more efficient. With reflection, stray light is collected by the reflectors and then redirected (*Figure 21.32*).

**Diffusion** When a lamp enclosure, is constructed of a translucent material, two benefits will accrue. The apparent size of the light source is increased and simultaneously there is a reduction in perceived brightness. One disadvantage as a consequence of the use of diffusers is that they absorb some of the light emitted from the source itself and so therefore there will be a reduction in the overall

**Figure 21.31** Light control by obstruction

**Figure 21.32** Light control by reflection

**Figure 21.33** Light control by diffusion

luminaire efficiency. *Figure 21.33* shows the concept of diffusion.

**Refraction** This method utilizes the prism effect so as to bend the light output from the bare lamp in the required direction. This method of light control has the benefits of effective glare control and additionally of producing an acceptable level of luminaire efficiency (*Figure 21.34*).

#### 21.6.2.2 Downlighter luminaires

Those luminaires classified as downlighters will emit the major proportion of their light output in the downward direction. They are typically ceiling-mounted or ceiling-suspended. When compared with uplighters, downlighters are far more efficient since they provide direct lighting of the working plane, and do not rely totally on light reflected from room surfaces.

#### 21.6.2.3 Uplighter luminaires

Those luminaires that are classified as uplighters will emit the major proportion of their light output in the upward direction. *Figure 21.35* shows the general principle of lighting using uplighters. When compared to downlighters, uplighters are relatively inefficient since they rely on light being reflected from room fabrics. This places a greater importance on the room decor and reflectance values.

#### 21.6.2.4 Luminaire materials

The materials from which luminaires are constructed typically include metals, glass and plastic. Glass had been used extensively in earlier luminaires but has largely been replaced by plastics, except for some specialist applications e.g. where the light source produces excesses of heat, in which case glass is preferred from a safety viewpoint. Furthermore glass still finds use in situations where there is the likelihood of physical damage to the luminaire, since glass will be more robust.

Two types of glass are in common use for the manufacture of the bowls of luminaires i.e. borosilicate glass which can withstand high working temperatures and soda-lime glass. Both of these types of glass have to be subjected to toughening processes in order to provide additional

**Figure 21.34** Light control by refraction

**Figure 21.35** Principle of uplighter luminaire

protection if they are likely to be installed and operated in environments where there are rapid temperature variations.

Plastics, which are either thermosetting or thermoplastic, find their main use in the construction of diffusers. Polystyrene, acrylic and polycarbonate are used for diffusers. Polycarbonate, which is used in the manufacture of some types of safety spectacles, has a greater impact resistance than acrylic although both materials have been used for the construction of enclosures for use in areas where the luminaires are subjected to acts of vandalism. A form of plastic known as glass-reinforced plastic (GRP) is often used for luminaire canopies.

#### 21.6.2.5 Mechanical strength of luminaires

Mechanical characteristics of luminaires include strength, windage resistance and resistance to vibration.

Luminaires must be capable of operating safely and efficiently within the environments in which they are expected to be installed. If they are operating in external environments they are likely to be subjected to meteorological factors such as wind, ice, snow all of which must be taken into account when considering the construction of the luminaires. Luminaires subjected to strong winds may also suffer the effects of vibrational oscillations that may lead to adverse operation.

## 21.7 Design techniques

The majority of industrial and commercial lighting problems are solved by the use of general lighting. One method of calculating the illuminance derived from a lighting system is known as the 'Lumen' method. Details of this are given below, procedure being grouped into logical steps.

**Step 1: Illuminance** Illumination values for various tasks are set out in the CIBSE Code for Interior Lighting.

**Step 2: Luminaire type** Consideration must be paid to all relevant factors, i.e. horizontal and vertical illumination requirements, glare prevention, efficiency, appearance, maintenance, economy, etc. For example, ordinary assembly work requires a certain amount of shadow to enable shape to be distinguished easily; therefore indirect lighting would be inappropriate, apart altogether from its relatively high running costs. The obvious choice for this class of work is the dispersive type of reflector.

**Step 3: Mounting height** The mounting height of fittings is usually dictated by the building construction, but, in general, it is advisable to make the height as great as possible compatible with good maintenance and installation facilities.

**Step 4: Room reflectance** It is now necessary to calculate, measure (or estimate) the effective reflectances of the three main room surfaces: (1) *the ceiling cavity* (area above the luminaires); (2) *the walls* (from the height of the working plane to the height of the luminaires); and (3) *the floor cavity* (area below the working plane).

**Step 5: Room index** From the room dimensions is calculated the 'room index' (RI), i.e. the ratio between twice the floor area and the area of the walls measured as the area between the working plane and the luminaires, i.e.

$$RI = (L \times W) / [(L + W) \times H] \Leftarrow$$

where  $L$  and  $W$  are the room length and width, and  $H$  is the mounting height. Results may be rounded to the nearest value in the series 0.75, 1.25, 1.5, 2.0, 2.5, 3.0, 4.0 and 5.0. A room in which  $L$  and  $W$  are many times greater than  $H$  will have a high room index, while if  $L$  and  $W$  are less than  $H$ , it will have a low room index. It is important to realise

that the room index is a measure of the relative, not the absolute, dimensions of the room.

**Step 6: Utilisation factor and number of luminaires** The room index affects the utilisation factor. The larger the room index, the higher the percentage of light reaching the working plane. The utilisation factor will also be affected by the reflectances. The higher the room reflectances, the more light will be inter-reflected around the room. Utilisation factors are provided for different combinations of room reflectance and room index. In more recent publications utilisation factors (UF) may have the letters F, W or C in parentheses to indicate whether they refer to the floor, walls or ceiling, respectively, although normally only UF(F) values are published.

Table 21.4 gives an example of standard utilisation factors used in lighting calculations.

Allowance must be made for depreciation in light due to dust and dirt on fittings and surroundings: this is in the form of a maintenance factor. For normal interiors the factor is typically 0.8; for dirty locations it may be as low as 0.4.

For installations in high-bay foundries it may be necessary to make additional allowance for light absorption due to dirt and smoke. The average illuminance  $E(F)$  over the working plane is given by

$$E(F) = [UF(F) \times n \times N \times \Phi \times MF \times CF] / A$$

where UF(F) is the utilisation factor for the reference surface  $S$ ,  $N$  is the total number of luminaires in the installation,  $\Phi$  is the light flux of each lamp (bare), MF is the maintenance factor of the installation, CF is the product of any additional correction factors necessary,  $n$  is the number of lamps per luminaire, and  $A$  is the area of the working plane.

Alternatively, the number of luminaires required is

$$N = [E(F) \times A] / [UF(F) \times n \times \Phi \times MF \times CF] \Leftarrow$$

**Step 7: Spacing of luminaires and layout** For a regular array of luminaires,  $SHR_{\max}$  is the maximum spacing/height ratio that will provide acceptable uniformity. When non-symmetric luminaires are used in long continuous runs, the maximum transverse spacing can be increased to  $SHR_{\max, tr}$ . In addition to these limits the sum of the transverse

**Table 21.4** Example of a standard utilisation factor (UF(F)) table for  $SHR_{\text{nom}} = 1.5$

Room reflectance			Room index

Rating: 65 W, 1500 mm.

Mounted: on ceiling.

Multiply UF values by service correction factors.

and axial SHR values should not exceed twice  $SHR_{max}$ . If  $SHR_{max}$  is not given, it can not be assumed to be greater than  $SHR_{nom}$  (the value for which the UF table is calculated).

$SHR_{max}$  and  $SHR_{max,lr}$  provide information only about the maximum spacing/height ratio that will result in acceptable uniformity on the horizontal working plane. In practical installations, obstructions or other factors frequently make closer spacing essential.

The spacing of units is limited by the mounting height, building structure and plant layout. In all cases it is recommended that spacing/height ratios (issued by the luminaire manufacturers) be not exceeded if even illumination is desired. Where freedom from shadow is required, closer spacings should be used. In calculating spacings it should be remembered that the mounting height should be taken from the working plane, be it the floor, a desk at 0.85 m or a work bench at 1.0 m.

Ceiling divisions, columns, shafting, ventilation trunking and other obstructions restrict possible layouts of outlets. It is thus desirable to draw a scale plan of the area showing all obstructions and plan the layout on this. In multistorey buildings the units should form, if possible, a symmetrical layout in the ceiling panels formed by the joints.

Especially where fluorescent lighting is concerned, the use of continuous trunking from which the luminaires can be suspended and which carries the wiring should usually be considered, as in many cases it can effect considerable economies in installation cost.

Where work benches or machines are located along the outer walls, the distance between the outside rows of luminaires and walls should not exceed one-third of the nominal spacing distance. If the wall space is a non-working area, this distance can be increased to one-half the nominal spacing. This should not be exceeded, as it is desirable to have a certain amount of light thrown upon the walls in order to maintain a reasonable brightness throughout the room.

Plant layout may determine the location of outlets, as in the case of the textile industry. Localised general systems are installed in such cases, the outlets being localised in relation to the plant.

An installation will not be satisfactory if the maximum spacing/height ratio is exceeded. Conformity, however, will still be unsatisfactory if there are obstructions (such as large machines); closer spacing is then essential.

### 21.7.1 Lighting systems

It is possible to categorise interior lighting into general lighting, localised lighting or local lighting:

**General lighting** A general lighting system is one that attempts to provide a constant illuminance across a working plane in an interior. It is however extremely unlikely that a uniform level of illuminance will be produced at all points across a horizontal working plane.

It has to be appreciated that general lighting does not take into account the visual tasks likely to be undertaken in an interior. This can have both advantages and disadvantages. One advantage is that it allows a degree of flexibility when locating individual areas within an interior where visual tasks can be carried out. A disadvantage of general lighting is that such systems can be very wasteful of energy since some areas within an interior are illuminated to a level greater than that required.

**Localised lighting** Localised lighting systems usually provide a required illuminance on the work areas in combination

with a reduced level of illuminance in non-working areas, for example walkways. An often-used example of this is found in open plan offices where workstations are lit using uplighters. Simultaneously walkways and other non-work areas are lit by means of a number of ceiling-mounted downlighters. It will be evident that this system is correspondingly less wasteful of energy than the general lighting system.

**Local lighting** Local lighting systems provide illuminance over a relatively small area in which the visual task is located. It is often used in combination with general lighting so that together the local lighting and general lighting will produce the required illuminance on, and surrounding, the visual tasks.

Figure 21.36 shows the differences between the types of lighting system described.

### 21.7.2 Lighting surveys

Lighting surveys are often undertaken in response to adverse criticism from workers who complain that the lighting in their workplace is in some way unsuitable and/or insufficient. Whilst such an allegation may sometimes be justified, it is often the case that in an environment where there are reported visual problems the cause is non-lighting in origin.

Such non-lighting influences on the visual environment must therefore be investigated before any decision is taken to implement a full lighting survey. Typical non-lighting causes include:

- changes in the condition of the decor, e.g. room fabrics have become dirty and their corresponding reflectance values have decreased;
- changes in condition of fenestration e.g. windows have become dirty and therefore the transmission of natural daylight to the room interior will be impeded;
- changes in layout of the interior e.g. workstations have been repositioned;
- changes in working practices and activities.

#### 21.7.2.1 Instrumentation

The major parameters of interest likely to be considered in a lighting survey include illuminance, luminance, reflectance and daylight factor. Equipment is available which is capable of displaying, either in analogue or digital form, more than one of the parameters listed.

#### 21.7.2.2 Illuminance measuring equipment

Such instruments typically incorporate a selenium or silicon photovoltaic cell. The specification of the instruments typically includes details of spectral response, angular response, linearity of response and operational characteristics of instruments in adverse temperature conditions.

The spectral response of the cells typically used in the construction of illuminance measuring instruments will differ from the response of the human visual system. It is therefore necessary to correct for this differential by applying some form of compensation. This is often achieved by using filters and when such filters are incorporated into an instrument, the device is referred to as colour corrected.

The magnitude of illuminance recorded by, and displayed on, an instrument is influenced by the cosine of the angle the incident ray subtends with the normal to the plane of the instrument detector. It is necessary therefore to apply

**Figure 21.36** Types of lighting system

some form of compensation that takes into account the direction of the incident light falling upon the light-sensing detector. Instruments, which are capable of measuring illuminance values accurately from any incident direction, are referred to as cosine corrected.

The electronic components incorporated into the device will influence the linearity of response of the measuring equipment and the equipment may also be affected by adverse temperature conditions.

#### 21.7.2.3 Luminance measuring equipment

Luminance measuring instruments incorporate photo-voltaic cells, which also require to be colour corrected, and which are required to have a linear response.

## 21.8 Lighting applications

### 21.8.1 Office and interior lighting

It is possible to classify the main requirements for optimum lighting conditions within interiors as:

- (a) health and safety;
- (b) visual performance;
- (c) aesthetics; and
- (d) personal comfort.

When striving to obtain an office environment, which is both aesthetically pleasing and acceptable to the eye, it is usual to include:

- (a) an analysis of those visual tasks that are likely to be encountered within an office;
- (b) a balance between the quantity of daylight entering an office interior and the corresponding requirements from artificial lighting;
- (c) a balance between direct and diffuse lighting contributions so that where practical no adverse three-dimensional and/or modelling effects will be produced;
- (d) the provision of an environment that is free from both glare and any associated distractions.

When considering the health and safety of personnel, office lighting should ideally allow room occupants to carry out their normal duties in a manner that, under normal conditions, is considered to be safe. The lighting provided must not, under any circumstances, place any occupants of the room at risk. Furthermore it is necessary to provide for the safety of occupants in the event of an essential evacuation of the premises. In the United Kingdom emergency lighting is a requirement under The Building Regulations and is covered by BS 5266 Emergency Lighting.

It is important not to overlook both aesthetics and personal comfort when considering optimum office lighting conditions. There is a psychological influence on the occupants

of an interior caused by the decor and room appearance and subsequently this is likely to have a 'knock on' effect upon worker behaviour that will ultimately affect output productivity.

#### 21.8.1.1 Sick building syndrome and building related illness

The term sick building syndrome (SBS) is used to describe a host of symptoms which appear to have a high incidence in some buildings and which have a definite work relationship. It is essential to distinguish between sick building syndrome and other illnesses, which are connected with buildings, or building services. These building related illnesses are typically much less common; they almost always have a clearly identifiable microbiological cause and usually affect relatively few occupants. The term building related illness (BRI) is often preferred for such conditions as humidifier fever and Legionnaire's disease.

Sick building syndrome (SBS) can be caused by a host of factors, one of which is lighting. The symptoms of sick building syndrome (SBS) include headaches, nausea, dizziness, irritation of eyes, nose and throat and general lethargy.

### 21.8.2 Factory lighting

Typical outdoor lighting installations at factories include general external yard lighting, loading bays and storage areas.

The objective for factory roadway lighting is to provide suitable and sufficient illumination so as to allow the safe passage of personnel both on foot and in vehicles. To this end care must be taken when designing a lighting installation for such areas in order to provide the required illuminance but simultaneously to avoid the development of glare being experienced by works' personnel. It is normal to monitor and control values of average illuminance and point illuminance and in so doing maintain acceptable values of uniformity ratio so as to avoid producing 'patchy' lighting.

Loading bays and storage areas require special attention including due consideration given to the elimination of shadows.

### 21.8.3 Security lighting

The aims and objectives of security lighting are:

- (a) to improve the likelihood of detection, identification and apprehension of intruders;
- (b) to improve the efficiency of other security measures in use;
- (c) to improve safety levels for authorised personnel.

Owners of shops will be concerned with the security of their premises especially where the sales rooms and associated areas contain stock, which could be of considerable financial value. It will be evident that in such situations the security lighting should pay particular attention to those areas where routine entry to the premises is gained, in addition to those areas of the interior that are visible externally.

Any lighting provided in the loading area will not only assist with the security of the premises but will also help with the normal operations of authorised personnel within the boundary of the premises.

One of the main considerations when contemplating the security lighting requirement for offices is the size of the

premises. With a small suite of offices or a single lock-up office it is difficult to justify the use of dedicated security personnel. Conversely the situation applying with larger office blocks often demands the use of security guards whose sole function is to patrol and guard the offices.

Factories or larger scale premises will create different problems. In addition to the theft of finished goods raw materials are also targets for criminals and the security of such premises must therefore, of necessity, commence at the factory gatehouse or main entrance.

When designing a security lighting installation it is essential to avoid the production of shadows. In addition to posing a danger for authorised workers on a site, shadows are likely to provide areas in which criminals are likely to remain undetected and from which they can therefore subsequently make good an escape.

### 21.8.4 Floodlighting

Floodlighting can be applied to many installations e.g. buildings, industrial premises and for sport.

Floodlit buildings are commonplace in town and city centres. Thoughtful siting of luminaires and careful selection of the types of light sources used can produce a floodlit effect which is both striking and pleasing to the eye. It is however important to appreciate that floodlighting is not a procedure for illuminating a building during the hours of darkness to the same luminance level, and in the same manner, as that provided by natural daylight.

For optimum floodlighting of buildings there should be a flow of light across the front of a building. The direction of this flow should not be identical to that of the direction of normal viewing of the building front. Any contravention of this recommendation will lead to an absence of shadows producing a building appearance that is seen to lack character.

It will be evident that the colour output of the light source(s) used in any floodlighting scheme is critical, and the deliberate production of a colour difference can be used to advantage in the process of highlighting different areas of a building.

Industrial floodlighting is a necessary commodity for those locations where outside work continues during the hours of darkness. Adequate lighting of the correct type will ensure that maximum benefit is obtained from external work activities. Suitable and sufficient working illuminance combined with effective glare control should enable visual task details to be detected clearly, concisely and with speed which should subsequently allow work to proceed with safety and without creating visual problems for the workforce.

In many industrial activities it is essential to be able to discern the surface colour of engineering and production materials and it will be evident that floodlighting contributes markedly to the ease with which this identification process is carried out. In such situations those light sources with poor colour rendering properties are totally unsuitable and examples of such light sources include low pressure sodium lamps.

Sports floodlighting incorporates luminaires mounted on towers or grandstand fasciae. Light sources must have good colour rendering properties in particular when colour television transmission of events is likely.

### 21.8.5 Public lighting

Public lighting can be defined as any lighting provided for the public use, which is usually maintained at the public's

expense. The functions of public lighting can be classified as:

- (a) to ensure the continued safety of road users and pedestrians;
- (b) to assist the police in the enforcement of the law;
- (c) to improve the environment for the benefit of residents; and
- (d) to highlight shopping areas and areas of civic importance.

When a driver is travelling along a road during the hours of darkness, objects are seen by one of two processes, either (a) direct vision (using surface detail) or (b) by silhouette vision. A driver will see as silhouettes either small objects at medium distances or large objects at greater distances. By directing the beams from the vehicle headlights on to the road so that they strike it at glancing angles (towards oncoming motorists) the whole of a road surface can be made to appear bright.

For optimum road lighting conditions the designer should strive for the following:

- (a) a uniform road surface luminance;
- (b) adequate and acceptable illuminance;
- (c) suitable silhouette contrasts of the road ahead; and
- (d) glare control from road lighting luminaires.

Low pressure sodium lamps have the highest luminous efficacy of artificial light sources and have been used exten-

sively for road lighting. Their colour rendering properties are very poor and many public lighting engineers use such monochromatic sources only for minor road lighting installations. High pressure sodium lighting is now used on many trunk roads, other major roads and in town centres and areas of civic importance.

### 21.8.6 Light pollution

Extraneous light, in various forms, is a public enemy of increasing proportions. Astronomers are often particularly aggrieved in respect of this offensive light inasmuch as they would prefer to view the night sky with as little stray light as possible. The situation occurs for a variety of reasons but in general terms it is due to either badly designed lighting installations or inaccurately aimed luminaires or a combination of both.

The likely consequences are sky glow or light pollution, where artificial lighting spills over, and therefore trespasses into, areas for which it is not intended. The situation becomes more pronounced when light is scattered through the night sky by particles of dust and droplets of water.

There appears little doubt that light pollution is a serious problem and unless the situation is addressed and subsequently reversed there is every possibility that the view of the night sky and all of the details contained therein, will be lost.

22.7.1	Electrical loads	22/26

## 22.1 Introduction

The environment in which we live and work has two basic elements: the external, over which we have as yet no control, although we are beginning to understand how our activities can moderate its characteristics; and the internal which can be maintained to specified conditions to meet our needs in terms of comfort and health.

Environmental control is still frequently considered only in terms of microprocessor- and software-based control systems which traditionally maintain specified conditions of temperature, humidity (in air conditioned spaces), illuminance and noise, to achieve comfort. This narrow concept of comfort has been affected by various aspects of the current debate on environmental and 'green' issues and a growing range of health-related criteria.

Until the energy crisis of 1973–1974, the specified criteria were achieved generally without any consideration of the efficient utilisation of energy used for the purpose. Since that time energy conservation and utilisation has become a major design parameter for all buildings and building-services systems. Because buildings in the UK use approximately one-half of the overall national energy consumption, there is considerable potential for saving by suitable integrated design and selection of equipment. Such savings affect both cost and environment.

The use of electrical energy is important in all forms of environmental control, whether it be for the supply of thermal power, circulation of air and water, or control. Apart from thermal power, where the choice of fuel is often governed either by its availability or the apparent economics during the design period, electricity will virtually always be involved with the other elements. The use of particular energy sources such as oil, gas, coal, electricity, etc., may be governed by the specific application. The comparison of fuels in terms of economics and costs to the client, as distinct from the primary energy consumption for each fuel is important and needs to be considered in selecting building-services systems, but as an indirect element of environmental control.

This review of environmental comfort is generally concerned with the internal or built environment, but the effect of design and operation of buildings on the external environment should not be forgotten. Any choice of materials or fuel used in buildings and the building's services affects the overall discharge of carbon dioxide (CO<sub>2</sub>) into the atmosphere. The CO<sub>2</sub> is considered to be the classic greenhouse gas, contributing to global warming, and design and operating decisions which reduce CO<sub>2</sub> emissions will help to minimise long-term climatic effects. If current moderate scientific opinion is accepted, global warming could have a significant effect on the internal environment during the life-time of buildings which are being erected now. It is therefore important to identify the full range of parameters which may affect comfort and health within the built environment so that interaction between external and internal conditions can be identified. Many of the suggested comfort parameters are not energy related nor are they affected by the external environment.

## 22.2 Environmental comfort

The indoor environment should be safe, appropriate for its purpose and pleasant to inhabit. The parameters to be considered include the thermal, acoustic and visual conditions and are now expected to encompass health and psychological factors.

### 22.2.1 Personal comfort

In human terms an individual senses skin temperature, not room temperature, although the latter affects the former. The body loses heat by evaporation of moisture from the skin, convection to the surrounding air and radiation to, or conduction with, cold surfaces. These mechanisms, together with the degree of activity and the type of clothing worn, tend to maintain the skin temperature constant (except for exposed extremities) over a wide range of environmental conditions. However, real comfort occurs in a much narrower range of climate, and individual requirements differ considerably both intrinsically and, again, according to the activity and clothing. The narrow zone of real comfort conditions is often classified as neutral or comfortable. This, is shown in *Figure 22.3* in terms of temperature,<sup>1</sup> and illustrates the degree of satisfaction for a group of people in a particular space, about the optimum neutral temperature for the group. The specified space temperature is therefore always a compromise and is only one of the criteria affecting comfort.

Other parameters can have a marked effect on the space temperature necessary to provide optimum satisfaction to the occupants. One example of these effects (*Figure 22.4*)<sup>1</sup> illustrates the elevation in space temperature required to compensate for increasing air movement.

Beyond the parameters which are identified above, there are now other elements which have to be considered and they are identified later, after the following sections on more traditional criteria. For many of these additional elements more research is required before their full effects on comfort can be characterised.

### 22.2.2 Temperature and humidity

The term 'space temperature' has been used so far to avoid confusion. Most people assume that space temperature specified in terms of the dry bulb air temperature defines levels of warmth. The previous comments indicate that this may not be valid, although temperature detectors in common use are mainly calibrated for, and measure, dry bulb air temperature. Alternative temperature indices may provide better definitions of comfort conditions or are used for design calculations: these include equivalent, effective, globe, dry resultant and environmental temperatures. Environmental temperature is used for calculation, and resultant temperature  $\theta_{res}$  is considered to be a measure of comfort dependent on internal dry bulb temperature  $\theta_{ai}$ , mean radiant temperature  $\theta_r$  and speed of air movement  $u$  as defined in

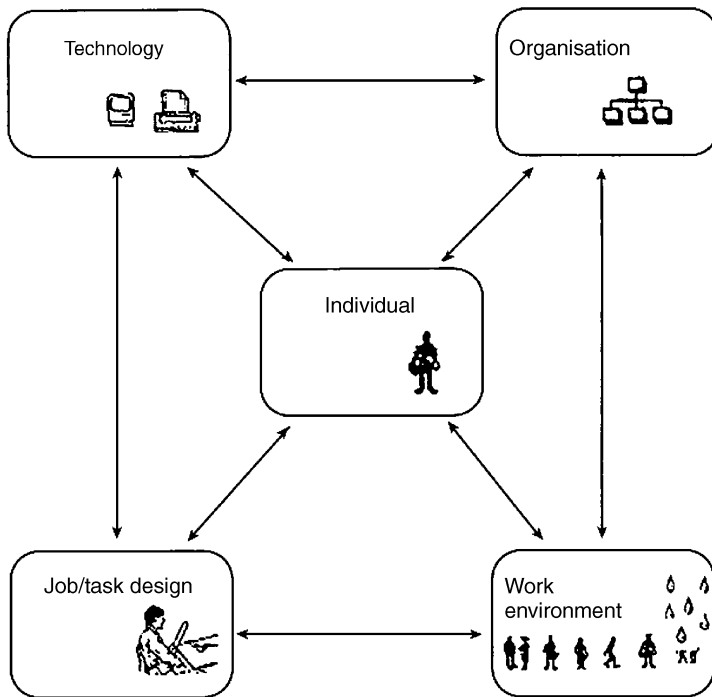

$$\theta_{res} = [\theta_r + \theta_{ai}\sqrt{(10u)}]/[1 + \sqrt{(10u)}] \Leftarrow$$

Given that the recommended values of  $\theta_{res}$  are those listed in *Table 22.1*, it is possible to adjust room temperature detectors or thermostats to a level suitable for comfort, for any mean radiant temperature and air velocity.

### 22.2.3 Parametric limits

Limits need to be applied to any specified comfort conditions, particularly in the case of temperature and humidity. Generally, in terms of human comfort, limits of  $\pm 2^\circ\text{C}$  about a specified temperature and a relative humidity (r.h.) of  $\pm 10\%$ , about a mean of 50%, will be acceptable. Limits more critical than is necessary will create additional and unnecessary costs.

There may also be statutory limits which have to be applied in terms of energy conservation. In the UK since

**Figure 22.1** Model of the work system

1974, outside the domestic sector, space temperatures<sup>2</sup> now have an upper limit of 19°C. This is only a partial limit, because the reference covers only the heating. To complete the limit the regulation would have to specify an upper limit of 20°C for heating cycles and a lower limit of,

say, 25°C for cooling cycles. Between these two limits there would be neither heating nor cooling input.

The level of humidity in a space can have a considerable impact on comfort, but in a heated building there is a limited range of control over its value. Artificially increasing

**Figure 22.2** The operator/engineer's environment

**Figure 22.3** Comfort vote for personnel at around the neutral temperature for varying criteria. Curve A is for people giving any of the three central descriptions. Curve B is for the central description alone. (Courtesy of CIBSE)

**Figure 22.4** Corrections to dry resultant temperature for air movement. (Courtesy of CIBSE)

the air change rate by opening doors and windows is unlikely to be acceptable in winter and is a palliative in summer. Fortunately the band of comfort conditions in humidity terms is fairly broad for most people, and a range of 40–60% r.h. is usually acceptable and, in the UK, often occurs in practice internally. Below approximately 35% r.h., static electricity effects occur and noses and throats may be affected and above, say, 65% the effect of stickiness may be felt. Air-conditioned systems are normally designed to avoid these extremes.

#### 22.2.4 Visual and acoustic parameters

The acoustic and visual impact on comfort conditions is extremely important. The correct level of illuminance for a particular task is important in its own right, but the overall aesthetics are a combination of the lighting level, the lighting source, the architectural finishes and their reflecting properties, and furniture and equipment. These aesthetics contribute to the comfort of the occupant.

Sound, in terms of personal comfort, is also related to the particular task. People's reaction to sound varies according to age and situation. Acoustics is both complex and subjective, and only a broad outline is included for the purpose of defining general criteria for comfort. Because the response of the ear is non-linear and less sensitive at low frequencies, it perceives equal loudness for various combinations of frequency and sound pressure levels, units of loudness being defined in phons. Sound pressure is a fluctuating air pressure sensed by the ear. The fluctuations are minute in relation to atmospheric pressure: sound pressure levels are specified in decibels. The levels are created by the sound

power (the power transmitted by the sound waves) which is normally considered only in reference to a sound source. Sound power levels ( $L$ ) are also referred to in decibels (dB).

$$L = 10 \lg(W/W_0) \text{ dB}$$

where  $W$  is the source power (in watts) and  $W_0$  is the reference level (normally 1 pW).

Sound pressure is proportional to the square root of sound power.

A series of equal loudness curves (*Figure 22.5*)<sup>1</sup> is split into three sectors defined by A, B and C, which correspond to the sensitivity of the ear under varying conditions and can be measured by instruments with weighting networks corresponding to these bands. The subjective reactions for comfort in buildings are normally related to the A scale and the noise levels are quoted in dB-A. It is common to specify acceptable background noise levels for annoyance and speech intelligibility by means of NR (noise rating) or NC (noise criteria) curves, the former being most commonly used in Europe. Both sets of curves attempt to express equal human tolerances to noise across the audible frequency spectrum and are based on subjective experimental data. Normally the curves specify noise levels between 4 and 8 units below the measured dB-A values, although the relationship is not constant. *Figure 22.6* shows the NR curves and *Table 22.2* lists the recommended noise ratings for various situations.

**Figure 22.5** Equal-loudness-level contours. (Courtesy of CIBSE)

**Figure 22.6** NR curves. Each curve is classified by a number corresponding to the speech interference level which was originally defined as the average of the sound pressure levels measured in the octave bands 600–1200, 1200–2400, and 2400–4800 Hz. The maximum permissible loudness level is taken to be 22 units more. Thus NR 30 has a speech interference level of 30 dB and a loudness level of 52 phons; this means that, for effective speech communication, the loudness level in a space designed to have a background level complying with NR 30 must not exceed 52 phons

**Table 22.2** Recommended noise ratings\*

Situation	NR value
Concert halls, opera halls, studios for sound reproduction, live theatres (> 500 seats)	20
Bedrooms in private homes, live theatres (< 500 seats), cathedrals and large churches, television studios, large conference and lecture rooms (> 50 people)	25
Living rooms in private homes, board rooms, top management offices, conference and lecture rooms (20–50 people), multipurpose halls, churches (medium and small), libraries, bedrooms in hotels, etc., banqueting rooms, operating theatres, cinemas, hospital private rooms, large courtrooms	30
Public rooms in hotels, etc., ballrooms, hospital open wards, middle management and small offices, small conference and lecture rooms (< 20 people), school classrooms, small courtrooms, museums, libraries, banking halls, small restaurants, cocktail bars, quality shops	35
Toilets and washrooms, drawing offices, reception areas (offices), halls, corridors, lobbies in hotels, etc., laboratories, recreation rooms, post offices, large restaurants, bars and night clubs, department stores, shops, gymnasias	40
Kitchens in hotels, hospitals, etc., laundry rooms, computer rooms, accounting machine rooms, cafeteria, canteens, supermarkets, swimming pools, covered garages in hotels, offices, etc., bowling alleys, landscaped offices	45

*NR50 and above*

NR50 will generally be regarded as very noisy by sedentary workers but most of the classifications listed under NR45 could just accept NR50. Higher noise levels than NR50 will be justified in certain manufacturing areas; such cases must be judged on their own merits

*Notes*

1. The ratings listed above will give general guidance for total services noise but limited adjustment of certain of these criteria may be appropriate in some applications.
2. The intrusion of high external noise levels may, if continuous during occupation, permit relaxation of the standards but services noise should be not less than 5 dB below the minimum intruding noise in any octave band to avoid adding a significant new noise source to the area.
3. Where more than one noise source is present, it is the aggregate noise which should meet the criterion.
4.  $NR \approx dBA \text{ value} - 6$ .

\*Courtesy of CIBSE.

In conditions of adverse background noise the acceptability of differing noise sources may not depend on their absolute level and frequency but on their relationship with one another.

Outside the areas of normal sedentary or light industrial environments noise can rise to levels which may be injurious to health. At 90 dB-A or higher, exposure to the noise in confined spaces can be tolerated only for specific periods, e.g. 8 h at 90 dB-A, 2 h at 96 dB-A and 0.8 h at 100 dB-A.

**22.2.5 Widening the environmental specification**

The traditional criteria for comfort have already been identified as temperature, humidity, illuminance and noise.

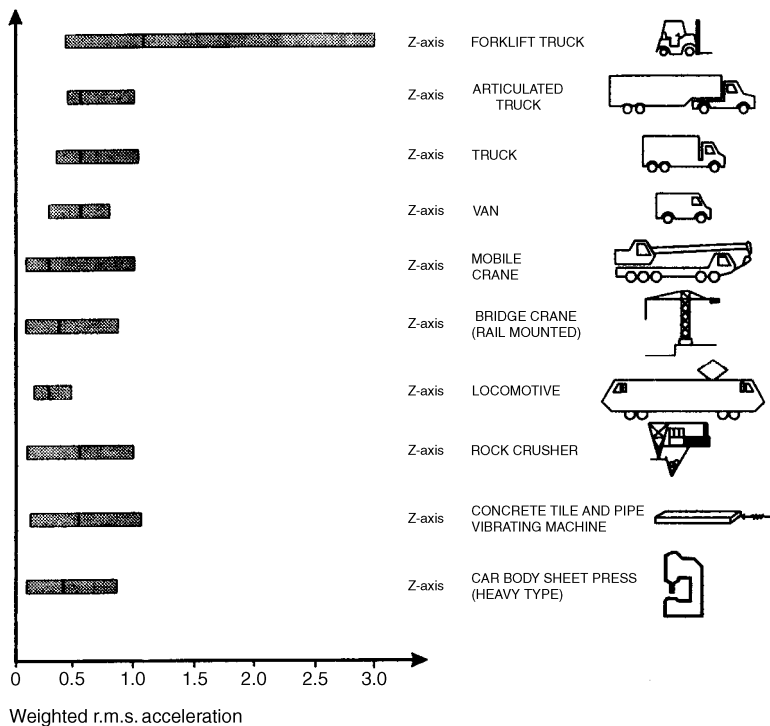

Figure 22.7 Examples of extra noise systems

There is much debate on the need to extend the criteria for defining a modern working environment which is comfortable and healthy. The range of additional possibilities is vast and it will take time before any of them become fully recognised and accepted nationally and internationally.

#### 22.2.5.1 Comfort criteria

There are several comfort criteria which are commonly accepted as being important but do not form part of the current environmental specification.

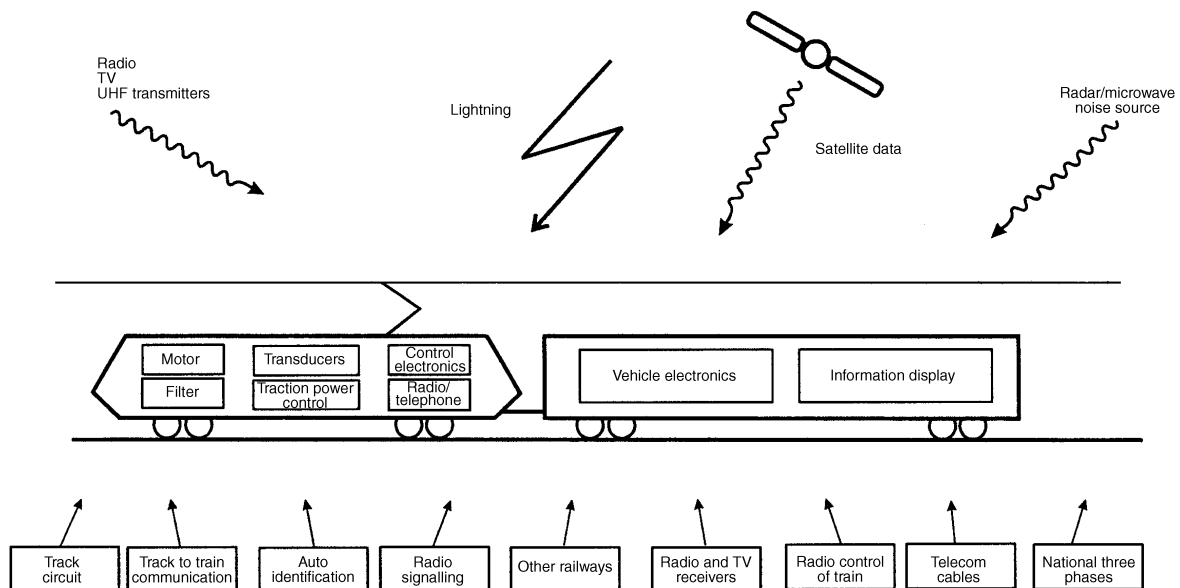

Figure 22.8 Examples of noise sources and disturbances in the railway environment

Figure 22.9 Harmful and non-harmful noise level

Figure 22.10 Body vibration levels (comfort and discomfort)

Figure 22.11 White finger vibration

Figure 22.12 Maximum (annoyance) noise levels

**Fresh air change and air movement** These criteria are less likely to be part of the project brief and are commonly selected by the designer. Design guidance is available and quantitatively defined in professional handbooks and selection is a function of user needs and design experience. Their more explicit specification should be addressed.

**Glare, veiling reflections, daylighting, luminance, etc.** This group of criteria, like fresh air and air movement, are rarely specified in a project brief or specification. They too are part of the designer's evaluation and selection process and suitable guidance is available. There are current research and study projects examining a range of postulated potential problem areas relating to light sources, systems and the health of the working population. A familiar example is the unsuitable lighting arrangements for occupants using display terminals. There is a publication from the Chartered Institution of Building Services Engineers (CIBSE) entitled *Lighting for Visual Display Terminals*, which addresses this problem.

#### 22.2.5.2 Colour finishes

There is another group of parameters which needs more consideration, some within the control of the architect, others the responsibility of the building-services engineer, and all of them require a co-ordinated approach by both disciplines. Colour finishes in a building and their reflectances, i.e. the amount of light which strikes the surface and is then reflected, are extremely important in terms of occupant satisfaction, and this applies as much to the furniture and equipment as it does to the walls, ceilings and floors. The same point could be made about the colour tint chosen for many window solutions, with the added point that it can detrimentally affect the occupants' perception of

the outside environment. This group of criteria may sound somewhat esoteric in terms of comfort and health, but they do require objective review and further research.

The recognisably engineering factors which may enter more directly into future environmental standards are listed below.

- (1) *Mean radiant temperature*—the effect of large hot or cold surfaces.
- (2) *Infra-sound*—the possible effect of low-frequency vibration
- (3) *Mains flicker and ultraviolet radiation from luminaires*—current studies and improvements in technology suggest that these are not, and need not be, problems.
- (4) *Ionisation*—the effect of negative or positive ions in the air; an area of continuing debate and argument.
- (5) *Information technology (IT) acoustics*—the effects of the various levels and frequencies of noise emanating from IT equipment may have a marked effect on occupancy comfort and fall outside the traditional specified noise criteria.

The parameters listed above are probably the most likely candidates to have a direct bearing on conventional environmental comfort, but there are other factors which may affect our comfort and health at work. They can be split into three further groupings.

#### 22.2.5.3 Pollutants

Modern society recognises the multiplicity of pollutants in our environment generally, but the following identified groups specifically affect the built environment and comfort:

- (1) tobacco smoke;
- (2) fibres and dusts (mineral, paper, ink from printers, etc.);

- (3) volatiles and organic vapours (from adhesives, etc.);
- (4) micro-organisms (bacteria, viruses, spores, dust mites, etc.); and
- (5) carbon dioxide.

All these pollutants, which may in some cases appear as odours, are created within the working environment, and very little is known about their concentrations, and the short- or long-term exposure effects at differing concentrations. Even less is known about mixtures of these contaminants and the possible 'cocktail' effect. It may be that a very small percentage of the working population is allergic to one or more of these pollutants. As the identified pollutants can exceed three figures, any summation of such allergies could conceivably affect a relatively large percentage of the occupants. On a longer term view, if any pollutants are identified as causing such problems,<sup>3</sup> their source materials could be banned, or fresh air change rates could be increased to lower the concentrations to safe levels—but only to a limited extent.

A recent study and tests by the Building Research Establishment, Garston on a UK building with a history of sick building syndrome (SBS) has indicated that a reduction in the dustmite population has also reduced the level of SBS complaints in the treated area.

#### 22.2.5.4 Psychological factors

The debate on comfort and health covers both the obvious and the less frequently addressed criteria which affect our physical and physiological reactions to our environment. It also extends to consideration of the psychological factors which are outside the professional competence of the architect and engineer. Designers may in future be guided by medically orientated research into design solutions which could alleviate the effect of factors, such as:

- (1) lack of job fulfilment;
- (2) repetitive/boring work;
- (3) lack of privacy;
- (4) lack of individual identity;
- (5) perceived lack of control over 'personal' environment; and
- (6) poor management.

#### 22.2.5.5 Sick building syndrome

Until recent times the design of building services was a function of an environmental specification which had to be met to achieve comfort. Nowadays the designer has to deal with several medically classified criteria apart from the, as yet, unresolved problems associated with SBS. Engineering designers are not professionally qualified to assess medical risks, but they can design to alleviate or eliminate such risks once they have been identified. Thus, design of buildings and building services can certainly contain the risks associated with Legionnaires' disease (and its associated family of illnesses), and radon, and they must always be considered in the design process. Less clearly defined, but possibly hazardous, are the effects from electromagnetic radiation generally, and high-voltage overhead cables in particular. Design teams may need to use consultant medical input as part of the design processes of the future.

The subject of SBS and its relationship with environmental comfort deserves some specific attention. As it is widely mentioned but not clearly understood. The World Health Organisation (WHO) identifies a range of symptoms for

SBS which cause genuine distress to some building occupants, but cannot be clinically diagnosed and therefore cannot be medically treated. They typically include:

- (1) stuffy nose;
- (2) dry throat;
- (3) chest tightness;
- (4) lethargy;
- (5) loss of concentration;
- (6) blocked, runny or itchy nose;
- (7) dry skin;
- (8) watering or itchy eyes; and
- (9) headache.

Affected individuals may suffer from one or more of these symptoms and the syndrome is characterised by the additional feature that the symptoms are said to disappear soon after the affected people leave the building.

*Is it important?* Sick building syndrome was reported as long as 30 years ago, but its significance, or apparent tendency to increase, has only been apparent over the last few years. Recent research<sup>4,5</sup> has indicated that it occurs more often in air-conditioned buildings than others, but as it does occur in heated and naturally ventilated buildings, the cause cannot simply be ascribed to air conditioning. Overall comfort and health in buildings cannot be satisfied by the heating, ventilating and air conditioning (HVAC) industry in isolation.

While SBS may be classified as an illness, there is no absolute proof that it is caused by any one factor or combination of factors. A large number of studies are being carried out,<sup>6</sup> often initiated because of the high level of occupant dissatisfaction or SBS symptoms in the working environment.

There is a body of evidence which suggests that levels of comfort, health or SBS may be caused by a combination of factors, but the mix and the weighting against each is indeterminate at present. Any of the non-medical parameters previously identified may individually, or in combination, contribute to SBS. To the list must be added design which does not conform to the current best practice and the quality of maintenance and hygiene in buildings.

#### 22.2.6 Machines and processes

Apart from comfort criteria for personnel, there are two other areas where environmental conditions may be important: machine rooms and process plants. The former covers such spaces as computer rooms and medical machine areas; and the latter, areas such as electronic manufacturing or food processing factories. In many ways the criteria are similar to those for personal comfort, but there may be requirements for closer limits and, in particular, air filtration becomes a significant factor, the number and size of particles being very closely defined according to the process. In certain critical processes the air movement patterns are also specified, laminar flow probably being the most difficult to achieve. While temperatures are often specified with limits of not greater than  $\pm 0.25$  or  $\pm 0.5^\circ\text{C}$ , with humidities to  $\pm 2\%$  r.h. or better, two points should be made. Limits specified may be unnecessarily stringent and need to be questioned. As an example, computer rooms in the past needed close limits if the machines were to operate correctly; but nowadays this is not normally necessary. The second point concerns the achievement of conditions throughout the treated space. Strictly, the specified conditions can normally be achieved only at the point of detection and control, the variation throughout the remainder of the

space being largely dependent on good plant design and distribution of the heating and cooling media.

### 22.2.7 Safety requirements

In environmental control the specified conditions and their limits have to be achieved, but generally only during normal periods of occupation. It is therefore necessary to consider the environmental conditions necessary under abnormal circumstances. Examples include: (1) emergency or maintained lighting levels when the normal system breaks down or during unoccupied hours, (2) the low limit temperatures to be maintained to prevent freezing or damage to equipment and furniture, and (3) the maintenance of humidity below a specified dewpoint condition to prevent condensation on cold glazing.

## 22.3 Energy requirements

To achieve comfort conditions energy is required. The selection of electricity, gas, oil, solid fuel or alternative energy sources is a function of the required conditions, the plant selected, the economics, availability of supply, client preference and, to some extent, crystal-ball gazing.

The calculation of the energy necessary to achieve a particular set of environmental conditions is based on a number of concepts ranging from the simple to the complex and covering both the actual loads for heating and cooling the spaces and the plant sizing to deliver these loads. More sophisticated techniques have been developed to improve the accuracy of calculations and predictions in terms of heating or cooling loads and energy consumption. It is necessary to remember that the more precise figures derived from these techniques are valid only so long as the buildings to which they are applied are built with the same precision and with materials having the same indices used in the calculations. Care must therefore be exercised to ensure that the calculation procedures do not aim for an order of certainty that cannot be achieved in normal construction.

### 22.3.1 Steady-state loads

In its simplest form the steady-state heat load for a space within a building may be defined as

$$Q = [\Sigma UA + \frac{1}{3}NV]\Delta\theta$$

where  $Q$  is the energy required (watts),  $U$  is the thermal transmittance of any element surrounding the space ( $\text{W/m}^2\text{K}$ ),  $A$  is the area of the element ( $\text{m}^2$ ),  $\Delta\theta$  is the temperature differential across the element ( $^{\circ}\text{C}$ ),  $V$  is the volume of the space ( $\text{m}^3$ ), and  $N$  is the number of external air changes per hour ( $\text{h}^{-1}$ ).

The thermal transmittance of a wall, roof, floor, etc., is based on an electric circuit analogue. Normally each wall, etc., is a laminar structure of parallel layers of different materials and air spaces, each having a thermal resistance depending on its composition, thickness and surface properties. Given the thermal resistances (in  $\text{m}^2\text{K/W}$ ) as  $R_{\text{si}}$  and  $R_{\text{so}}$  for the inner and outer surfaces,  $R_1, R_2, \dots$ , for the component layers, and  $R_a$  for the air spaces, the thermal transmittance (in  $\text{W/m}^2\text{K}$ ) is

$$U = 1/[R_{\text{si}} + R_1 + R_2 \dots + R_a + R_{\text{so}}]$$

Tabulated  $U$  values for a wide range of construction elements<sup>7</sup> are available for different exposures: some are

given in *Table 22.3*. There are certain factors for which allowances may have to be made to the tabulated figures. The values quoted are for homogenous areas of construction, whereas in practice edge details and corners affect the figures. In addition, cold bridging can affect the values, i.e. the effect of wall ties between the inner and outer skin of the building or the framing round windows. Some examples of the ventilation rates used in normal calculations are detailed in *Table 22.4*.

The use of this method enables the heating load (or sensible cooling load) to be calculated for steady state conditions based on a minimum (or maximum) outside design condition and the additional assumption that the heating (or cooling) system will operate continuously. In practice systems generally operate intermittently and the building behaves dynamically. It is to cater for these factors that the more sophisticated calculations are introduced.

### 22.3.2 Dynamic or cyclic loads

To examine the dynamic performance of buildings, i.e. the energy requirements or loads under cyclic conditions, a procedure is used where the factors of admittance ( $Y$ ), surface factor ( $F$ ) and decrement factor ( $f$ ) are introduced, the admittance having the greatest effect. The factors are functions of the thickness, thermal conductivity, density, specific heat capacity, position and frequency of energy inputs of each of the materials used in the construction. These have analogues with reactive loads in electric circuits. Consequently, there are phase changes ( $\phi_y$ ,  $\phi_F$ , and  $\phi_f$ ) associated with them which, because the fundamental frequency is one cycle per day, are expressed as time lags/leads to the nearest hour.

The use of these factors leads to some complex equations which define the cyclic heat requirements for the building. The admittance can be thought of as the thermal elasticity of the structure, i.e. its ability to absorb heat; the decrement factor is a measure of how a cyclic heat input is attenuated as it passes through the structure; and the surface factor is a measure of how much of the cyclic input at a surface is readmitted to the space.

On thin structures the admittance equals the static  $U$  value; on multilayer constructions the admittance is largely determined by the internal layer. Thus, insulation on the inside of a concrete slab gives an admittance close to that of the insulation alone, whereas if the insulation is within or on the outside of the slab, the admittance value is virtually that of the slab alone. Decrement factors range from unity for thin structures of low thermal capacity, decreasing with increasing thickness or thermal capacity. Surface factors decrease with increasing thermal capacity and are virtually constant with thickness. Sample values of these three factors are shown in *Table 22.3*.<sup>7</sup>

Other factors affecting the load requirements include environmental temperature, solar gains, internal gains and the latent load for air conditioning plants, i.e. the amount of moisture that has to be removed (or added) to the treated air.

Environmental temperature ( $\theta_{\text{ei}}$ ) has already been mentioned and it is a concept used in carrying out load calculations, as it defines the heat exchange between a surface and an enclosed space. Its precise value depends on room configuration and the convective and radiant heat transfer coefficients of the surfaces. For the UK and hot climates it may be shown that

$$\theta_{\text{ei}} = \frac{1}{3}\theta_{\text{ai}} + \frac{2}{3}\theta_{\text{m}}$$

**Table 22.3** Thermal transmittance, admittance, decrement and surface factor for various constructions\*

Construction (outside to inside)	U (W/m <sup>2</sup> K)	Admittance		Decrement		Surface factor

where  $\theta_{ai}$  is internal air temperature and  $\theta_m$  is mean surface temperature.

Solar gains affect load calculations in two ways. First, there is the effect of solar radiation on the heat transfer characteristics of the building fabric, which is covered by the use of a parameter known as sol-air temperature ( $\theta_{eo}$ ). The definition of  $\theta_{eo}$  is that temperature which, in the absence of solar radiation, would give the same rate of heat transfer through the wall or roof as exists with the actual outdoor temperature and the incident solar radiation, i.e. it is an artificial outside temperature to take into account the effects of solar radiation. The second factor covers the direct solar radiation gains through windows, some of which have an immediate effect and some of which is absorbed into the internal structure and readmitted subsequently. Both types of gain affect energy consumption, but in terms of load they are ignored for heating calculations and included for air conditioning load purposes.

Internal gains from lights, machines and occupants may be substantial. Again, in heated buildings the gains affect the energy consumed by the environmental plant but are not normally taken into account in calculating the design load (the energy input required for the coldest day). For air conditioning loads the inclusion of these gains is most important.

Latent gains are ignored in heated buildings but for air conditioning a considerable proportion of the maximum

cooling load may consist of latent cooling, i.e. the removal of excess moisture from the air because of the use of fresh air for ventilation and internal gains from occupants and, possibly, processes.

### 22.3.3 Intermittent heating and cooling

The calculation of loads for steady-state and cyclic situations leads naturally to consideration of the effects of running the plant intermittently to satisfy only the specified environmental conditions during periods of occupation. Inherent in this are the following.

- (1) The preheat period necessary to bring the building up to temperature under varying climatic conditions—in particular, on the coldest day for which the load is calculated.
- (2) The thermal response of the building during preheat, which will depend on its construction, insulation and ventilation.
- (3) The thermal response of the plant when first switched on.
- (4) The ratios between preheat, normal heating and plant-off periods.
- (5) Relative running and capital costs.

**Table 22.4** Air infiltration rates for heated buildings\*

\* Extracted from CIBSE Guide A4. Extracts from Table A4.12. Courtesy of CIBSE.

While the actual calculations can be complex and related to the dynamic states already mentioned, there are some basic points which illustrate the situation. In a steady state or dynamic analysis with continuous plant operation, loads for particular spaces may be calculated and the output equipment sized on this basis. When intermittent plant operation is introduced, the situation illustrated in *Figure 22.13* is typical.

**Figure 22.13** Intermittent-heating temperature/time curves

Here BC represents the period of occupation for which an internal dry bulb temperature of 20°C is required. CA represents the normal temperature decay in the space for a particular set of external weather conditions, and the area ABDA is the energy required to restore the temperature to 20°C at the start of the occupation period.

Because the normal load calculations are based on a constant temperature internally, it is obvious that if the temperature falls as shown, the energy input has to be increased above the steady state requirement, in order to raise the temperature to the required level. Calculating the amount of additional energy becomes part of the load calculations and may be based on variations of the cyclic state techniques already mentioned. The thermal response of the building and the time at which the plant is to be switched on are major factors in the calculations: *Figure 22.13* illustrates some of the variants which have to be taken into account. On the coldest day for which the system is designed the energy input is calculated in terms of the power to satisfy a switch-on time designated by point A. The actual position of A is temperature and time dependent, as indicated by points A<sub>1</sub> and A<sub>2</sub>.

Point A<sub>1</sub> represents a situation where the temperature decay has been allowed for longer than that required for A. It is clear that the power input capacity to achieve point B from A<sub>1</sub> must be greater than that for point A, because the differential temperature is greater and the time allowed is reduced. But the actual energy for the purpose is the comparison of areas ABDA and A<sub>1</sub>BFA<sub>1</sub>. Therefore, apart from the calculations for the load requirements the economics of plant costs against cost in use (energy costs in this case) have to be evaluated.

The second point A<sub>2</sub> represents the situation after a non-standard shutdown (e.g. weekends) when the normal load is based on heating from A. Again it is necessary to calculate the load for condition A<sub>2</sub> or to arrange for alternative operation of the plant so that, for example, the temperature is not permitted to drop below A.

### 22.3.4 Plant capacity

While it is possible to calculate all the heating and cooling loads for achieving environmental comfort conditions in various spaces, including the sizing of individual output terminals, the selection of main plant to supply the necessary energy is another matter. The actual terminal size for a space has to take into account all the elements already considered, which clearly illustrates that capacity is rarely based on the steady-state load for continuous plant operation. Economic factors can sometimes inhibit optimum selection. The choice of suitable terminal sizes is reflected in the main plant selection, which has to cover the following points:

- (1) heating plant capacity for intermittently heated buildings is normally based on simultaneous peak loads for all the spaces in the building, with such exceptions as the domestic sector, whereas cooling plant assumes diversity between the peak loads in various conditioned spaces (some diversity is permitted for continuously heated buildings).
- (2) heating or cooling plant capacity should be sufficient to cater for process requirements in addition to the environmental load; e.g. the domestic hot water load may be purely for washing but may also include kitchen or restaurant requirements.
- (3) sizing of source units should be such as to permit efficient operation under part-load conditions.

In respect of (3), particularly for multiple boiler or chiller installations, the environmental load in most cases only reaches the design peak for a small percentage of the total operating hours per annum, and the efficiency of boilers and chillers normally falls as their output decreases from the specified design level. It is therefore important to choose the units so that at, say, 25% of design load the operating source units are matched to the requirement to maintain a high efficiency.

The choice of refrigerant in chillers is environmentally important. Chlorofluorocarbons (CFCs) are currently the most common refrigerants in chillers used for commercial purposes and they deplete the atmospheric ozone layer and act as greenhouse gases. Under the internationally accepted Montreal Protocol, CFCs are scheduled to be phased out within the next 5–10 years and alternatives have to be provided which are environmentally safer. The current alternatives may be less efficient refrigerants than the CFCs they replace and more energy will then be required to produce the same cooling output, with a consequent increase in CO<sub>2</sub> released to the atmosphere.

### 22.3.5 Computer-aided design

The use of the computer for environmental comfort design is generally restricted to calculation of loads and annual energy consumptions, and to check whether the summer-time temperature in the building rises to a point where air conditioning is essential.

Computer programs enable far more sophisticated techniques to be employed without laborious arithmetic. However, they should be used only as a design tool for the project, which still requires practical knowledge.

The programs for UK use are generally based on detailed extensions<sup>8</sup> of the techniques already outlined. Among the criteria which can be incorporated are the effects of shading provided by building configurations and overhangs, which affect both the load and energy consumption.

Apart from providing the calculated loads, energy-consumption programmes can provide the annual figures based on hourly weather data over a full year for any location and type of plant, so that a comparison between plants is rapidly available.

### 22.3.6 Energy consumption

There are three specific points to be identified in considering energy consumption: (1) degree-day figures, (2) energy budgets, and (3) energy targets.

The degree-day is a concept that permits energy consumption in a building to be monitored from year to year against a monthly datum. It is normally used only for the comparison of consumption in heated buildings, although a modified form is being considered for use with air conditioning. Degree-days measure the interval for which the outside temperature drops below a specific value (normally 15.5°C) and the amount by which it does so. The monthly figures are published for various areas. The base of 15.5°C is used in the UK, but other figures are used elsewhere to broadly represent that outside condition for which no system heating is required to maintain a suitable internal temperature: internal gains, etc., are always assumed to provide a rise of several degrees.

The energy budget for a building is the estimated annual energy consumption of a building. It is necessary for the cost-in-use evaluation.

**Table 22.5** Energy targets for heated buildings

Building	Consumption per annum	
	(GJ/m <sup>2</sup> )	(kW-h/m <sup>2</sup> )
Offices <sup>1</sup>	0.47–1.19	130–330
Factories <sup>2</sup>	0.68–1.08	190–300
Warehouses <sup>2</sup>	0.54–0.97	150–270
Schools <sup>3</sup>	0.36–1.26	100–350
Shops <sup>4</sup>	0.61–1.44	170–400
Hotels <sup>4</sup>	0.86–1.55	240–420

*Notes:*

- (i) The figures are for heated and naturally ventilated buildings.
- (ii) The range of consumption is a function of the thermal insulation, air sealing and efficiency of the heating system.
- (iii) Figures are for conventional hours of occupancy and lighting levels. The factory figures include a 20% allowance for process gain.
- (iv) The figures are for the UK.

Energy targets define the design aim for energy use in buildings, related to type, usage and location. The figures may be quoted in terms of power or energy per unit area (e.g. W/m<sup>2</sup> or kWh/m<sup>2</sup> p.a.). The official energy unit in SI terminology is GJ/m<sup>2</sup> p.a., where 1 GJ ≈ 278 kW-h. Buildings are now being designed to meet such energy targets and there is a trend towards making such figures mandatory in certain parts of the world. Table 22.5 lists the targets for a variety of buildings in various locations.

## 22.4 Heating and warm-air systems

The majority of heating systems in the UK use water as the means of distributing thermal power (with steam as one variant of water). Electricity as a direct source of thermal power is an alternative which has advantages in certain situations but is frequently dismissed on the grounds of comparative energy cost. Water may be utilised for pure heating systems via emitters which produce radiative and convective heating, or for air heating systems where fan assisted devices produce warm air via a heat exchanger. The characteristics of boilers, by both type and use, are generally known in the engineering professions and are not covered here.<sup>9</sup>

### 22.4.1 Radiators

Radiators are the most common form of heating system. There is a roughly equal split between the radiant and convective heat output. On water systems cast iron for radiators has been largely replaced by mild steel. The radiant emission  $Q$  is a function of the difference  $\Delta\theta_i$  between the temperature of the ambient air and the mean of the internal liquid, according to the expression

$$Q = k(\Delta\theta)^n$$

where  $k$  is a constant depending on dimensions and  $n=4\pm3$  for radiators. Electric radiators and tubular heaters are rarely used outside domestic or small commercial premises and even then only because no other form of heating is available.

### 22.4.2 Convectors

Convectors may be natural or fan convectors: both are common. The natural versions may be in upright cases with top and bottom grilles for air circulation, or used as skirting heating. Their emission may be designated in a form similar to that for radiators, but  $n = \frac{1}{35}$  for upright types and 1.27 for skirting versions. Water flow rate can have a considerable effect on emission. Fan convectors provide a form of air heating. They are normally controlled by switching on and off by means of a thermostat. In the emission formula,  $n$  is unity.

Convectors using electrical power for the thermal output are unusual compared with the water power versions.

### 22.4.3 Warm-air systems

Warm-air systems vary from domestic units to industrial systems. Some sophisticated versions which duct warm air through a large building complex may be treated as air conditioning systems without cooling and humidification elements, but such systems are rare.

A substantial proportion of heaters, with nil or minimal ductwork, are freestanding and distribute air locally on a recirculation basis without the introduction of fresh air. If the air volume is freely distributed, the complete unit is usually started and stopped by means of a space thermostat, or one mounted in the recirculation air inlet to the unit. Where the air flow is restricted, by manual or thermostatically controlled dampers to control the temperature by varying the air flow, it is necessary to ensure that the unit and fan are switched off when the air volume is reduced to a predetermined level.

The primary source of thermal energy for these units may be oil, gas or electricity. The latter is used in domestic units and in some commercial applications.

### 22.4.4 Storage heating

*Underfloor heating* can be operated with hot water or electrical energy as the thermal medium. The floor construction, covering, thermal time constant, temperature control and the idiosyncrasies of the user make system calculation difficult, and underfloor heating is consequently uncommon. Its future may depend on using low-grade heat spread over large emitting surfaces at temperatures of 23–30°C, possibly with solar panels as the heat source.

*Storage heaters*, electrically fed, are employed in domestic and commercial premises, which avoids the need for central heating plant. For adequate thermal capacity the units are unavoidably heavy (60–300 kg), with ratings of 0.5–6 kW. The refractory heat-storage blocks have heating element temperatures up to 900°C. The heaters are normally run on off-peak supply, emission from the units being regulated to match the periods during which the heat output is required. 'Natural' storage units radiate during the off-peak charging period. They are generally less satisfactory than 'fan assisted' units, which are insulated to restrict output during charging, the output being controlled by timers and thermostats to start and stop the fan, which controls most of the heat output.

The charge during the permitted period should be regulated in accordance with internal and external temperatures. Energy regulators are available for this purpose (see Section 22.5.2).

Other systems are based on large and well-insulated water storage tanks, electrically heated off-peak by boilers or immersion heaters. In some cases the storage temperature

may exceed 100°C, which necessitates a pressurised vessel. Water is circulated (or, for the high-temperature case, injected) into conventional heating or air conditioning systems during the periods required.

### 22.4.5 Air conditioning

Air conditioning is the filtering, washing, heating and cooling of air to achieve specified temperature and humidity levels. In temperate climates building design and services can usually achieve reasonable comfort conditions without air conditioning, but a system may be found necessary (a) if the extreme conditions are not tolerable, (b) if the building design requires it, (c) if urban noise and dirt have to be reduced, and (d) if internal heat gains (e.g. computer rooms) have to be accommodated.

In an air conditioning system air is moved by fan power through the relevant space, which results in a physical sensation of air movement quite unlike that in normal heated spaces and with simple air heating. Clients and occupants have to be forewarned of this, otherwise there is a likelihood of complaints about the environment which are unwarranted.

#### 22.4.5.1 Systems

Most systems have a section of plant which adjusts the humidity, to ensure that air passed into the conditioned spaces is suitable for the specified humidity (a 'dewpoint' condition of about 10°C). The dewpoint plant is described in Section 22.5.1.3. After dewpoint treatment, air is ducted at high or low velocity, for which duct size, fan and acoustic treatment differ. Common systems available are given in the following paragraphs.

*Constant volume* Normally this uses branched ducting, each branch with a reheater controlled by a space temperature detector.

*Dual duct* Air from the main plant is split into two duct systems: one carries cold and the other carries preheated air. Both ducts traverse the building. Each space has a mixing unit, connected to both ducts and adjusting the hot/cold ratio in accordance with a room temperature detector.

*Variable volume* Cold air is distributed to individual spaces through terminals, which throttle the rate of air supply and are controlled by room temperature detectors. Throttling raises the static pressure in the ductwork, the effect being used through a control system to vary the air flow through the supply and extraction fans. Methods of control may be mechanical, or by the several speed control methods applicable to electric motors. As some air is always necessary in a space for ventilation, the terminals do not close in normal operation, and continue to feed in some cooling air. The system is therefore best applied to buildings that require cooling throughout the year, or to systems that incorporate small reheaters (although in the latter case the variable-volume system may be inappropriate). In general, the control of air volume and consequential reduction of air treatment provides a low energy system.

When the air supply from any terminal is throttled back to the minimum design volume, the air distribution pattern will obviously differ from the maximum volume situation. In extreme cases this can create environmentally unacceptable conditions. Many systems are now designed so that the terminal supplies a constant air volume consisting of a variable cooling component from the main air plant with the

remainder provided by recirculated air from the controlled space. This has the effect of maintaining both the correct air distribution pattern and the requisite amount of cooling.

**Induction** Air is supplied at high velocity to terminal induction units, mainly perimeter mounted, which are fitted with heating and cooling coils. Air is forced out of nozzles in the unit at a velocity high enough to induce entrainment of recirculation air from the space in the discharge jets. Thus, the space air is circulated through the unit, which provides the necessary quantity of conditioned fresh air from the main air plant. The heating and cooling coils are fitted with control valves and sequenced according to the requirements of the space temperature detector, to maintain the correct conditions. An extract system removes the equivalent amount of air to that supplied by the main plant. This type of system is rarely used nowadays.

**Fan coil** This has some similarity to the induction system but the air is supplied at relatively low velocity to the units, each of which has its own fan. The coil configuration and control is similar to that for the induction unit, but electrically there is a dual requirement for a distribution system to serve the fractional kilowatt one-phase fans and to switch them off during plant-off periods.

**Reversible heat pump cycle** This system is often used when the main plant air is distributed through a ductwork independent of the units, and sometimes with a non-air-conditioned fresh air supply. Each unit contains a reversible cycle compressor so that it can produce either cooling, or heating in a heat pump mode. The energy transfer medium to and from the units is by a circulating water system with the water temperature controlled at approximately 24°C. Each unit then extracts heat from, or supplies heat to, the circulating water, depending on whether the unit is on the heat pump or chilling cycle mode. The circulating temperature is maintained by sequencing a cooling tower heat exchanger to lower the temperature, or a non-storage calorifier to raise it. The latter may frequently be electrically fed.

Units are generally 'packaged' to include controls. The most common have a 1 kW compressor with a one-phase motor and a fan of less than 100 W; but 3 kW (one- or three-phase) units with fans of power more than 100 W are available.

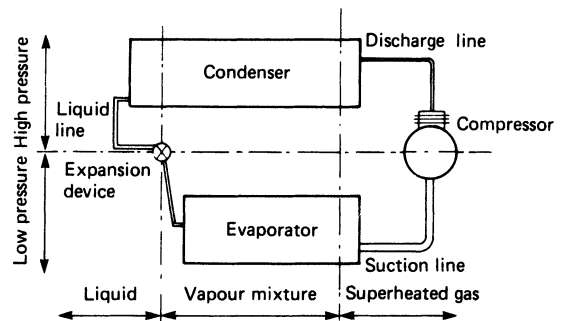

#### 22.4.6 Cooling plant

In essence, cooling plant for comfort conditioning is indicated schematically in *Figure 22.14*, which shows a single machine and tower, but multiple systems are more common. The temperature of the chilled water is controlled by  $T_{P1}$  operating the evaporator system and the heat extracted from the primary water appears in the condenser. The cooling tower dissipates this heat and returns the water to the condenser at a fixed temperature dictated by  $T_C$ , which by varying the position of valve  $V_1$  controls the amount of tower cooling.

Cooling towers are basically forced or induced draught types, the terms describing the method by which air is drawn past the sprayed water in the tower for cooling. Air-cooled condensers are also used where, in simple terms, the action of the tower is replaced by air blast cooling. Chillers can be of reciprocating, centrifugal, absorption and screw forms, all of which operate on a refrigeration cycle (*Figure 22.15*). The system circulates a refrigerant which has liquid and gas phases and a boiling point at atmospheric pressure

**Figure 22.14** Schematic diagram of a single chiller and cooling tower.  $V_{1A}$  is an alternative valve position for  $V_1$ , and  $T_P$  is an alternative to  $T_{P1}$  for specific cases only

**Figure 22.15** Scheme of a vapour-compression refrigeration cycle. (Courtesy of ASC Ltd)

well below that of water. Heat is absorbed by the gaseous and liquid mixture in the evaporator which then becomes a superheated gas; the absorbed heat is extracted from the primary chilled water circuit (*Figure 22.14*), and this is the prime function of the whole system. The gas is then passed through the compressor, which raises the gas pressure and also its boiling (or condensing) point. The condenser then extracts heat from the gas at this higher temperature and condenses it to a liquid again at a relatively high temperature and pressure; this process extracts heat from the refrigerant using the higher temperature water available in the tower circuit (*Figure 22.14*). The liquid then passes through the expansion valve which reduces both the temperature and pressure of the liquid as it expands to the gaseous and liquid mixture state for the cycle to repeat. The use of the expansion device does not alter the total heat content of the fluid.

Chillers<sup>10</sup> can be made by manufacturers operating internationally, motors may be rated (as in the USA) on a basis of 60 Hz, and may not be suitable for working on a frequency of 50 Hz. Again, 60 Hz control circuitry for one voltage may require modification for 50 Hz and a different voltage. Both input and output are expressed in kilowatts. This may cause confusion, because the output is 3–4 times the input, indicating the 'coefficient of performance' of the system.

Cooling towers have caused some outbreaks of Legionnaires' disease and there are certain situations where their use may be forbidden or restricted, particularly for hospitals and medical facilities. The alternatives, which are evaporative condensers or air blast coolers, use more energy per unit of heat rejection. Where cooling towers are properly maintained, with suitable water treatment, the risk is minimal.

#### 22.4.6.1 Chillers

**Reciprocating machines or compressors** These operate on the compression of the refrigerant in a system analogous to that of an internal combustion engine, except that the 'fuel' is contained in a closed loop and an auxiliary motor drives the pistons. Compressors have various numbers of cylinders (up to 16) and methods of control. Machines are available for inputs up to 150–220 kW, corresponding to outputs up to 500–700 kW.

**Centrifugal chillers** Centrifugal machines use a rotating impeller which performs the compression operation on the gas by centrifugal force. Figure 22.16 shows how the impeller is included in the system. One- or two-stage compression is normal. The control of output is normally by means of inlet guide vanes (not shown in the figure), which are actuated according to the load demand and alter the angle of entry of the gas into, and the performance of, the impeller.

Standard machines are available for outputs of 500–700 kW or greater, but not below 500 kW. Electric motor drives are most common and they may be hermetically sealed into the machine. The electrical rating is from 1/3 to 1/4 of the output rating and for machines above 500 kW input motors, operated economically at 3.3 kV or higher.

**Absorption machines** Absorption machines also rely on a refrigeration cycle. Analogy with other systems is best considered with the low-pressure section created by a permanently evacuated or high-vacuum system, and compression achieved by heating. The refrigerant fluid is a mixture of water and a fluid (normally lithium bromide) with an ability to absorb water. However, it is the water that acts as the refrigerant, as it will boil at low temperatures in a partial vacuum.<sup>10</sup>

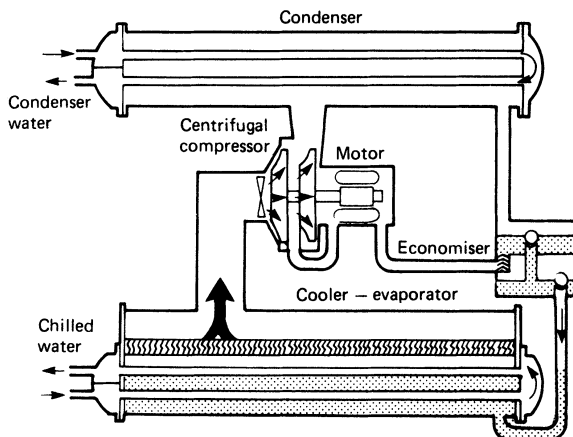

Figure 22.16 Scheme of a centrifugal chiller

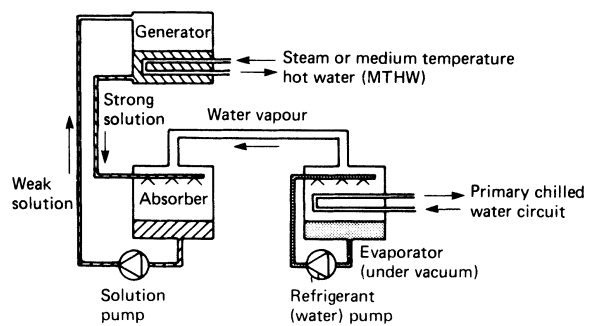

Figure 22.17 Scheme of a basic absorption cycle

Water evaporates more quickly if the surface of a given volume is extended. Rather than using a vessel with a large surface area, this is best achieved by spraying. Figure 22.17 shows how the heat from the cooling load can be picked up by the action of water boiled in vacuum, the chilled water coils being immersed in the sprayed water. Because of its affinity to lithium bromide the water vapour is carried away from the evaporator to the absorber, where it is mixed to provide a lithium bromide solution. If these were the only cycle components, once the lithium bromide had become diluted its capacity for absorbing water vapour would be reduced and an equilibrium position reached whereby no further evaporation of the water and no further useful water cooling could take place.

The weak solution from the absorber can be pumped to a generator where, with the addition of heat, the water vapour can be boiled out of the lithium bromide to produce a strong solution which is returned to the absorber. Here it is sprayed to increase the surface area and, as in the evaporator, increase the capacity to absorb the water vapour from the evaporator. This secondary cycle maintains the absorbent at an operating level, but a water supply is required to replace the water vapour evaporated from the evaporator. If the rejected water vapour from the generator were passed to a fourth vessel, a condenser as shown in Figure 22.18, the vapour at a high temperature could be condensed and returned to the evaporator to complete the cycle. In addition to eliminating the need for make-up water, the fourth vessel provides a vacuum-tight system.

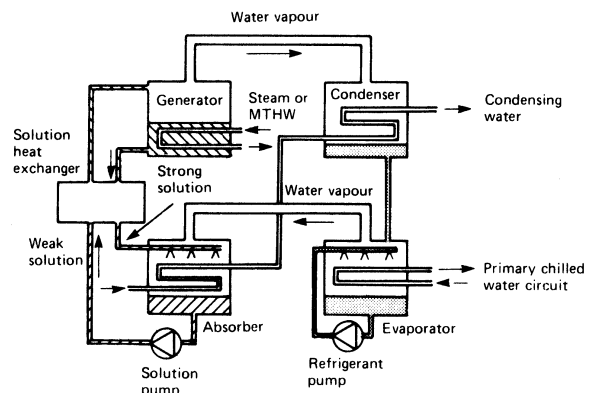

Figure 22.18 Scheme of a full absorption cycle

When the lithium bromide solution absorbs water, heat is generated: it consists of the heat of condensation of the absorbed water plus the reaction heat between the lithium bromide and water vapour. To increase the capacity of the lithium bromide to accept the water vapour, it is kept cool by passing the condenser water first through the absorber and then onto the condenser.

Because the generator is hot and the absorber cool, the cycle efficiency can be increased by a heat exchanger which heats the weak solution pumped from the absorber to the generator and cools the strong solution returning.

In the diagrams used to describe the absorption cycle the flow of water vapour is restricted between evaporator and absorber and between generator and condenser, by the size of the connecting pipes. In practice this is overcome by housing the evaporator and absorber in one shell and generator and condenser in a second. Alternatively, all can be housed in one common shell with a division plate.

The machines are made in two basic size ranges. At the lower end the most common unit is the gas fired domestic refrigerator and direct gas fired units are also made for commercial use in outputs from 10 to 100 kW. The upper range is for outputs of 350 kW and higher, although 1500 kW is generally the minimum.

Energy for heating cycles associated with absorption machines is normally back-pressure steam from a primary process at 200 kPa (2 bar) or from medium-temperature water at 120°C. The steam system makes efficient use of energy which might otherwise be wasted.

**Screw machines** These belong to a range of positive displacement compressors, claimed to have advantages over conventional compressors in terms of reduced operating noise, lower operating speed and increased thermal efficiency. The machine essentially consists of two mating helically grooved rotors, a male (lobes) and a female (gullies), in a stationary housing with suitable inlet and outlet gas ports (*Figure 22.19*). The flow of gas in the rotors is both radial and axial. Compression is obtained by direct volume reduction with pure rotary motion. For clarity, the description of the four basic compression phases is here limited to one male rotor lobe and one female rotor interlobe space.

- (1) **Suction:** as a male lobe begins to unmesh from a female interlobe space, a void is created and gas is drawn in through the inlet port. As the rotors continue to turn, the interlobe space increases and gas flows continuously into the compressor. Just prior to the point at which the interlobe space leaves the inlet port, the entire interlobe space is filled with gas.

- (2) **Transfer:** as rotation continues, the trapped gas pocket is moved circumferentially around the compressor housing at constant suction pressure.
- (3) **Compression:** further rotation starts meshing of another interlobe space at the suction end and progressively compresses the gas in the direction of the discharge port. Thus, the volume of the trapped gas within the interlobe space is decreased and the gas pressure consequently increased.
- (4) **Discharge:** at a point determined by the built-in volume ratio, the discharge port is uncovered and the compressed gas discharged by further meshing of the lobe and interlobe space. During the remeshing period of compression and discharge, a fresh charge is drawn through the inlet on the opposite side of the meshing point.

Machines are available for outputs ranging from 250 to 2000 kW with both open and hermetic motor drives. The electrical input is from 1/3 to 1/4 of the output.

#### 22.4.7 Cooling storage

Thermal storage systems have traditionally been used for the purpose of heating hot water overnight, see Section 22.4.4. The major advantage is reduced heating costs, not a reduction in overall energy consumed.

The principle has now extended to thermal storage for cooling systems where ice or low temperature phase change materials are used for the purpose, also in well insulated tanks. The charging of the stores is normally carried out at night by electrically powered chillers, although absorption chillers using gas firing or steam/high pressure hot water could be used. The system has several advantages in that smaller chillers can be selected than would be the case if they had to meet the peak daytime cooling load, the power supply system and maximum demand is therefore smaller and, again, cheap tariff electricity can be used for most of the operating load. The use of the systems also reduces the amount of chlorofluorocarbons (CFCs) or hydrochlorofluorocarbons (HCFCs) used in the air conditioning systems and can claim to be environmentally attractive.

All thermal storage systems need to be evaluated in terms of their pros and cons. The advantages mentioned above have to be carefully weighed against the costs of additional storage space, which can be large.

### 22.5 Control

The importance of controls to achieve comfort conditions has always varied according to the sophistication of the plant to which they are applied, the conditions specified and the economics of providing them. With cheap energy, simple control systems were the norm and comfort conditions were often of low priority and specified only as minimal levels. Energy is now expensive and comfort conditions are considered a more critical factor of human tolerance. Control systems are therefore commonly applied to all types of environmental system, performing the dual role of maintaining comfort conditions and conserving energy. In this combined role it is significant that for heated buildings in the UK a change of 1°C in normal space temperature will affect the energy consumption by as much as 10%.

The most common parameters considered are temperature, humidity and time. Generically, controls are either electric/electronic or pneumatic. The latter system uses

Figure 22.19 Screw-chiller operation. (Courtesy of ASHRAE)

clean dry compressed air as the motive power and is rarely independent of electric/electronic elements, whereas the former system uses electric motive power alone. Pneumatic systems tend to be used where there are many terminal controls, normally on air conditioned systems. Electric/electronic systems are now competitive with pneumatic terminal controls and it is rare to find new commercial buildings with pneumatic control systems. The systems described below are based on non-pneumatic systems. Where run and standby air compressors are supplied for pneumatic control systems, the electrical supply must be capable of starting and running both compressors together.

### 22.5.1 Controllers

Intrinsically, controllers operate in a two-position or a modulating mode. The former is recognised by on/off thermostats operating a device such as a fan or two-position control valve; the latter is a combination of detector and controller which can vary the position of the control valve over its full range of travel. The type of controller is selected according to the application.

#### 22.5.1.1 Boilers and chillers

The controls for heating and cooling sources are normally supplied as part of the equipment. When multiple sources are used and sequential control is required to achieve a constant heating or cooling flow temperature, the electrical interlocking requirements are significant. *Figure 22.20* shows an arrangement for boilers in parallel. The interlocking necessary to achieve a constant flow temperature, for sequential operation which matches the load requirements, permits any source to lead the sequence, and various standard safety features need to be included. The control interlocks are extremely complicated when using relays and timers, etc., but modern usage normally adopts a software-driven solution which drastically reduces the hardware content of the interlocking package.

#### 22.5.1.2 Heating systems

The control of heating covers the majority of systems in the UK. There are two elements to be considered: central plant control and terminal control. Apart from controlling the flow temperature from the boiler(s), central plant control for radiator and convector systems (the greatest number of heating systems) is carried out mainly by weather compensators. *Figure 22.21* illustrates such a system where the temperature to the load is controlled in accordance with external temperature. In cold weather water is supplied to

**Figure 22.20** Flow-controlled multiple modulating boilers in parallel. Sequential control is from the detector in mixed flow-constant volume through boilers. The system controls any three of four sources.

**Figure 22.21** Basic scheme of a weather compensated system

the load at the boiler flow temperature, i.e. with valve V closed to the bypass and the setting of  $T_i$  corresponding to the boiler control temperature. As the outside temperature rises, a signal from  $T_e$ , passed via the controller, resets  $T_i$  downwards.  $T_i$  controls the position of the motorised valve V to mix water from boiler with water from the bypass (which is the return from the load and at a lower temperature than the boiler flow), to correct the temperature. As the temperature  $T_i$  decreases, the output from the terminals is reduced and may be matched to the load by selection of the temperature characteristic. *Figure 22.22*, curve 1, illustrates a typical characteristic.

The actual characteristic varies according to the system design parameters and to heat losses from the building, and may be varied in a number of ways. The characteristic may be generated and adjusted from point A (curve 2) or point B (curve 3) or points A and B (curve 4). A–C represents the limit condition which is governed by the boiler temperature, and may also be used for warm-up situations during which the compensator system is overridden.

A single compensator is incapable of dealing with varying internal loads or solar gain, and additional controls are employed for this purpose. These may be zonal controls, where an additional thermostat and control valve acts as a local trimming device to detect local gains, or terminal controls on each emitter. The latter permits individual temperature control of each space and might appear to make the compensator redundant. However, the compensator

**Figure 22.22** Typical compensator characteristics

**Figure 22.23** Proportional band effect on control setting. The temperature is shown for a set point of 20°C with a proportional band of 2°C

still provides two advantages: heat loss from the distribution mains is reduced as the outside temperature rises, and the reduced circulating temperature prevents individuals from calling for excessive temperatures in mild weather.

The most common terminal control for these systems are thermostatic radiator valves (TRVs), which are self-acting devices requiring no external supply. TRVs have one characteristic which is common to many control systems: they are proportional controllers. This means that they provide their set temperature only at one position of the valve, normally the mid-position as indicated in *Figure 22.23*. A specific change in temperature from this setting is required for the valve to take up any new position, which means that the valve moves from fully open to fully closed over a range of space temperature and that a particular valve position is related to a specific temperature. The sustained deviation from the set point which this describes is known as 'offset'. The range of temperature over which the valve performs its full travel is the 'proportional band' and TRVs have a fixed band which varies according to source and type. Typically the band is 2–3°C: thus, if the setting is 20°C, the space temperature rises to 21°C with the valve fully open and drops to 19°C with it fully closed (a 2°C band). This characteristic is useful in energy conservation terms, as it

decreases the internal temperature at times of greatest load, thus reducing energy consumption, always assuming that the 19°C used in the example is acceptable to the occupants.

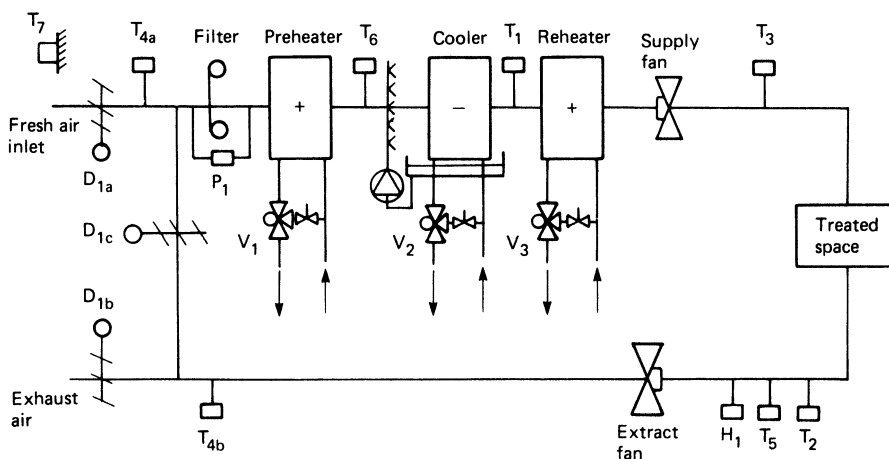

Controls for domestic heating systems<sup>11</sup> would not normally include a compensator, and TRVs or room thermostats controlling small motorised valves are more common. The use of a single room thermostat starting and stopping the complete system is common, but should be upgraded for both energy conservation and comfort. Warm air systems may be controlled by thermostatically controlled motorised dampers interlocked with the plant heat exchanger and fan.

### 22.5.1.3 Air-conditioning systems

Air-conditioning system controls are similar to those for heating in respect of the final emitters, i.e. a temperature detector-cum-controller, often proportional in character, which modulates either a control valve or a damper (or both in sequence) to maintain the required temperature. If the terminals depend on the sequential operation of heating and cooling, it is again possible to use the width of the proportional band to provide both comfort and energy conservation. The control may be adjusted to provide heating from 19 to 21°C and cooling from 22 to 24°C, with a dead zone between 21 and 22°C with neither heating nor cooling action.

The control of conditions in the main air-handling plant is a vital element for the overall space environment and is probably the most complex requirement in the heating, ventilating and air conditioning (HVAC) field. The aim is to achieve a stable dewpoint (fully saturated air) condition, which defines the amount of moisture in the conditioned air. The relation between dry bulb temperature, wet bulb temperature, humidity and total heat (enthalpy) is fully defined in psychrometric charts. Attainment of a particular dewpoint condition is sufficient to provide a specified set of relative humidity conditions in a space, taking into account the moisture pick-up (latent gain) from the occupants. *Figure 22.24* illustrates a typical dewpoint plant which contains basic controls and the necessary override and safety features. The details are related to the systems described in Section 22.4.5.

The dewpoint is controlled by  $T_1$ , which sequentially modulates a preheater battery control valve  $V_1$ , dampers  $D_{1a}$ ,  $D_{1b}$  and  $D_{1c}$ , which operate in parallel, and a cooler

**Figure 22.24** Scheme of the dewpoint.  $T_1$ , dewpoint detector;  $T_2$ , return-air-temperature detector;  $T_3$ , low-limit detector;  $T_4$ , enthalpy detectors/comparators;  $T_5$ , boost-limit thermostat;  $T_6$ , frost-protection thermostat;  $T_7$  free cooling enthalpy detector;  $H_1$ , return-air-humidity detector;  $P_1$ , differential pressure switch;  $V_1$ , preheater valve;  $V_2$ , cooler valve;  $V_3$ , reheater valve

battery valve  $V_2$  to maintain a constant saturated temperature condition. The reheater, which is part of many systems, is controlled by the extract temperature detector  $T_2$ , modulating the control valve  $V_3$  to maintain a constant space temperature. The low-limit detector  $T_3$  is sometimes employed in the discharge duct to override  $T_2$  and maintain the discharge temperature above a predetermined limit.

The modulation of the dampers is the 'free cooling mode', using air for cooling prior to the use of mechanical cooling. Conditions can occur where the dampers need to be overridden. When the external temperature rises above the return air temperature (or, more precisely, when the enthalpy, or total heat, of the outside air exceeds that of the return air), it is more economic to cool return air than outside air. A detection device is therefore required to measure the total heat. The enthalpy of the outside air can be measured directly ( $T_{4a}$ ) as being above the design room value, or by dual detectors ( $T_{4a}/T_{4b}$ ) which compare the room and outside air total heat conditions. In either case, when the room total heat is exceeded by the outside air, a signal from the device drives the dampers to the minimum fresh air position, determined by the amount of air necessary to satisfy the fresh air ventilation requirements, which may be a statutory design parameter.

At night or during other shut-down periods the dampers are normally driven to the zero fresh air position. They remain in this position after plant start-up until the space temperature reaches a predetermined level as detected by  $T_5$ . During this boost period all the air is recirculated, valves  $V_1$  and  $V_3$  are fully open and the spray coil is de-energised. Thermostat  $T_6$  protects the plant in cold weather conditions. If for any reason the temperature of the preheater drops to approximately  $2^\circ\text{C}$ ,  $T_6$  operates to shut down the plant and give an alarm.

It is also possible to satisfy the dewpoint condition without mechanical cooling, whenever the enthalpy of the external air is below that approximating to the dewpoint condition. This is accomplished by detector  $T_7$ , which holds off the chiller and cooling-tower plants whenever the enthalpy is below the predetermined level.

In rare cases a humidity detector ( $H_1$ ) mounted in the extract duct from the conditioned space is provided to monitor excessive or reduced latent gains in the space. It then resets the dewpoint detector ( $T_1$ ) to compensate.

A differential pressure detector ( $P_1$ ) fitted across the plant filter is a standard control item to provide a warning of high pressure across the filter for both maintenance and energy conservation purposes.

Some interlocking features are desirable on all dewpoint plants. One is associated with fire defence. It is becoming standard practice, sometimes mandatory, to ensure in the event of smoke or fire that the plant shuts down and that firemen can start the extract fan independently of the supply fan, with the dampers run out of sequence. A frequent associated requirement is for recirculation dampers to be fully closed to facilitate smoke exhaust. The basic dewpoint control, and the various additional functions described, illustrate the possible complexity of the interlocking diagrams, which parallel those of the multiple boiler systems described previously. The sustained offset with proportional controllers makes them unsuitable for this application because the dewpoint temperature control is often critical for the comfort conditions required. Thus, floating or two-term controllers are used which do not suffer from offset.

In energy conservation terms, systems which treat all the air and bring it to a dewpoint condition are inefficient. Alternatives are frequently used, where the cooling and heating coils may be controlled in sequence from the detector

in the return air duct, and humidity control is only employed at the upper and lower limits of the specified conditions, by using the latent cooling capacity of the cooling coil, or injecting moisture, respectively.

## 22.5.2 Time controls

The use of time switches is generally accepted. On large plants optimum start controls are becoming commonplace. The principle of operation of optimisers is to compare the external conditions with a representative internal condition so that the plant switch-on time is varied to achieve the required internal comfort conditions only at the time of occupation. In contrast, time switches are set to ensure that the conditions can be achieved on the coldest day, which means that in milder weather the building reaches comfort conditions earlier than necessary. Optimisers are therefore used for energy conservation, and can save 7–10% of the energy used with time switch control. The operation is shown graphically in Figure 22.25. As in Figure 22.13, BC represents the period of occupation and CA the temperature drop for the design coldest day. As the external conditions improve, the decay curve moves to  $CA_1$ ,  $CA_2$ , etc., and the switch-on time is calculated by the optimiser and is delayed, moving from S to  $S_2$ , etc. A conventional time switch operating at S when the decay curve is  $CA_2$  would waste energy equivalent to area  $XYA_2BX$ . Optimised stop facilities are also available.

## 22.5.3 Building management systems

Control systems for building services have moved steadily from stand-alone control loops towards arrangements where a high degree of central supervision is provided—largely automatic, with manual override applied for specific circumstances. There has been a progression from electro-mechanical supervisory data centres, through electronic building automation systems to the current energy management (EMS) and building management (BMS) systems which depend on microprocessor/software technology. Energy management is just one, albeit important, of the facilities offered by a BMS, which acts as the controller,

Figure 22.25 Optimised start of heating plant

monitor and fault locator for all aspects of the built environment and can provide a wide range of other management functions.

The latest generation of microprocessor-based systems are now used to replace the traditional stand-alone controllers used in control loops and the means of control has passed from analogue to direct digital control (DDC). On any but the smallest BMS (which can be a single programmable controller with a number of analogue and digital inputs and outputs), the equipment configuration will be similar to that shown in the block diagram of *Figure 22.26*. The data-gathering panels (DGP) in modern systems will be microprocessor based and incorporate levels of software which make them largely independent of the central processor. The main criteria and possible uses are listed briefly below.

*Data transmission* This may be multiplexed multicore distribution, single or two wire trunks for pulse coded messages, or a fibre optic system. Where remote buildings are coupled to one system British Telecom or Mercury lines may be used for transmission.

*Scanning* Typically scan times are between 2 and 30 s, although the point-to-point scan may be much faster. Multiple scan times can be employed, one for analogue signals and others for high- and low-priority alarms.

*Hardware and peripherals* These include the following:

- (1) data inputs from two-position and analogue devices, and data outputs for control switching and set-point adjustment;
- (2) outstations, which may be relatively simple data processors or intelligent systems, with stand-alone capability;

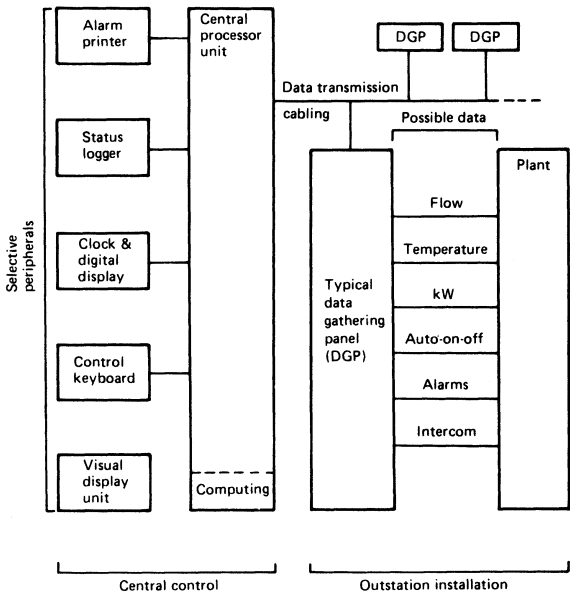

- (3) intercom, which may be a feature additional to the transmission system;
- (4) central processor, which contains the memory for automation and alarm functions, often with a back-up power supply;
- (5) operator's keyboard and display unit;
- (6) printer(s) for common or separate logs and alarms;
- (7) visual display units in monochrome or colour;
- (8) permanent displays such as annunciator panels or mimic diagrams.

*Software* This covers the following:

- (1) alarm priorities;
- (2) alarm inhibiting;
- (3) analogue alarms;
- (4) integration, e.g. energy consumption;
- (5) totalisation, e.g. summation of motor run times, etc;
- (6) time switch, including optimised start;
- (7) event initiated sequences, e.g. an alarm which initiates a specific sequence of operations;
- (8) load shedding and lighting control;
- (9) restart after power failure: prevents electrical overload on restart;
- (10) process control, e.g. the use of the centralised system as the controller for individual loops (DDC);
- (11) optimum damper control (see Section 22.5.1.3);
- (12) security, e.g. patrol tours and card entry;
- (13) interlocking, e.g. the use of software in place of conventional relays, timers, etc;
- (14) fire, i.e. alarms and specific event initiated sequences;
- (15) programmed maintenance, i.e. the use of stored data to produce a work schedule for maintenance and service;
- (16) facilities management.

An example in block form of a building automation system is shown in *Figure 22.26*.

*Economics* The cost evaluation for a proposed scheme should include consideration of the following:

**Figure 22.26** Block diagram of a typical building automation system. DGPs will normally include their own software capability for control functions. The central processor unit may range from a main frame machine to a microprocessor unit

Savings	Expenditure
Reduction of energy	Capital cost of system
Reduction in maintenance staff	Interest on capital cost
Increased plant life with programmed maintenance	Additional specialist staff
Use of software for interlocking in place of relays, timers, etc.	Maintenance of the automation system
Avoidance of duplicate systems (e.g. fire and security central consoles)	Preparation of detailed programmed maintenance format
	Collection of data and producing particular software

## 22.6 Energy conservation

The subject of energy conservation and the efficient use of energy is of interest in all branches of engineering design. The provision of satisfactory environmental conditions consumes such a large fraction of the national energy budget that energy conservation cannot be divorced from comfort. The means of reducing energy consumption range from using less energy by more effective building design and more efficient HVAC systems, to lowering comfort standards and

reclaiming energy that would otherwise go to waste. Lowering comfort standards is a difficult objective to promote. Heat reclaim methods are numerous and in many cases are applicable also to industrial processes, and they often improve the efficiency of existing systems.

There is also the problem of effective maintenance and servicing of existing installations, which can contribute to both energy conservation and satisfactory environmental comfort standards.

### 22.6.1 Systems

The importance of heat reclaim systems has always been recognised but in practice their application has been very restricted until recently. Because a heat recovery system is frequently part of a sophisticated installation, it should be integrated into the more comprehensive requirements of the design philosophy. Some of the more common systems are described below.

**Thermal wheel** These are rotating air-to-air heat transfer devices between two separate air streams in parallel and adjoining ductwork. The speed of rotation will not normally exceed 20 rev/min and the heat recovered decreases with speed. The control of energy transfer is effected by varying the speed or the exhaust air quantity passing through the wheel. Normally, only sensible heat is recovered, but versions exist which reclaim latent heat as well. A standard arrangement is shown in Figure 22.27. The temperature of the air supplied to the space (or other elements of the plant) is controlled by varying the speed of the drive motor. Control can also be achieved by bypass dampers to reduce the air passing through the exhaust air section. It is necessary to check that the energy saved by heat transfer is not exceeded by the additional fan power required.

**Liquid coupled indirect heat exchanger (run-round coil)** This system is simple. The general arrangements are shown in Figure 22.28. The pump may be controlled by an externally mounted thermostat  $T_1$ , which runs the pump whenever the external temperature is below the design exhaust air temperature. Alternatively, a more sophisticated arrangement would be to use a differential thermostat  $T_{2E}$ ,  $T_{2S}$  which runs the pump only when the temperature of the exhaust air is higher than that of the supply air. The capital cost of the plant and the additional pump and fan horsepower must be equated to the energy saved before such a system is adopted.

Figure 22.27 Variable speed control of thermal wheel

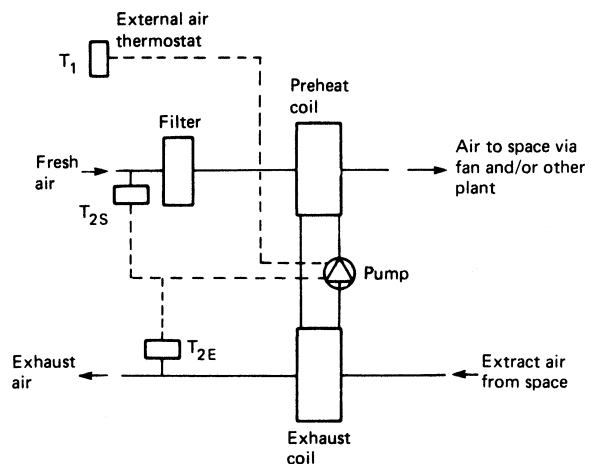

Figure 22.28 Scheme of a heat-reclaim run-round coil.  $T_1$ ,  $T_{2S}$  and  $T_{2E}$  are detectors for different methods of control

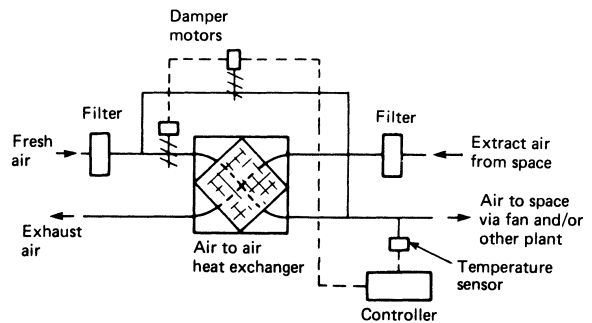

Figure 22.29 Scheme of heat reclaim by an air-to-air heat exchanger

**Cross-flow stationary recuperator (air-to-air heat exchanger)** This device is an alternative to the thermal wheel but will provide only sensible heat transfer. The general arrangement is shown in Figure 22.29. The control system is similar to the bypass damper arrangement described for the thermal wheel.

**Heat pump** The use of heat pumps in HVAC systems is increasing. The most common form incorporates a refrigerant compressor unit with evaporator and condenser where the functions of the latter two elements may be reversed to give heating or cooling cycles as required. This arrangement is shown in Figure 22.30, where the heating cycle mode illustrates the generic definition of a heat pump system. This type of unit is described in Section 22.4.5.

Heat pumps are frequently used purely for heating, but whether in this mode or as reversible units, they are available with air-to-air, water-to-water and air-to-water heat transfer. The selection of refrigerant is important to ensure that maximum efficiency is achieved for the specified range of inlet and outlet temperatures.

In some heating applications, particularly where heat is being extracted from outside air, the external coil (acting as the evaporator) will tend to ice up and a defrost control system must be used. This requires an arrangement for

**Figure 22.30** Reversible cycle units. (a) Heating cycle (heat pump); (b) Cooling cycle (chiller)

allowing hot gas to be passed through the coil for a short period, or the use of separate electric heaters.

**Heat pipe** This simple device is becoming an accepted heat reclaim component; it contains no moving parts and can be fitted in a manner analogous to a thermal wheel. Essentially, it consists of a sealed and evacuated tube containing a refrigerant, e.g. Freon, and lined with a wick. The action is shown in *Figure 22.31*: (a) shows that the application of heat vaporises the liquid refrigerant, which is then cooled at the top of the tube (giving up its latent heat), absorbed in the wick and returned to the bottom of the tube. This system is utilised in heat reclaim as in (b), where banks of tubes replace the thermal wheel in *Figure 22.27*.

**Figure 22.31** Heat pipes for heat reclaim

**Double-bundle condenser** One common method of heat reclaim normally considered in all air conditioning systems is the double-bundle condenser. *Figure 22.14* shows the conventional condenser, but it is obviously advantageous to use the rejected heat rather than discard it in the cooling tower. The arrangement is shown schematically in *Figure 22.32*, where one tube bundle is used for the tower heat rejection circuit and the other for heat reclaim to the heating systems in the building. The system is controlled in sequence so that the tower circuit is brought into use only when there is no requirement for reclaimed heat. Temperatures of 45°C can be attained from the reclaim circuit without difficulty.

## 22.7 Interfaces and associated data

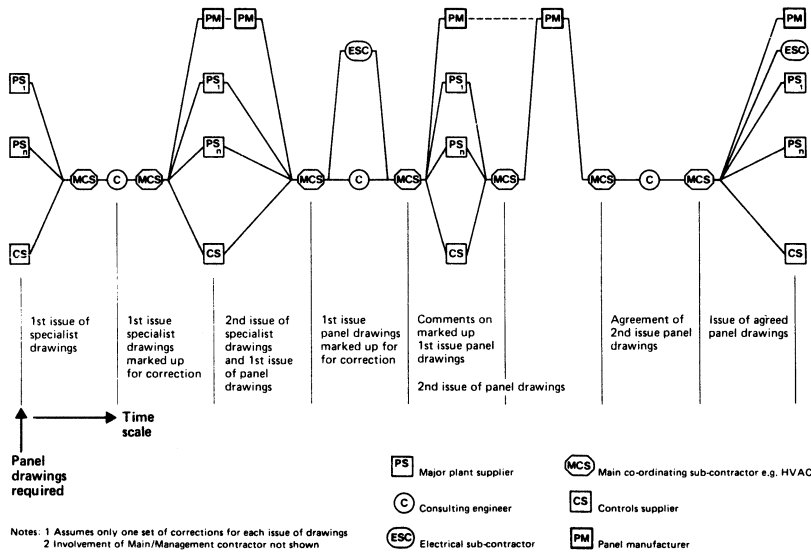

Modern buildings continue to become more complex and sophisticated, a fact which is generally accepted. Whether all the complexities are necessary is discussable, but not relevant here. What does need clarification is the treatment of the various interfaces which occur between all the parties involved in the building process starting with the developers/designers and ending with the tenants. If these interfaces are not clearly identified and treated, the environment and its control in the final building will be unsatisfactory and inefficient.

The first stage in this process is recognition that all the design disciplines should be involved with the client from

**Figure 22.32** Basic scheme of a double-bundle condenser for heat reclaim

# BASIC CONTROL PANEL WIRING DIAGRAM PROGRAMME

## BASIC SITE CO-ORDINATION FOR CONTROLS AND T&C

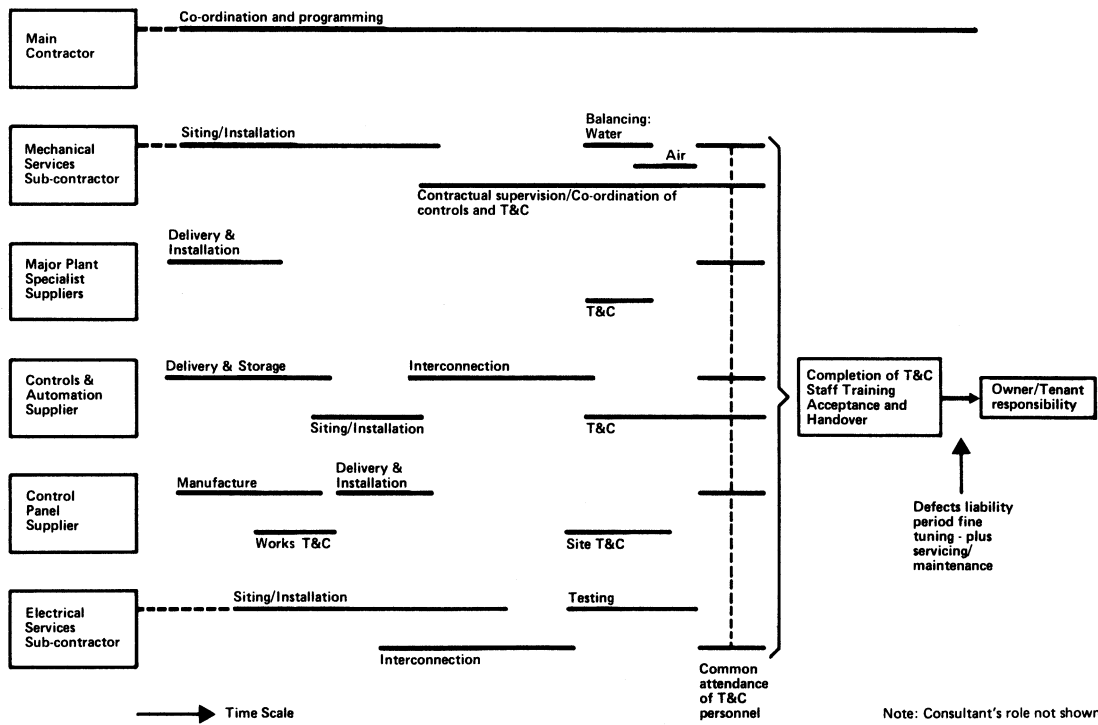

Figure 22.33 Examples of interfaces and co-ordination

the concept stage onwards. Very frequently architects are the only discipline initially involved, followed by the structural engineers and then the mechanical and electrical (building services) engineers. The ultimate tenants and their requirements are all too rarely involved until after the design is completed. With the complexity of modern buildings, the increasing pressures of environmental issues and the multiplicity of interfaces, it is essential that design teams are multidisciplinary in nature (with builder and tenant involvement if possible) from the very inception of the project. Just two examples of how these interfaces affect the way environmental control is achieved are shown in *Figure 22.33*. The first shows the quickest route to obtain approved control panel diagrams and at best it takes many weeks. The second shows how the setting up and commissioning of the environmental controls and automation systems has to be planned.

The interface requirements of the systems shown in *Figure 22.33* refer to well-defined elements in the environmental-control process. When the considerations have to include the more subjective environmental control issues of the greenhouse effect, ozone depletion by chlorofluorocarbons (CFCs), internally/externally created pollutants and the physiological and psychological reactions of occupants to their working environment, the interface problems can be overwhelming. Only a co-ordinated approach by all concerned can achieve the necessary environmental control.

### 22.7.1 Electrical loads

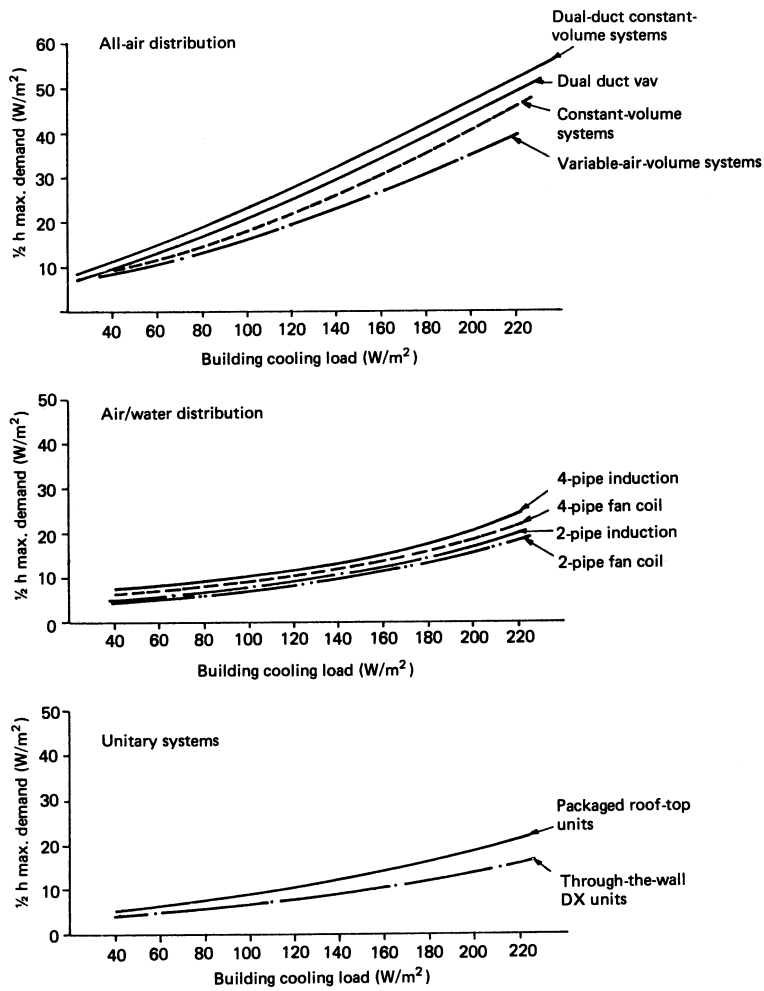

Environmental control and issues are often inextricably related to energy and its effective use. Mechanical and electrical engineers working on the building services of buildings, often worth half the total cost of the building, have an extremely important role in minimising energy consumption. At one level they need to work with the architect to ensure an efficient fabric design and at the other they need to define electrical loads at the concept stage so that transformers and switchgear can be sized and suitable space provisions made.

Electrical-load figures are supplied in many forms, and at the concept stage in the design process considerable expertise is required to correctly assess suitable figures which will

generally withstand the various changes during the design process. This has to be borne in mind when considering *Figures 22.34* and *22.35*. The curves in *Figure 22.34* represent typical maximum demands for fans and pumps for different types of air-conditioning system, while those in *Figure 22.35* indicate maximum demands for different types of chiller. Lighting load data are voluminous and are best obtained from CIBSE Lighting Division publications, or manufacturers.

## 23.1 Introduction

Electromagnetic Compatibility (EMC) has now become a major consideration on any project involving the design, construction, manufacture and installation of electrical and electronic equipment and systems. Electrical equipment must be designed not only to meet a functional technical performance specification but due consideration must also be given to the interaction the equipment has with the electromagnetic environment in its intended operating location. If the equipment is expected to operate reliably in a steel works, for example, it is imperative that the designers, purchasers, installers and operators are aware of the nature of the electromagnetic environment and the potential for unwanted coupling to the equipment which could cause equipment mis-operation or malfunction. For example, for safety-related equipment, any interference to the operation of the system could have serious consequences. Equally, electromagnetic disturbance generated by the equipment itself could cause interference to radio reception. In the case of domestic radio and TV reception this may adversely affect the quality of reception, but can also block emergency channels and in some cases, e.g. a radio controlled crane, could cause malfunction with potential reliability and safety implications. Generally, both aspects of controlling emissions from the equipment and providing adequate immunity to the expected electromagnetic disturbances in the intended operating environment are key features of any equipment or system design.

The need for emission control has been recognised for many years and most countries have introduced legal regulations to support the efficient utilisation of the electromagnetic spectrum. This is manifest in the form of requirements to comply with EMC emission standards in product certification. In some territories such as Europe and Australia, the legal requirements also address immunity aspects. For most manufacturers of good quality equipment this is not an added burden because they are keen to demonstrate to their customers that the equipment will prove to be reliable in the field, and moreover, recognise that any actual incidents of malfunction could be damaging and costly to the business.

Fortunately there are advantages for both equipment suppliers, purchasers and operators in the availability of nationally or internationally approved high quality EMC standards for both emissions and immunity which can be referenced in contractual agreements as well as providing an excellent foundation for the designers of the equipment. Manufacturers and users alike can apply these standards to their mutual advantage, particularly in the planning of major projects.

EMC considerations need to be addressed at the outset of the development. It is well known that the costs of achieving EMC conformity rise almost exponentially with the delay in first considering the requirements. The key issue in addressing EMC matters is to adopt a strategic approach where the EMC requirements are recognised and clearly understood at the design concept stage, through the product development to in service use, and throughout the lifetime of the equipment.

## 23.2 Common terms

There are a number of common terms used in the science of EMC. EMC itself can be defined as the ability of equipment to operate satisfactorily within its intended electromagnetic

environment without contributing to the disturbance level in that environment such that radio communication is not adversely affected. Other related terms are RFI and EMI: RFI is radio frequency interference, which is usually defined as interference to radio services in the radio bands, 9 kHz to 300 GHz; EMI, electromagnetic interference, is generally accepted as interference both in the radio frequency bands and in the low frequency region d.c. to 9 kHz.

Because of the large ranges of values that are dealt with in EMC it is customary to express emission limits and system performance in logarithmic ratios, i.e. in dBs. For a voltage or current value, the value in dBs is given by  $20 \cdot \log_{10}(\text{ratio})$  and for power ratios,  $10 \cdot \log_{10}(\text{ratio})$ . It is important to recognise that 1 dB in voltage is equivalent to 1 dB in power, although the linear ratios are different, 1.12 and 1.26 respectively.

Electric and plane wave fields are expressed in Volts/metre or dB( $\mu\text{V}/\text{m}$ ) and magnetic fields are expressed in Amps/metre or dB( $\mu\text{A}/\text{m}$ ). (1 Amp/metre is equivalent to 1.25 micro Tesla of magnetic induction in free space.)

## 23.3 The EMC model

An example of electromagnetic coupling between two items of electrical equipment is illustrated in *Figure 23.1*. Electrical disturbances generated by equipment #1 may be coupled to equipment #2 by a variety of means: conduction via a common connection to the mains supply, inductive and capacitive coupling between interface and power conductors, and by direct radiation. Conducted coupling tends to be the dominant coupling mechanism at lower frequencies e.g. below 1 MHz, where conductor impedances are low; capacitive and inductive coupling is more important at higher frequencies where the capacitive impedance between long parallel runs of conductors is relatively low. Radiation coupling dominates at frequencies where the length of the radiating conductor is comparable with a wavelength. For a small computer system, radiation from cables will be prominent in the range 30–300 MHz but at higher frequencies, direct radiation from circuit board tracks dominates. Due consideration must be given to these effects in designing and installing equipment and systems.

There are many types of coupling that may occur in any particular application and the key factor for the designer is to recognise and understand the various mechanisms. The simple but effective model source-path-receptor model shown can be applied effectively in dealing with overall requirements (*Figure 23.2*).

For the equipment designer, his product must be considered both as a source of disturbance and as a potential receptor to disturbances in the intended environment. Emission control is achieved by recognising the potential sources of disturbance within the equipment and the paths by which they may couple to the outside world and cause interference in radio communications. Examples of significant sources of internally generated electromagnetic disturbance are given in *Table 23.1*.

Emission control is achieved by effective design, filtering and suppression measures. The level of control that is normally required is that sufficient for interference free reception of radio communication and radio and TV broadcast services.

But the designer of electronic equipment must also consider his product as a receptor of electromagnetic disturbance in the intended operating environment. For the equipment to work reliably in the field the designer

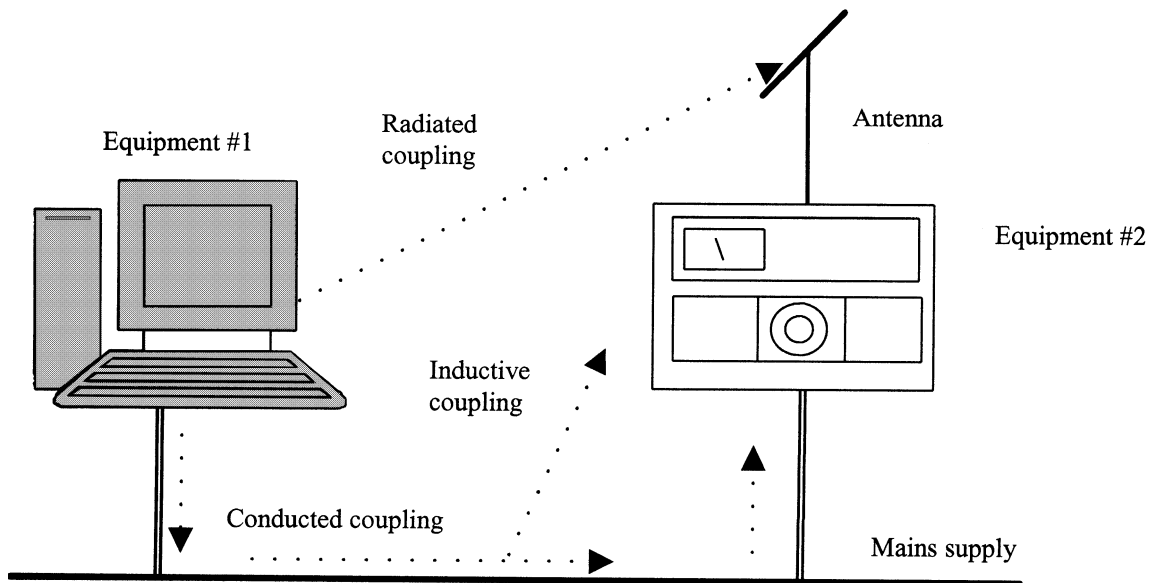

Figure 23.1 Example of electromagnetic coupling between two items of equipment

Figure 23.2 Source-Path-Receptor model

must consider the types and nature of electromagnetic disturbances which are likely to be present, their magnitude, and even their probability of occurrence if it is a safety related system. Generally there are two categories, man made and naturally occurring, as shown in *Tables 23.2 and 23.3*.

For radio transmitters and overhead power lines, the level experienced by the receptor circuit will depend on the separation distance from the source. Some VHF and UHF rf transmitters are designed so that the field strength at ground level does not exceed 1 Volt/metre but mobile and portable transmitters such as mobile phones can generate field levels of up to 100 Volt/metre close to the antenna. In cases where the equipment is intended to be operated close to one of these sources, compliance with commercial EMC standards may be insufficient and additional measures may be required, either in the equipment design or the installation, to ensure that the equipment will operate reliably in practice.

The electrostatic discharge is a high voltage disturbance, typically 8 kV, with a very short rise time, about 1 nanosecond, and generates high level spectral components extending to high frequencies and careful equipment design is often required to provide adequate protection. The residual effects of a lightning event are high voltage surges of about 2 kV but with longer durations and much greater energy.

The degree to which electronic equipment may be affected by the electromagnetic disturbances in the environ-

ment depends on many factors but is primarily dependent on: a) the coupling between the equipment, b) the magnitude of the external source, and c) the sensitivity of the internal electronics. In broad terms, any semi-conductor device in the equipment must be considered as a potential receptor.

Most digital electronic devices generally require a signal of at least 0.5 Volt to change state and for protection against ESD with a peak amplitude of 5 kV, the designer must provide a circuit isolation in excess of 10 000 to one or 80 dB. The first 60 dB may be relatively easy to achieve through natural circuit losses but the next 20 dB will inevitably require careful design. Analogue semiconductor devices have higher sensitivities with devices in the control application requiring only millivolts of disturbance to cause interference. Here the main concern is the continuously applied or long duration disturbance such as from radio transmitters. An applied field of 3 Volt/metre could induce a voltage of 3 Volts into a conductor connected to a remote analogue sensor causing an rf current of up to 10 mA to flow in the wiring. To reduce this level of disturbance to acceptable proportions high degrees of isolation, possibly in the order of 60–70 dB are required. Most of the coupling at high frequencies is in common mode and there will be an inefficient coupling to a differential voltage that could be confused with the wanted signal, but inevitably some form of circuit protection, often in the form of filtering will be required.

## 23.4 EMC requirements

The overriding requirement in the supply of equipment to the customer, or in placing the equipment on the market, is to meet the accepted or agreed conformity assessment requirements. For supply of defence equipment for example, the manufacturer will be required to demonstrate that the equipment complies with the EMC specification for the project, such as DEF STAN 59-41 in the UK. The manufacturer ensures that the equipment is tested to the standard and submits the test report to the project office for approval. In the case of equipment for residential, commer-

cial or industrial application, emission control regulations apply in most territories, and compliance with a relevant EMC standard must be demonstrated. In Europe, Member States have transposed the provisions of the EMC Directive 89/336/EEC into their own legislation. For the vast majority of equipment types, the manufacturer can apply a relevant standard, which is one harmonised by the Member States and published in the *Official Journal* of the EC, and make a self declaration of conformity also applying the CE Mark. It should be noted that the CE Mark denotes compliance with all applicable directives which are likely to include at least the Low Voltage Directive in addition to the EMC Directive. Market entry and free circulation of the equipment within the EC is then permitted.

The relevant EMC standards are of three types, high frequency emissions standards for the protection of the radio spectrum, low frequency emissions standards for the protection of the power distribution network, and immunity standards for demonstrating the equipment's robustness in the presence of electromagnetic disturbances. Typical emission limits, in this case for Information Technology Equipment are presented in *Figure 23.3(a)* and *(b)*.

Limits for equipment intended for residential application are generally more severe by 10 dB because of the shorter separation distances and tighter coupling that can occur in domestic premises.

Standards are available for the protection of the power distribution network. Mains harmonics such as generated by high power semiconductor switching devices can cause problems in the supply of electricity for which limits apply for the frequency range 0–2 kHz. Voltage fluctuations due to switching of heavy loads, which can cause lighting flicker is another low frequency phenomenon for which relevant standards exist. For example, equipment containing switch mode power supplies or switching heating loads as in air handling units will be subject to the standards listed in *Table 23.4*.

The European immunity requirements are primarily based on international IEC standards. Both product specific, and generic standards (to be applied where no product standard exists), are based on a raft of basic standards addressing fundamental EMC phenomena. These are listed in *Table 23.5* together with typical levels for a commercial or light industrial application.

The descriptions for these two environments may be insufficient in some applications. For example if the equipment is to be installed in an airfield environment, immunity may be required against radar transmitter fields of up to 100 V/m and these requirements would need to be incorporated in the technical specification for the project.

23.5 Product design

In designing equipment for EMC conformity it is important to identify the primary paths whereby electromagnetic energy may be transferred. These are conduction and induction via the power lead and interface cables, radiation from the PCB circuit tracks and radiation leakage through apertures and discontinuities in any shielded enclosure. The aim of designing for EMC conformity is to provide sufficient attenuation in each of the relevant paths such that emission control and provision of adequate immunity is achieved at an economic cost to the product. For many protection measures e.g. shielding and filtering there is reciprocity between measures for emission control and for immunity, although the required degree of attenuation in a particular path may be different. Experience with previous generations of similar products and some exploratory work in determining the immunity margins by testing to the level of equipment misoperation, can provide valuable information as what is the more critical, aspect emissions or immunity. Further development work can then concentrate on testing to only the critical EMC phenomenon.

For equipment contained in metal enclosures which can provide a reasonable degree of shielding, there are a number of important considerations. As shown in *Figure 23.4*, the barrier for the power cable is a filter mounted at the point of entry for the cable.

Similarly, unshielded signals lines to inputs and outputs entering the enclosure should also be filtered at the point of entry. Where screened cables are employed, usually for the protection of sensitive circuits, or for emission control for high frequency signals, the cable screen should be regarded as an extension of the shield of the enclosure.

Where metal enclosures are not employed, the transfer of high frequency electromagnetic energy must be controlled by good design at the circuit board level. The use of multi-layer PCBs offers such a facility but sometimes there appears to be a cost penalty associated with the more complex structure and fabrication. These costs should be compared with the costs of retrospective remedial measures

should the equipment fail to comply with radiated emission and radiated immunity requirements. Generally, most designers accept that the multi-layer board provides a good margin of compliance if properly configured and is the preferred option.

23.6 Device selection

The selection of the type of semiconductor device or integrated circuit technology can have an effect on overall EMC performance. Although the trend is for faster devices for higher processing speeds, emission control is easier with slower devices. *Figure 23.5* shows the waveform of a digital signal and its associated spectrum. The spectrum starts to decay at 20 dB/decade at just below  $1/(\pi\tau_r f)$  where  $1/T$  is the repetition rate, but decays even faster at frequencies above  $1/(\pi\tau_r f)$  where  $\tau_r$  is the rise-time. Lower clock rates and longer rise times thus reduce high frequency emissions.

For improved immunity, circuit bandwidth is important, the narrower the bandwidth, the lower the energy from impulsive disturbance and there is a greater probability of discriminating against high frequency single frequency disturbances. Although device selection may not be a prime consideration in designing for EMC conformity because of performance constraints, knowledge on the basic principles can be extremely valuable.

23.7 Printed circuit boards

Tracks on circuit boards can act as antennas and can radiate signals efficiently at high frequencies. There are essentially two basic mechanisms, monopole and loop type.

Where for example the signal from a high frequency clock oscillator is taken to another device on the circuit board and the return conductor is not immediately adjacent to the signal line, a loop is formed which will radiate the signal and generate a field at a remote point (*Figure 23.6(a)*). Taking the example of TTL logic for a 1 mA signal at 200 MHz in a 3 cm<sup>2</sup> loop the field at 10 m would equal the limits of EN 55022 Class B. The areas of all such loops are to be minimised for lowest radiated field. Similarly, immunity to rf radiation and possibly other types of disturbance such as indirect electrostatic discharges (ESD) would also be improved by this measure.

However a more important mechanism is where a voltage is generated across the length of the ground return on the

Table 23.5 Immunity levels

<i>EMC phenomenon</i>	<i>European basic standard</i>	<i>Typical disturbance level a.c. power port</i>

Dips and interruptions	EN 61000-4-11	30% for 10 ms 60% for 100 ms	30% for 10 ms 60% for 100, 1000 ms

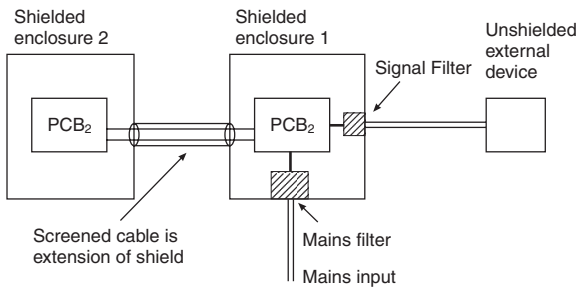

Figure 23.4 Design concepts

Figure 23.5 Waveform and spectrum of a digital signal

board where the voltage drives into an attached wire or cable causing it to radiate as a monopole (Figure 23.6(b)). This is a far more efficient radiation mechanism and can give rise to high emission levels. The key factor is to ensure that the cable shield termination is connected to the metalwork of the enclosure and not to the zero volt conductor/plane of the printed circuit board.

Multiplayer PCBs are effective at achieving the design aim of reduced loop area and close tracking. The ground plane acts as the high frequency earth return for all signals and all the high frequency energy is effectively contained within the layer of insulations. Compared with a single sided board, EMC performance is improved by up to 30 dB by this measure.

## 23.8 Interfaces

The multi-layer PCB circuitry communicates with the outside world through attached shielded interface cables and it is important to minimise the amount of high frequency energy such as high order clock harmonics from exiting the equipment via the interface. One method of control (Reference 1) is to isolate the interface connectors on a

piece of 'clean' earth ground plane having only a single point of connection to the main part of the board.

The clean interface ground is bonded to the equipment chassis at the cable port; the decoupling capacitors are thus far more effective than they would be if terminated to the noisy ground of the main part of the pcb.

Digital signal interfaces may require additional protection against incoming transient disturbances particularly where the interface cable is unshielded or the pins are exposed to ESD. Here transient suppression in the form of gas tubes and Transorbs may applied to good effect, provided a good low impedance earth is available.

## 23.9 Power supplies and power-line filters

Many power supplies are of the switch mode types. These are well-known sources of high levels of high frequency disturbance, comprising harmonics of the switching frequency and cover the spectrum up to 30 MHz. These power supplies usually contain well designed high performance filters which attenuate the internally generated disturbance to levels below the most stringent emission limits. Any disturbance generated by the electronic circuit powered by the SMPSU is also attenuated strongly and there is usually no requirement for additional power line filtering for either emissions control or immunity.

The power supplies are usually supplied compliant to national and international EMC standards and the selection of the power supply can then be based solely on functional requirements.

Where a separate power line filter is installed in equipment a single stage filter can often be selected by choosing the largest line inductance at the rated current. However, overall EMC performance is generally determined by EMC tests on the complete system because the practical terminating impedances are usually unknown for all the modes of propagation, and calculations or estimates based on manufacturers' data can often be accompanied by high uncertainties.

The performance of the filter will be critically dependent on the filter installation method. Figure 23.9 shows an example of bad installation practice. The performance is severely degraded by cross coupling via the bundled input and output wires and the earth is provided by a wire. The impedance of the wire is in series with the suppression capacitors between the power conductors and the equipment chassis and the high frequency performance of the filter will be degraded. The metal body of the filter should be bonded directly to the chassis via a shake-proof washer and not by a wire and the input and output wires should

Figure 23.6 Radiation from printed circuit board tracks: (a) differential mode radiation (loop type); (b) common mode radiation (monopole type)

Figure 23.7 Ground plane board

be separated and aligned 180 degrees in opposition to one another.

23.10 Signal line filters

Where there is no shield for the signal cable a signal line filter may need to be employed and should be installed at the point of entry to the equipment enclosure. It is important to ensure that the introduction of the filter does not cause too much attenuation of the wanted signal. Generally low pass filters are employed and for digital data circuits the half power point of the filter response should be no lower than the 9th harmonic of the fundamental data rate in order to preserve the quality of the waveform. Installation is also important for signal line filters. The decoupling capacitors should be connected to a good chassis ground.

The simplest form of signal line filter is the capacitive filter comprising a series of 1 nF capacitors from each line to ground at the point of entry of say an RS232 cable to the equipment enclosure. These may be obtained incorporated within the 'D' connector.

In most cases an 'L' filter can be employed using series inductance (denoted 'L' in the figures) but where extra stages are required e.g. for additional protection, a 'T' filter

is usually preferred to a 'Pi' filter because it is less dependent on a good earth.

For some high integrity systems, the signal line filters are used in conjunction with screened cables, the filter components often being incorporated within the plug or socket at the end of the cable. However, the small size available will limit the value of series inductance that can be employed and the series elements often comprise a ferrite sleeve or series of beads that give good performance, but only at the higher frequencies.

Additional protection for analogue circuits such as operational amplifiers can be achieved by the use of a balanced (equal value) pair of series resistors at the input pins and by 1nF decoupling capacitors at the input. It is important to de-couple the supply rails using capacitors having a good rf performance to minimise unwanted potential differences and to reduce the size of loops to avoid coupling with applied electromagnetic fields.

23.11 Enclosure design

Metal equipment enclosures can be configured to provide an effective barrier to electromagnetic waves. Basic shielding theory states that an incident wave is partly reflected at the surface and is then attenuated in its passage through the medium. The total shielding loss is the sum of the reflection and absorption losses. There is another factor known as the secondary reflection loss but this is only taken into account for very thin shields where the absorption is less than 10 dB.

For most practical low frequency applications, a reliable minimum measure of shield performance can be obtained by calculating the absorption loss factor.

$$A = 431 \cdot \pi \cdot (f \mu_r \sigma_r)^{1/2} \text{ dB}$$

where t is the thickness of the material in millimetres, f is the frequency in MHz and  $\mu_r$  and  $\sigma_r$  are the permeability and conductivity relative to copper respectively. For a 0.5 mm copper sheet at 1 MHz, the absorption loss is 65 dB, more than adequate for most commercial/industrial requirements of 20–40 dB. However the same copper sheet provides only 0.5 dB at 50 Hz. If effective protection is required against power frequency magnetic fields, higher permeability materials such as steel ( $\mu_r = 300\text{--}1000$ ) will be required. For a 20 dB attenuation at 50 Hz the thickness of the steel will need to be about 5 mm. The high frequency performance of practical enclosures is not so much dependent on the inherent properties of the material but far more on the apertures and discontinuities in the surface.

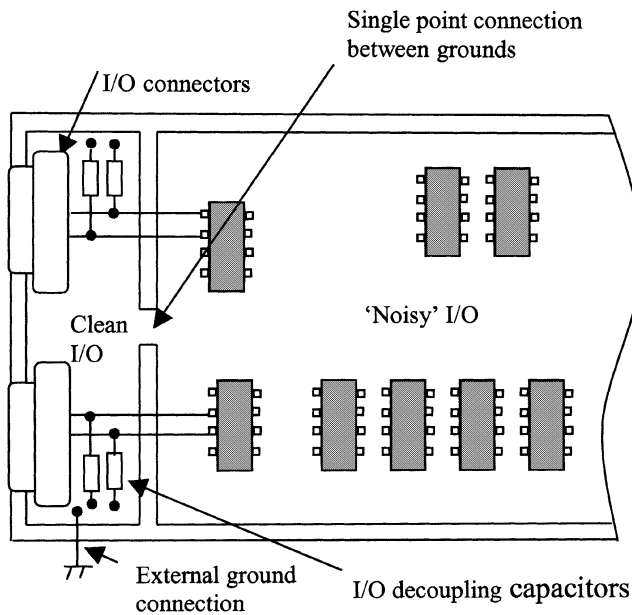

Figure 23.8 PCB interface design

Figure 23.9 Example of very poor filter installation

Electromagnetic energy will leak through apertures to a degree dependent on the ratio of the aperture diameter to wavelength. Where the aperture diameter is one half wavelength it is virtually transparent. The degree of attenuation at lower frequencies can be easily derived using the expression  $SE = 20 \log_{10}(2D/\lambda)$ , where  $\lambda$  is the wavelength at the frequency of interest and  $D$  is the largest dimension of the aperture. For high attenuation  $D$  must be as small as possible. For large apertures for ventilation etc., a mesh may be used to cover the area thus providing an effective shield. In general terms, a large number of small apertures is preferred to a small number of large apertures.

Discontinuities in the surface can also degrade shielding performance, especially where the length of the slot is one half wavelength. The length of the slot should be reduced by providing more points of contact between the sections. Ideally there should be a good surface to surface bond at the connections between modules in a rack enclosure, and the additional expense of modules with rf spring fingers along the edge will pay dividends both for reducing the transfer of electromagnetic wave energy but also in protecting

against ESD. Gaskets can also be used to achieve good high frequency electrical bonding between metal panels and enclosure sections. However, the enclosure must be designed from the outset to accept the gasket.

Many enclosures are not metal, but plastic or other non-conducting material. These would provide no shielding to electromagnetic waves but it is possible to introduce a shielding effect by various means. These include painted, sprayed, sputtered or plated metallic coatings to the inside surface of the plastic enclosure or by using metallic loaded plastic material. Generally these measures produce only low levels of shielding, e.g. less than 30 dB, but they can be extremely effective in improving the situation for marginally non-compliant equipment.

## 23.12 Interface cable connections

Cable characteristics can have an impact on the EMC performance of a system. Unshielded twisted pair cable is often used for low and medium speed data links. In the presence of an incident electromagnetic wave, voltages will be induced in the cable both in common mode and differential mode. Although the differential voltage is minimised at low frequencies by the twists in the cable, the common mode voltage remains and will be applied to the circuit to which the cable is connected. The balance of the circuit is therefore crucial and if the impedances to ground at the circuit are equal, the conversion to unwanted differential mode noise is minimised. The difficulty is that parasitic components such as stray capacitance tend to unbalance the circuit at high frequencies and the ability to reject common mode disturbance reduces rapidly with increasing frequency, thus causing interference.

Additional protection can be provided by the addition of an outer screen usually of copper braid or aluminium foil. At high frequencies, the electromagnetic energy is confined to the inner and outer surface layers of the screen by

Figure 23.10 Shielding theory

Figure 23.11 Apertures and discontinuities in Enclosures

skin effect and isolation between the inner conductors carrying the wanted signal and the external environment can be readily achieved through good cable screen design. Screened cable performance can be characterised by its surface transfer impedance ( $Z_t$ ) which is the ratio of the voltage induced on the inner conductor to a current in the outer surface of the outer conductor. The shielding effectiveness of coaxial cables is given approximately by  $SE = 20 \cdot \log_{10}(50/Z_t)$ . The transfer impedances of various types of screened cable are shown in Figure 23.12.

At low frequencies performance is determined by the self impedance of the screen conductor. For the single copper braid for example, the weave allows energy to pass through the shield and high frequency performance is reduced, although the level of performance is usually adequate for most purposes. For special applications such as for cables carrying very low level signals in an intense electromagnetic

environment such as a nuclear power station the outer screen is composed of many layers including inductive materials as in super screened cables, and excellent performance is achieved.

Having the correct termination for the cable shield is an important consideration in achieving the maximum performance of the cable. Ideally the cable screen should be terminated in a 360° peripheral glanded connection as shown in Figure 23.13.

If the cable screen is made up into a 'pigtail' connection, performance at high frequencies will be severely degraded and pigtail screen connections should be avoided. At high frequencies the impedance of the pigtail connection becomes significant and is a point of common coupling between the inner conductors and the external environment, increasing emissions and reducing immunity to external disturbances.

Figure 23.12 Transfer impedance of various types of screened cable

Figure 23.13 Correct 360° peripheral termination of screened cable

### 23.13 Golden rules for effective design for EMC

- (1) Consider the location and design of EMC 'barriers' at the concept stage.
- (2) Consider the use of multi-layer printed circuit boards with good layout and interface design.
- (3) Select filters for unscreened power and/or signal cables entering the enclosure.
- (4) Ensure correct filter installation at the point of entry to the enclosure.
- (5) Connect the screens of interface cables at the point of entry to the enclosure by a glanded 360° peripheral connection.
- (6) Bond the enclosure sections and minimise the size of apertures for best enclosure shielding.

### 23.14 System design

For distributed systems comprising several or many electronic equipment interconnected by cables, good cable installation practice combined with other earthing and grounding measures can be applied to good effect to improve system reliability in the presence of electromagnetic disturbances. These measures for improving immunity are equally effective in reducing emission levels from an installation and will ease the task of operators and system installers in ensuring compliance with the essential requirements of the EMC Directive. The main methods of control are: cable segregation, where cables of various types are routed in groups so that cross talk or disturbance pick up is minimised, cable separation where cables with high levels of disturbance are spatially separated from the cables carrying sensitive signals and isolation by the use of earthed conductors which reduce coupling between cable types.

In a first step towards good EMC engineering practice, the following general guidelines should be observed:

- **Cable segregation:** Sensitive cables such as signal cables may be grouped together; mains cables, including power feeds and lighting circuits, carrying up to 250 V may also be grouped together but the cable types should not be mixed.
- **Cable separation:** In addition to the groupings, data, telecoms or sensitive cabling should be separated from three-phase cables used for heavy electrical inductive load switching e.g. air conditioning, welding equipment and motors by the largest practicable distance.
- **Isolation:** Metal cable trays, if not already in use, should be implemented. Having an adequate low impedance for the frequencies in use, and with good earthing, the tray will effectively become a partial screen for the cables.
- **Shield termination:** Cable shield termination is also a key factor in controlling EMC but the best practice is often dependent on the particular circumstances. For low frequency applications the shield may be terminated at only one end in order to mitigate against ground

Figure 23.14 Screened cable termination methods

Table 23.6 Cable type classification

Cable type	Characteristics
Very sensitive	Low-voltage or low-currents as from sensors
Sensitive	Signalling cables. 24 V flat cables for parallel data transfer
Indifferent	AC power between 100 V and 250 V, depending on the EMC properties of the apparatus connected
Noisy	AC and DC relay feed line without protection measures such as filters or diodes
Very noisy	Leads to DC motors with brushes, switched power lines, cables and earth wires in high voltage switchyards, etc.

noise currents but this will reduce its effectiveness, particularly against magnetic fields.

For cables carrying low frequency signals, cable terminations have to be designed carefully to avoid coupling with noise currents flowing in the ground. If the sensor is not directly connected to ground as in Figure 23.14(a) above it may be possible to terminate the screen at both ends, thus providing maximum protection against inductively coupled disturbances. If the sensor is grounded as in Figure 23.14(b), the voltage drop across the ground impedance to noise currents in the ground will give rise to high currents in

the shield and noise voltages may be present at the input to the amplifier. This can be overcome as shown by terminating the cable at one end only, thus avoiding the ground loop, but the performance of the shield may be reduced. If high performance is required under all conditions e.g. with the sensor grounded it may be necessary to introduce transformer coupling or opt-isolation in order to minimise unwanted coupling.

Cables transporting similar signals can often be bundled together. With cables transporting different signals it is possible to differentiate between cables as shown in Table 23.6.

The five types of cables listed above should be separated in sequence from each other by at least 150 mm on cable trays or racks. That means that a very sensitive cable should be separated from a sensitive cable by at least 150 mm, and from a very noisy cable by at least 600 mm. In this latter case, a minimum separation distance of 1 m is recommended if cable racks are used.

The use of a parallel earthing conductors (PEC) can reduce common mode currents in signal leads by reducing the system common mode impedance and the loop area. Routing cables through trays, conduit or ducting has the effect of introducing a parallel path for disturbance current, which not only is capable of diverting and withstanding high currents but also of providing the necessary low impedance thus protecting the signal cable. Additional connections to earth should be made at regular intervals for very long cable runs.

Using trays or racks of sufficient wall thickness when used to separate cables, can provide both PEC and differential mode reduction in cross-talk. They can often be laid next to each other. Another solution is to keep some

Figure 23.15 Stacking conduits to avoid cross-talk

distance between shallow conduits for the different types of cables, for example by stacking them (*Figure 23.15*).

Earthing and bonding are key features in the EMC design of a large system or installation. Earthing is the connection of the exposed conductive parts of an installation to the main earthing terminal of that installation; bonding is an electrical connection maintaining various exposed conductive parts and extraneous conductive parts at substantially the same potential. The general requirements of an earthing network are to provide safety and to provide a low impedance path for currents to return to source.

The current preferences are for a multiple bonded earthing network which is compatible with the measures for lightning protection (*Figure 23.16*). The frame of the building is bonded to the lightning conductors to avoid flash-over with multiple connections to earth electrodes.

Internal to a building, the recommended approach is a three-dimensional network, one earthing network per floor, each network connected to one another and to the earth electrode. The mass of inter-connections is called a common bonding network (CBN). In some cases e.g. telephone exchanges an earthing mat may be installed but only connected to the building frame at one point to provide a mesh isolated bonding network (IBN). The main feature of the CBN is that each floor of a building should have a meshed ground network beneath the floor with multiple connections between the floors. The mesh network can take the form of not just the dedicated ground structure, but installed cable trays (metallic), water pipes and ducts. The meshed earthing scheme will produce an earthing system which should have low impedance, and a high probability of remaining so, even if a number of earth connections become corroded and fail.

**Figure 23.16** Preferred method of earthing network

## 23.15 Buildings

In most practical applications, electrical and electronic equipment is installed and used inside a building. Where the building is exposed to intense sources of electromagnetic disturbance, some additional protection may be required. For example, buildings on airfields are often illuminated by the incident radiation from high power radio and radar transmitters in the near vicinity, where the fields are in excess of the equipment immunity test levels of 3 and 10 Volts/metre. Measures such as shielding on the windows may be a minimum requirement but in some cases shielding of the room containing the electronic equipment may be required. This introduces the concept of protected zones which can also be developed for protection against other threats such as lightning strikes (*Figure 23.17*).

Such protection is usually considered at the design stage but can be introduced retrospectively in some cases on a small scale. The need for additional measures is usually determined by a site survey of the electromagnetic environment at the building location. Other sources that often need to be considered are overhead power lines and overhead railway a.c. electrified lines. Here the magnetic field at the power frequency can cause distortion of the display on computer monitors. The threshold for distortion is about 1 Amp/metre and provision for some measure of control, usually by re-location or local shielding for the monitors, should be made if the field is likely to exceed this level.

## 23.16 Conformity assessment

In Europe, products placed on the market must comply with the essential requirements of the EMC Directive. (The exceptions are military equipment, which must meet defence standards, and equipment covered by other directives which address EMC e.g. medical devices.) The manufacturer is required by law to make a declaration of conformity stating that the product complies with relevant harmonised standards referenced for application under the EMC Directive. He may then apply the CE mark to his product and will obtain the benefit of free circulation of the product within the Single European Market without experiencing any barriers to trade. It should be noted that the CE Mark denotes compliance with *all* applicable directives which for

**Figure 23.17** Protected zone in a building

**Table 23.7** European directives and EMC standards

<i>Product</i>	<i>Directive</i>	<i>EMC Standards</i>
Household equipment	EMC Directive 89/336/EEC	EN 55014-1 and -2
Maritime navigation equipment	EMC Directive 89/336/EEC	EN 60945
Lighting equipment	EMC Directive 89/336/EEC	EN 55015 and EN 61547
Information Technology Equipment	EMC Directive 89/336/EEC	EN 55022 and EN 55024
Railway Equipment	EMC Directive 89/336/EEC	prEN 50121 parts 2–5
Low Voltage Switchgear	EMC Directive 89/336/EEC	EN 60947
Radio and TV receivers	EMC Directive 89/336/EEC	EN 55013 and EN 55020
Radio and radio-telecommunications equipment	RTTE Directive 99/5/EC	Applicable TBR, EN or ETS standards
Medical equipment	Medical Devices Directive 93/42 EEC	EN 60601-1-2
Motor vehicles	Automotive EMC Directive 95/54/EEC	The directive contains the technical requirements

most products, will also include the electrical safety requirements of the Low Voltage Directive 73/23/EEC.

For finished products, complex components and systems, the manufacturer has the option of either applying appropriate harmonised EMC standards i.e. those approved by the European Commission or can prepare a Technical Construction File where the harmonised standards are not available or are not applied in full. Generally most manufacturers apply the harmonised standards as the most cost-effective route and this usually means that the product must be tested to EMC standards to determine compliance.

Table 23.7 presents examples of the requirements for common types of electrical and electronic equipment.

It is the responsibility of the manufacturer to determine which directives apply to his product but information is usually generally available from standards bodies such as the BSI, from EMC test laboratories and Competent Authorities such as the UK's Department of Trade and Industry.

The European assessment requirements for fixed installations are somewhat different. The installation may comprise compliant (CE marked) equipment and/or non-compliant equipment. The installation must meet the 'essential requirement' of the EMC Directive, i.e. not to cause interference and not to be affected by electromagnetic disturbance. There is no necessity for declaring compliance nor for CE marking. However the installation designer should ensure that the equipment is installed according to good engineering practice and is advised to maintain a file containing a description of the EMC measures taken, together with any test data etc. This file should be available for inspection by the authorities if challenged at some later date. The key issue is the acceptance by the designer or operator of non-compliant equipment. This is permissible but becomes the responsibility of the operator if interference results and therefore the operator should ensure that this equipment is compatible with its environment either by imposing some contractual requirements for EMC characterisation on the supplier or by in-situ confidence testing.

### 23.17 EMC testing and measurements

For the vast majority of electrical and electronic equipment, compliance with the relevant technical specification is achieved by testing to EMC standards. Emissions measure-

ments can comprise two types, a) tests for low frequency phenomena such as power frequency harmonics and voltage fluctuations to protect the power distribution network, and b) high frequency emissions to protect the radio spectrum. For commercial and industrial products, high frequency emission measurements are normally made over the frequency range 150 kHz to 1 GHz but some standards call for measurements down to 9 kHz. It should be noted that it is becoming increasingly necessary to measure emissions above 1 GHz to protect cellular and other radio systems.

The low frequency phenomena are usually measured with proprietary test instrumentation dedicated for that purpose comprising a harmonics analyser and flicker meter. Most high frequency tests comprise measurements of conducted disturbance over the frequency range 150 kHz to 30 MHz and radiated disturbance at higher frequencies, 30 MHz to 1000 MHz. The different test methods effectively reflect the propagation mechanisms that dominate in practice.

Conducted disturbance measurements on the mains power input comprise a measurement of rf voltage across a passive network (50  $\mu$ H/50 ohms) having an input impedance representative of the rf impedance of the mains at high frequencies. The voltage is measured using a calibrated EMC measuring receiver or spectrum analyser. Most modern instrumentation systems are computer controlled for maximum efficiency.

Radiated measurements are performed on a test range meeting particular requirements for path loss, or in a facility giving results which can be correlated to those on the test range. The standard test range comprises an open area site which is flat and free from reflecting objects and typically having the dimensions shown in Figure 23.18. A significant proportion of the area should be covered by a conducting ground plane in order to achieve the site attenuation calibration requirements.

Shielded enclosures lined with radio-wave absorbing material or ferrite tiles on all internal sides except the floor can be constructed to achieve site attenuation performance characteristics comparable with an open area test site. Due to cost limitations, most chambers are built to accommodate a 3 metre range and some additional calibration work may be required to relate the results to the 10 metre range, particularly for physically large items of equipment.

Measurements of field strength are made using a receiver or spectrum analyser and a calibrated antenna situated at a fixed distance from the equipment under test. A key factor

**Figure 23.18** Dimensions of the CISPR open area test for radiated emissions

**Table 23.8** Test equipment

Test	Equipment
ESD	ESD Gun
Fast transients	Transient generator and coupling clamp
Surges	Surge generator
Dips and interruptions	Dips generator
Rf fields	Signal generator, power amplifiers, antennas
Rf voltages	Signal generator, power amplifiers, coupling networks

in emissions measurements is to configure and operate the product in a manner which is both representative of practical use, yet maximises the emissions from the product. For products and small systems which contain cables some pre-testing is often required to determine the optimum configuration for test, particularly for radiated emissions tests.

Immunity tests are performed by subjecting the equipment to electromagnetic disturbances of the type and maximum level that the product is likely to encounter in its intended operating environment. For many of the tests, specialised test instrumentation is required, providing the well-defined disturbance characteristics described in the standards. The instrumentation is commonly available from a number of specialist suppliers and the tests which involve the direct application of disturbance voltages are relatively straightforward.

The facilities for subjecting the product to disturbance fields are more complex and costly. The rf field immunity test is performed inside a shielded room lined with radio-wave absorbing material or ferrite tiles and the costs of purchasing and installing the facility are often quite high. The test method requires that the test volume is pre-calibrated to achieve the desired test level. There is an additional field uniformity requirement for the maximum level of field over 75% of a 1.5m square area to be no greater than twice the required test level. Rf power over the frequency range 80–1000 MHz is fed to a dedicated radiating antenna in the room from a signal generator and high power amplifier. The system is usually computer controlled to achieve the calibrated level in an efficient and reproducible manner.

To simulate coupling with rf fields at frequencies below 80 MHz, a common mode voltage test is applied to the cables attached to the product, i.e. the mains leads and signal and interface cables using coupling/decoupling networks

(CDNs). The measurements are usually made inside the shielded enclosure for convenience and to avoid causing interference to radio services.

Immunity to power frequency magnetic fields is performed by setting up current flow in a loop around the product or preferably by placing the product within the confines of a Helmholtz coil.

In immunity testing, the configuration and operating conditions of the equipment under test can be very important. These conditions are usually specified in the EMC standard applicable to the product but in the absence of specific information the test engineer must attempt to adjust the conditions for maximum sensitivity to the applied disturbance. This can be difficult because immunity testing does not give a resultant variable, only an attribute of compliance or non-compliance, and care is required to follow the specific instructions of the standard and the advice and guidance of the manufacturer. Monitoring of the product's performance should be performed in a non-invasive method that does not influence the coupling of the applied disturbance. In addition the criteria for assessing the product's performance need to be clearly established prior to testing. For example for an analogue instrument such as a temperature sensor, the margin of acceptable error, say 1%, needs to be stated in the User Manual.

### 23.18 Management plans

For all product, system or installation developments, compliance with EMC requirements can be made much easier by the adoption and adherence to an EMC management plan. This would probably be integrated within a broader conformity assessment programme which would include

**Table 23.9.** Product development process

Product development stage	EMC input
Design Concept	Apply EMC control principles
Design Process	EMC design measures
Prototype	Pre-compliance EMC tests
Production Prototype	EMC certification
Production	Conformity in production tests
Upgrades/modifications	EMC re-assessment

safety and other approvals. The plan would be prepared at the inception of the product development with an intention of achieving complete compliance at the lowest cost and in the shortest timeframe both at the initial certification stage and also through the lifetime of the product. The plan would include Control Plans which would specify the intended operating electromagnetic environment, any particular EMC elements in the Technical Specification, a Compatibility Matrix to identify couplings with other systems, EMC Test Plans, and applicable codes of practice to aid the design team. *Table 23.9* lists the EMC inputs required at the various stages of a product development.

Procedures can be set up for regular EMC design reviews and formal acceptance of supplied sub-assemblies or equipment from sub-contractors. In some cases, particularly for large systems and installations, it may be necessary to establish procedures for dealing with concession requests and dispensations where supplied items are non-compliant.

## 24.1 The scope of electrical safety considerations

### 24.1.1 General overview

It has often been said that electricity poses hazards quite unlike any other hazard which commonly presents itself to persons in the workplace and elsewhere, including in the home. Electricity has the capacity to kill and injure through electric shock, through burns and through fires started electrically. Other dangers involving the use of electricity may be found in the aberrant and dangerous actions of electrically controlled machinery and the maloperation of plant control systems based on relay and/or computer logic circuitry.

Electrical accidents, unlike most other industrial accidents, are more likely to involve professional and supervisory staff. In some situations they may be at greater risk than most other staff particularly where electrical power distribution circuits are being switched or maintained. In a typical year<sup>1</sup> 47% of electrical accidents involved electrically skilled persons and out of a total of 805 electrical accidents 57 were to supervisory and testing staff. Electricity has a stealth and power which are often disregarded even by electrical engineers and other electrically trained persons.

All those who are involved in potentially hazardous work with electrical equipment, such as the testing of high-voltage apparatus or supervising the alterations to circuits in an important substation, have statutory legal duties of which they must be aware. They must conduct their work in accordance with the statutory requirements and ensure that those under their control also conduct their work properly. In the UK these are criminal law obligations, quite distinct from liability for negligence in civil law which may also arise if matters go wrong. All engineers should make themselves aware of the statutory requirements and of the potential liabilities which they run as persons with responsibilities for the health and safety of themselves and others.

Nearly all electrical accidents, even those at low voltages (e.g. 230 V a.c.) are potentially fatal and the causes and remedies are now almost completely understood. There is no shortage of guidance on the various hazards presented by electricity and on the statutory requirements relating to these. In Great Britain much of this guidance is published by the Health and Safety Executive (HSE) which has the main responsibilities for safety and health legislation arising from 'work' activities and the enforcement of this law.

Other considerations in the context of health and safety of which electrical professionals should be aware are the various directives of the European Union (EU), such as the 'Low Voltage Directive' 73/23/EEC, the 'Machinery Directive' 98/37/EC and the 'ATEX Directive' 94/9/EC which have a safety content. A raft of EU directives and domestic implementing legislation covers the generality of health and safety on hazards other than from electricity but these are outside the scope of this discussion. For further details on these refer to the HSE, DTI and other sources listed below, some of which are available on-line through their Internet websites.

#### 24.1.1.1 Control of staff and permits to work

In the context of persons 'at work', the emphasis in all work on electrical equipment must be that this normally be conducted with the equipment de-energised and made safe, i.e. 'dead' working. 'Live' working is a specialised activity and is permitted only in exceptional circumstances. No one should be allowed to do anything which carries electrical

risks without the provision of adequate precautions to reduce the risk of injury to a minimum. The persons must also have the necessary skill, experience, technical knowledge and other resources to do the work safely. Managers and supervisors must therefore satisfy themselves that no one is asked to do any work for which they are not competent and specifically authorised by the management. Such authorisation is usually through a formal process of instruction and examination in company procedures.

Particular care must be taken with students, trainees and apprentices. Apprentices are often expected to learn to carry out potentially dangerous jobs during their apprenticeship but they must be carefully supervised.

When work must be done where electrical danger may be present, and some electrical work (particularly in testing and maintenance) cannot be made absolutely safe, instructions must be precise and unambiguous. Procedures must be observed correctly. All necessary and relevant technical manuals and drawings etc. should be available.

Much 'dead' work is carried out under 'permit to work', particularly in the electricity generation, transmission and distribution industries which have an established and universal system of safety rules (with local variations for each electricity company). Permits usually relate to equipment which has been made dead. Permits must be issued and cancelled in an orderly and clearly defined manner. A full record must be kept so that it is possible, at any time, to find out what is going on, who is involved or at risk, and what precautions have been taken.

The permit must state clearly and fully to whom it is issued (this person should be present at all times and is responsible for what happens), name those persons who may be present in the working area, and state what special precautions have been taken to prevent danger. The safe and unsafe areas must be stated on the permit, preferably supported by means of a diagram, and clearly indicated on the actual work site by means of flags and barriers etc. The work to be done must be clearly described and no other work may be carried out because this could entail risks not contemplated by the person issuing the permit, who may not have taken the extra precautions necessary.

At the end of the work there must be a clearly defined procedure for handing over. A check must be made that all persons have been withdrawn from the work site and the result recorded. Before the permit is cancelled, a statement must be recorded (preferably on the back of the cancelled permit and also in the log book, where one has been kept) of what work has been done, what has not been done, and what steps have been taken to make the site ready for resumption of normal operations. Until a permit has been cancelled the person to whom it was issued remains responsible for the conduct of any work on that equipment.

If the work lasts for more than one shift there must be an appropriate method of hand over to ensure that the new shift supervisor is familiar with the state of the work and the terms of the permit. It is often preferable to cancel the first permit and to issue a new one. Sometimes the person with the authority to issue permits takes charge of the work, in which case they should issue a permit to themselves.

Experience has shown that all this detailed procedure is essential. The routine not only ensures that there is a record which will help to identify the cause of any mistake, but the action of writing down all the details helps to prevent anything being overlooked. Since all key persons involved must sign all of the records and statements the routine reinforces the understanding of the various instructions and helps to ensure that these instructions have been read and understood.

Some testing and research work presents its own hazards. As the conditions may vary greatly it is difficult to lay down general rules and safety depends largely on the skill of the staff. For certain work earth-free areas with power supplies isolated from earth are provided and used in conjunction with other precautions such as the use of unearthed tools (such as very low voltage soldering irons).

Routine high-voltage testing is normally carried out in enclosures with interlocked doors and provision for supervision from the outside. Where unskilled or semiskilled persons do routine testing on a production line arrangements must be made, by guards and interlocks for example, to ensure that they are not exposed to live conductors operating above 25 volts a.c. or 60 volts (smooth) d.c. thus eliminating likely shock risks.

#### 24.1.1.2 *Non-electrical causes*

Many electrical accidents are the result of mechanical and other causes. Examples of these causes are mechanical stresses, thermal shock on insulators, resonant vibrations of conductors leading to fractures, low-temperature brittleness or corrosion fatigue. Too often however the causes are banal, such as a badly constructed joint or a loose connection. To deal with such troubles it is necessary to have more than a narrow interest in electrical matters. Much of electrical safety engineering requires a good understanding of mechanical engineering and the strength of materials because many accidents involving electricity are due to a poor understanding of the properties of materials. However, electrical accidents are also largely due to the uses and abuses to which otherwise sound equipment is subjected.

A further dimension in electrical accidents is that the stealthy power of electricity is inadequately understood. Even many electrical engineers, perhaps because their training and experience may not have exposed them to the destructive capabilities of electricity, can be disrespectful of this power. For example, very few engineers actually get to witness a substantial power arcing fault and few get to examine the after effects of a serious electrical fire, explosion, arcing fault or other dangerous occurrence. However, those that do usually find themselves surprised and acquire a deeper respect for electricity.

The official report on the enquiry into the disastrous explosion and fire at Flixborough in 1974 (which featured the mechanical failure of a temporary modification to the naphtha cracker) stated that engineers should have academic and practical training in all branches of engineering outside their speciality which may affect their work. This might seem to imply the need for training in the many fields of expertise of only tangential interest to one's own discipline but in reality one person can seldom expect to understand every aspect of a particular plant, apparatus or process on which they have to work. There is often a need to draw upon shared expertise with colleagues or even to seek outside help in order to deal properly with certain problems. The key point is that the engineer should recognise his or her limitations. If the competence, experience or expertise are inadequate to the circumstances then help should be sought.

#### 24.1.1.3 *Design standards*

The integrity of much electrical equipment is now greatly assured through a comprehensive range of published Standards which have been established nationally and internationally through the various consensus seeking Standards organisations such as the British Standards Institution

(BSI), the European Electrical Standards body, CENELEC, and the International Electrical Standards body, IEC. The work of these bodies has contributed hugely to the safety and integrity of much electrical equipment over many decades. However, safe use of equipment also relies on the correct interpretation of the scope of the Standards applying to that equipment. A Standard is only one link in a chain.

It is worth remembering too that with few exceptions Standards are written in a consensus seeking forum comprising representatives from the various interested groups. These groups usually comprise manufacturers, or their trade associations, government bodies, test houses and inspection agencies and, to a lesser extent, representatives of the actual users of the equipment.

British Standards have fulfilled a useful role over decades but it must now be recognised that almost all Standards work is conducted in an international forum with the needs, hopes, customs and expectations of domestic users being subject to a large measure of international influence. This internationalisation is not always welcomed by some but it is inevitable.

Traditionally British Standards have been drawn up in a manner which recognise some basic principles of electrical engineering safety. Some of these are:

- The insulation of conductors should be unable to come into contact with moving parts.
- Earthing terminals should be adequately locked against loosening. These terminals shall not serve for any other purpose, e.g. for securing parts of the case.
- Electrical connections should be so designed that the contact pressure is not transmitted through insulating material other than ceramic or other materials not subject to shrinkage or deterioration.
- Soldered connections should be so designed that they keep the conductors in position if the conductor breaks at the point of connection

In many situations it is important that fingers, steel rules etc. cannot touch live or moving parts of electrical equipment and a number of probes have been devised to test and prevent this, including a standard test finger which is hinged to mimic the reach of the fingers on a human hand.

#### 24.1.1.4 *Investigations*

Most engineers will, at some time, have to investigate an accident or plant failure. The purpose of an investigation is to ascertain the facts and initiate any necessary action. The first requirement is to make sure that all the relevant information has been obtained and that it is correct. Persons who have witnessed a severe accident are often shocked and emotionally distressed. They may be quite unable to distinguish between what they have seen and what they think they ought to have seen, or perhaps what they have imagined when trying to rationalise their confused memories. Some people may also have good reason for wanting to mislead while others quite genuinely lose all memory of events immediately leading up to the accident. Sometimes however, the person injured is less upset and a better witness than the on-lookers.

It is important to remember that the impossible does not happen, and the improbable only happens occasionally. Accidents are usually the result of several contributory factors coinciding whereas a machinery design or a procedure is likely to have been based on only one factor occurring at a time.

It is important to examine the debris and all equipment very carefully after a failure and be critical of stock wiring diagrams; they frequently contain mistakes or refer to the

wrong apparatus. It is common for modifications not to have been recorded properly.

Having determined how an accident has happened, it is important to find out why. This usually involves the highly complex issues of interfaces between humans and machines and the management of staff. Temperament is important in some jobs and boredom, stress, overwork, rivalries, physical and mental health and all human emotions play a role in the workplace. An example of the importance of temperament matching the task is that of a plant control engineer who may have long periods of dull routine punctuated by occasional emergencies when quick and correct decisions are necessary. It is a job which suits only certain types and where the consequences of error can be extremely serious.

#### 24.1.1.5 *Written reports of accidents*

If an accident report is muddled or unconvincing, the time spent on the investigation will have been wasted. A report should err slightly on the long side rather than be obscure but it is preferable that it conveys the main points lucidly and concisely.

Reports that recommend action by managers or directors will fail if the reports are incomprehensible to these people. Good report writing is an art which usually requires much concentration and practice. Some pointers are:

- Careful preparation pays dividends. Well chosen headings and a planned layout are essential. The argument needs to be thought out clearly and arranged in a logical sequence so that, as far as possible, each paragraph follows naturally from the one before. If this thinking is done thoroughly the actual writing of the report will take on a natural flow which will be limited only by the speed at which one can write or type.
- Each sentence should carry the argument forward starting in such a way that the reader half expects what is to follow.
- Care is needed with punctuation. For example, commas should not be used excessively or in order to divide up a sentence like the brackets in an algebraic equation.
- Avoid long and involved sentences. Economy of words is a virtue. Short words are preferable to long ones, common words preferable to obscure ones. Words should express exactly the concept or message which must be conveyed. A Thesaurus can help identify the best words for the purpose. All doubted meanings should be checked with a good dictionary; it is really astonishing the diversity of understanding which even the commonest words have among most people (e.g. acute/chronic). Avoid technical jargon as far as reasonably possible. It often has surprisingly limited currency.
- Put all the supporting documentation into appendices in order to keep the main text succinct. The main text of the report should 'stand alone', i.e. it should be a readable narrative with a clear and logical progression of its own without the need to refer to the appendices.
- Check spelling. (Computers can now do much of this automatically, although one needs to be aware of international differences.)

Some relevant publications on this topic are given below.<sup>3</sup>

### 24.1.2 Recent developments

#### 24.1.2.1 *Technical*

An important development in recent years has been in the application of 'solid-state' devices and computers to electrical

control. Even in the traditional areas of electrical power generation, transmission and distribution the use of micro-electronics is now commonplace throughout all modern networks, from control rooms to protection relays. The reliability of most conventional hardware is now well established and it is possible to compute the probable 'life before failure' of most items of equipment. This, however, does not help to trace those defective components which operate only in emergency and could have remained unused and defective but undetected for years. It is virtually impossible to detect all weak links with certainty.

The weaknesses of the software in a computer system are even more difficult to detect. The embedded nature of software faults puts this type of fault into a special and sinister class of its own. However, the usefulness of computers makes it imperative that this weakness be understood and accommodated where computers are used in safety related applications. An enormous quantity of work has been done to get to grips with this problem and is the subject of comprehensive guidance and Standards.<sup>4</sup>

An associated development has been the increasing use of fibre optics for the transmission of information and instructions and the subsequent development of 'optical' switches and relays. These reduce fire and explosion hazards. They also eliminate the disturbance of control systems and telecommunications by electrostatic and magnetic induction and by gradients in the ground and structures caused by power faults and lightning discharges.

Another important development has been the realisation of the seriousness of the toxic hazards arising from the use of polychlorinated biphenols either through leakage into the environment or through the production of toxins arising from fires. These coolants were used increasingly from the mid-1950s to about 1975 to replace mineral oil in power transformers and capacitors to reduce the danger from fire and explosions. Oil-less, otherwise referred to as 'dry' or sometimes as 'air cooled', transformers have been used to some extent but, even if not immersed in an insulating liquid, conventional solid insulation is itself a fire risk. In addition, these transformers are prone to failure caused by moisture absorbed from the air and from surface contamination and tracking in industrial situations. Fire risks due to oil escape are an important industrial hazard and the losses have at times amounted to several million pounds per incident. Bulk oil type high voltage power switchgear has also been involved in many accidents, fires and explosions involving the combustion of the oil and its arc breakdown gases. There is now an understandable trend away from this type of switchgear equipment towards sulphur hexafluoride (SF<sub>6</sub>) and vacuum technology at the lower power distribution voltages.

There have also been important developments in understanding the difficulties caused in control, telecommunication and instrumentation systems by electrostatic and electromagnetic radiation. Microelectronic 'chips' can be destroyed by the tiny energy levels in static electricity charges normally carried by the human body and special precautions are necessary in their handling. Electromagnetic radiation by electrical equipment and its susceptibility to such radiation is the subject of the Electromagnetic Compatibility (EMC) Directive 89/336/EEC.

#### 24.1.3 Legal and administrative

The principal criminal legal provisions in Great Britain covering the safety of persons at work are contained in the Health and Safety at Work etc. Act 1974. Under this Act

are gathered numerous other Acts of Parliament dealing with safety of the workplace and other, secondary, legislation such as Regulations. Of principal interest to engineers will be the Electricity at Work Regulations 1989 which apply to all electrical equipment used at work and all 'at work' activities. Other important regulations are; the Management of Health and Safety at Work Regulations 1999, the Provisions and Use of Work Equipment Regulations 1998, Personal Protective Equipment at Work Regulations 1992 and the Managing construction for health and safety, Construction, Design and Management Regulations 1994.

A breach of these regulations becomes a criminal matter which may result in prosecution of the offender (employer, employee or self-employed person) in the criminal courts. The maximum penalties are several thousand pounds in the lower courts, whereas in the higher courts, depending on the circumstances of the offence, the maximum penalties are up to 2 years imprisonment and/or an unlimited fine. Most cases are dealt with in the summary courts, e.g. Magistrates Courts. The enforcement authorities are the Health and Safety Executive (HSE) and the Local Authorities. Information on recent prosecutions and fines may be seen on the HSE website.

Electrical safety in situations other than those involving persons 'at work' can be subject to other legislation, for example the Consumer Protection Act 1987 and the Electrical Equipment (Safety) Regulations 1994 which were made under that Act. Those regulations govern the safety at point of sale of all domestic appliances which are sold to members of the public.

The safety of the public from the electricity distribution system in the UK is a matter for the Electricity Supply Regulations 1988, as amended. Those regulations relate to the Electricity Act 1989 and they place duties on the electricity power supply distribution companies in respect of electric overhead lines, cables and other apparatus. They are enforced by the Engineering Inspectorate of the Department of Trade and Industry.

The well-known Regulations for Electrical Installations published by the Institution of Electrical Engineers (the Wiring Regulations) are a code of good practice and are published as a British Standard, BS 7671:2001. These are not statutory regulations and are therefore not enforced through the criminal courts. Mostly they are used as a benchmark of safety in contracts for new installations of electrical fixed wiring. The sixteenth edition of these Wiring Regulations was first published in 1991 and the Regulations have been amended several times since with several Codes of Practice published in support.<sup>5</sup>

## 24.2 The nature of electrical injuries

### 24.2.1 Types of injury

Electrical injuries are of three main types: electric shock, burns, and falls caused by electric shock. There is a fourth category of very temporary discomfort or incapacity which is not serious but very painful while it lasts. This is conjunctivitis (or arc eye) which may be associated with shock and burn accidents, but is largely confined to electric arc welding.

### 24.2.2 Electric shock

Serious electric shock is almost entirely associated with alternating currents and is rare when low or medium

voltage direct currents are concerned. Shock is not, however, a single phenomenon but is a general term for the excitation or disturbance of the function of nerves or muscles caused by the passage of an electric current. It is usually painful but is not necessarily associated with actual damage to the tissues of the body. The most common feature is severe stabbing and numbing pain at the points of entry and exit and sometimes along the path of the current through the body. This is frequently accompanied by involuntary contraction of muscles associated with the path of the current. It may even lead to torn muscles.

As a direct result of a moderately severe shock hand muscles may contract so tightly as to grip the conductor from which the shock current is being received leaving the victim quite unable to release their grip by voluntary action. This is an extremely dangerous situation and has resulted in many fatalities. Another possible result of muscular contraction is that the muscles of the chest, diaphragm and glottis may contract strongly and thus prevent breathing. This can lead to death by suffocation. Death may also be caused when breathing is stopped due to electric current passing through the respiratory control centres of the central nervous system.

#### 24.2.2.1 Hold-on current and permissible leakage

A typical characteristic showing the relationship of 'hold on current' to the frequency of the a.c. supply (*Figure 24.1*) indicates that the lowest values of current occur in the band of between 10 to 200 Hz which includes normal mains operating frequency.

#### 24.2.2.2 Ventricular fibrillation

It is generally believed that the great majority of fatal electrical accidents are caused by ventricular fibrillation, the muscles of the heart going into spasms which prevents the heart acting as an effective pump. Death follows quickly in these circumstances due to lack of oxygen supply to the brain.

**Figure 24.1** Relationship between the frequency and the let-go current based on experimental results. Such curves are of qualitative rather than quantitative value

A great deal of experimental work to investigate such effects has been undertaken on animals and this has been central to the production of international Standards documents on the subject of electric shock and its effects on humans and animals.<sup>6</sup>

#### 24.2.2.3 Limitations of experimental results

Because of the practical and ethical difficulties in experimenting on humans and because there are substantial variations between humans in their susceptibility to electric shock, the results from such research must be interpreted carefully so that adequate margins of safety are built into equipment and work practices which depend on this knowledge. A 0.5% risk of death is too high to be acceptable (Table 24.1). There is an essential difficulty in extrapolating from animal to human subjects and it is also the view that the susceptibility of human subjects can be considerably affected by subjective considerations, there is evidence that the effect of an electric shock is greater when either the shock is unexpected or the person is abnormally afraid of electricity.

#### 24.2.2.4 Body resistance

The impedance of the human body from hand to hand or hand to foot is variable. It depends on the area of contact and is affected by whether the hands (or feet) are dry, moist or wet, the condition of the skin and on the frequency and voltage of the current. Values are thought to range from 1–10 k $\Omega$ . These variations are discussed at some length in the international Standards on electric shock.

**Table 24.1** Current (r.m.s.) (mA) to give rise to various physiological sensations with a.c. 50 Hz\*

Physiological sensation	Percentage of test subjects		
	5	50	95
Current just perceptible in palms	at mA 0.7	1.2	1.7
Slight prickle in palms as if hands had become numb	at mA 1.0	2.0	3.0
Prickle also perceptible in the wrists	at mA 1.5	2.5	3.5
Slight vibrating of hands, pressure in wrists	at mA 2.0	3.2	4.4
Slight spasm in the forearm as if wrists were squeezed	at mA 2.5	4.0	5.5
Slight spasm in upper arm	at mA 3.2	5.2	7.2
Hands become stiff and clenched; letting go live parts is still possible; slight pain is already caused	at mA 4.2	6.2	8.2
Spasm in upper arm, hands become heavy and numb; prickle all over arm surface	at mA 4.3	6.6	8.9
General spasm of arm muscles up to the shoulders; letting go of live parts just about possible (let-go current)	at mA 7.0	11.0	15.0

\* Current path: hand–body–hand.  
From Friesleben and Fitzgerald.

#### 24.2.2.5 The limits of safety

Recommendations about the safe operating limits are more useful for practical situations if stated in terms of supply voltages rather than ‘hold on’ or fatal currents, which are difficult to determine for real situations. Table 24.2 gives information which is in accordance with experience and practice. There can be no exact determination of these limits, but they are given as a guide.

#### 24.2.2.6 Effect of frequency

The results shown in Figure 24.1 indicate that 50 or 60 Hz is almost exactly right to produce the maximum excitation of a nerve ending, but that the nerves could not respond to substantially higher frequencies. Radio frequency burns may be serious however and there are possible situations where such oversimplified rules might not apply.

#### 24.2.2.7 Respiratory arrest

Experience of electro convulsive therapy indicates that, in the absence of severe damage to the nervous system (which is rare), respiratory arrest from a shock involving only the head is unlikely to persist, unless presumably the shock has lasted long enough to cause a dangerous reduction of oxygen in the blood (anoxaemia). Since head shocks are very infrequent this is not of great importance. Even the possibility of asphyxia in persons unconscious from electric shock appears to be uncommon. However, there is experience that artificial resuscitation does aid recovery, although the reasons for this are obscure. It may simply be that some external massaging of the heart is sufficient to transfer enough blood around the brain to sustain life even if the blood is depleted in oxygen. The recommendation has traditionally been that when a person is unconscious and not breathing artificial resuscitation should be immediately commenced. Both works ‘first-aiders’ and electricians should normally be instructed how to do this since a medical diagnosis is rarely quickly available and prompt action is essential. Artificial resuscitation should be continued until breathing is resumed or for a minimum of 1 hour. (The operator should then stand by to give further help if breathing falters). Knowledge of the effectiveness of artificial resuscitation in practice is necessarily based largely on records of such action. There is an 85% chance of recovery provided that resuscitation has not been abandoned after a period of less than 1 hour. The patient should be under close observation for some time after recovery, as there is some danger of relapse.

### 24.2.3 Other injuries

#### 24.2.3.1 Acoustic shock

Accounts of the after-effects of lightning strikes frequently refer to temporary or permanent impairment of hearing and sometimes ruptured eardrums. This is in most cases almost

**Table 24.2** Approximate threshold shock voltages at 50 Hz a.c.

Minimum threshold of feeling	10–12 r.m.s.
Minimum threshold of pain	15 r.m.s.
Minimum threshold of severe pain	20 r.m.s.
Minimum threshold hold-on volts	20–25 r.m.s.
Minimum threshold of death	40–50 r.m.s.
Range for fibrillation	50 or 60–2000 r.m.s.

certainly caused by the intense acoustic shock wave sent out when a column of air (the lightning channel) rapidly expands on being suddenly heated to about 15000°C by the passage of the enormous current in a lightning discharge. The range of danger is probably limited to a few feet.

#### 24.2.3.2 Arc eye

This is a painful condition resembling pepper in the eyes and develops some hours after exposure (even momentary) to an intense source of ultraviolet light. It occurs mainly when a person works near arc welding and looks directly into the brilliant light given out by the electric arc.

Fortunately 'arc eye' lasts only a short time, no more than a day or two, and although painful leaves no permanent injury. Treatment is by the application of a soothing lotion.

This complaint is easily prevented by the use of protective goggles with side protection, as worn by welders. The usual victims are assistants and bystanders without goggles, although ordinary glass cuts out much of the ultraviolet light.

Theoretically there is a risk of a form of cataract caused by prolonged exposure to infrared light which affects persons who work for long periods on glass furnaces, etc.

#### 24.2.3.3 Fractures and torn muscles

Strains and fractures may arise from falls following an electric shock, e.g. from a crane or ladder. It may not be apparent at the time that the victim has suffered an electric shock and that the heart may be in fibrillation. If they are unconscious artificial resuscitation would be the advised first aid treatment.

#### 24.2.3.4 Burns and side effects

Burns are probably the most serious after-effect of electrical accidents. They are the principal danger with direct currents or at very low voltages (below about 80 V). With low alternating voltages shock is the typical injury although there may also be severe burning. At extra-high voltages shock may not be as important it being the actual current and flash burns which tend to be severe with large areas of the body affected. Severe electrical burns have led to many deaths, usually after several days or even weeks of painful suffering. Burns may be of several types:

**Contact burns** These occur when the person has touched a live conductor. They may be local and very deep reaching to the bone, or very small, being just an area of 'white' skin which may be easily overlooked at a post-mortem examination. The position of such small burns may be important in reconstructing an accident and should be recorded.

**Arc burns** These may be extensive, and of any degree, particularly when there has been a high-voltage flashover. Provided that the person survives the initial wound and surgical shock, and the surface area involved is not too large, they are likely to make a good recovery because the injury should be largely sterile. They may, however, be badly scarred or even lose a limb. The large fault current levels which now exist on many low voltage distribution circuits poses a serious risk of arc burns if a flashover is caused. There have been a considerable number of fatalities to electrical staff due to this cause, usually when they have attempted to work on live low voltage (230/400 volt)

busbars and switchboards without adequate training and proper insulated tools.

**Radiation burns** These burns arise from short-circuit arcing and are, in effect, a severe form of sunburn. Some radio frequency (RF) equipment can also impart burns which can be deep. RF burns usually occur due to contact with the charged conductor but this will depend on the power output of the equipment and the frequency.

**Vaporised metal** When an open fuse or small conductor fuses some copper (silver or tin) is vaporised and at close quarters this may burn or impregnate the face or hands. This is usually harmless unless it enters the eyes in which case the result is potentially serious.

**Deep burns and necrosis** There is the potential danger of deep burns destroying tissues below the skin even though superficially there is only a small injury. Thus electrical burns, and in particular high-voltage contact burns, must be taken seriously and the person kept under medical supervision. However, such burns are rare.

**Metal fume fever** This is caused by inhaling metal or metallic oxide fumes, e.g. by a welder working in an enclosed space.

### 24.2.4 Protection against electrical injuries

The obvious remedies for protecting personnel from electric shock, burns or radiation effects are to make live metal inaccessible and to keep persons separated from the dangerous plant, machinery or process. Another approach is to use protective equipment and defined work practices.

The Health and Safety Executive recommends many preventive measures in its various guidance documents but in particular it recommends the following through its Memorandum on the Electricity at Work Regulations 1989:<sup>7</sup>

- Using low (and safe) voltage.
  - Insulating and/or enclosing live parts.
  - Preventing conducting parts not normally live from becoming live by one or more of the following:
    - (a) earthing and automatic disconnection of the supply,
    - (b) double insulation,
    - (c) separating the supply from earth, and
    - (d) limiting electrical energy.
  - Selecting equipment suitable for the environment in which it is to be used.
  - Using equipment as defined in the maker's instructions.
  - Ensuring that electrical equipment is adequately maintained.
  - Avoiding the use of electricity altogether where its use would be dangerous.
- The following aspects are also worthy of note:
- Metalwork in the vicinity of functional conductors may become live by electromagnetic or electrostatic induction. Serious or fatal shock is unlikely on most circuits although some serious accidents have occurred due to mutual induction on parallel running power lines.
  - When work is to be carried out on (dead and isolated) high voltage power equipment conductors these conductors should be earthed. Potentially dangerous electric charges may otherwise accumulate on unearthed conductors either from the slow release of charge from the high

voltage insulation (dielectric relaxation) or from induction from adjacent circuits.

- It is possible to receive severe shocks from leakage over the surface of insulation at quite low voltages, e.g. 230 volt. Contamination of the surface of insulation by moisture and conductive salts can give rise to dangerous levels of surface leakage currents.

### 24.2.5 Toxic hazards

Toxic hazards arise as indirect results of electrical accidents. In this category are the hazards associated with the use of polychlorinated biphenols, which have been used in place of mineral oil in transformers, and those associated with carbon monoxide poisoning from incomplete combustion of insulation or oil.

Care is also needed in the handling of sulphur hexafluoride (SF<sub>6</sub>) which has been degraded by arcing since toxic by-products may have been produced.

### 24.2.6 Conclusions

Electric shock is not a single simple phenomenon and is not perfectly understood. The majority of electrical accidents occur at the common domestic and commercial electricity supply voltages, i.e. 230 and 400 volts, and a high proportion of electrical accidents are serious or fatal. Artificial resuscitation for persons unconscious after a shock is effective and should be continued for at least one hour or until hospitalisation.

Electrical burns may cause death in extreme cases where they are extensive. In other cases however, although they may be deep they are largely sterile and therefore tend to heal quickly and well, although they may leave scars. Damage to muscles may be serious and amputation may be necessary in very bad cases. Attention should be paid to small burns caused by contact with high-voltage conductors because there may be serious deep-seated damage (necrosis) which is not visible.

## 24.3 Failure of electrical equipment

### 24.3.1 Causes

There are two fundamental causes of failure of electrical equipment, mechanical failure or electrical failure of insulation.

#### 24.3.1.1 Mechanical causes

The safety of electrical equipment depends to a large extent on sound mechanical design. The majority of circuit-breaker failures are mechanical rather than electrical in nature. Typical faults are loose joints leading to overheating or arcing and the existence of voids and contamination in insulation causing arcing and breakdown products. Where the insulation is bulk oil the products of arcing are themselves highly flammable (acetylene for example) and have often led to explosions.

Fractures may be caused by resonant vibrations of current carrying conductors either from purely mechanical movement or from electromagnetic forces leading to fatigue hardening and subsequent breakage. Where metallic elements are stressed in a corrosive atmosphere (e.g. damp or polluted atmospheres) along with alternating forces, failure

may occur at comparatively low stress. Some steels, which under normal conditions exhibit considerable ductility, will fail at low temperatures by brittle fractures with no ductile deformation.

Mechanical failure of insulators may displace conductors and cause short circuits. Ceramic insulators are brittle but have great strength in compression. However ceramic insulators are vulnerable where they are used in tension or shearing situations. They are now largely confined to outdoor overhead lines and switchgear where their robust construction makes them less susceptible to mechanical failures although they are then vulnerable to vandalism.

#### 24.3.1.2 Breakdown of insulating materials

The electrical breakdown of insulating materials may also occur as follows:

- Mechanically, as by friction or tearing.
- As a result of excessive electrical stress.
- As a result of excessive temperature (and occasionally very low temperature) or temperature cycling. The latter may cause mechanical stresses as a result of differential expansion or contraction.
- Chemical and physical reaction with other materials, e.g. oxidation, contamination or the leaching out of important ingredients which may lead to de-plasticisation, i.e. they become brittle. The ingress of water is a very common contamination leading to 'treeing' and eventual electrical breakdown.

Failure is rarely the result of inadequate electrical breakdown strength where reasonably pure materials are used. In practice, insulation is rarely designed to be stressed to more than 10% of its strength as determined by laboratory tests. It fails because of impurities, lack of homogeneity, the unavoidable variations in commercially available materials as well as in those natural products such as paper, wood and petroleum products. The insulation performance of most commercially used materials is now well documented and standard testing procedures have been established.

### 24.3.2 Particular equipment

#### 24.3.2.1 Switchgear

Hazards associated with switchgear failure include fire, explosion and electric shock. There is a particular risk to the technical staff who require to operate high voltage switchgear and to conduct testing and maintenance on this equipment. Unfortunately oil circuit breakers and fuse switches have been the cause of many serious accidents and fatalities have not been rare. Some of the most expensive fire losses have also been caused by switchgear.

An important proportion of these accidents and losses are caused by failure of circuit breakers to operate correctly but many accidents are caused by mechanical problems with auxiliary equipment such as isolators and from failure of routine and emergency operating procedures. The causes of high-voltage switchgear failures are typically as follows.

- Poor maintenance leading to contamination of insulation and loose connections etc.
- Incorrect or inappropriate use of test equipment on live equipment.
- Unrestricted repeated operations of oil circuit breakers (OCBs) leading to breakdown of the oil insulation and/or to contact collapses.

- Hesitant operation of manually closed switches onto faulted circuits leading to panic opening on fault and the consequent fault arc drawn at the contacts of a non-rated switch.
- Failures of PTs (potential transformers, often referred to as VTs or voltage transformers) and failures of CTs (current transformers).

#### 24.3.2.2 Transformers

Fires and explosions in oil-immersed power transformers have been less common than in oil-immersed switchgear and the immediate results are, on the whole, less damaging. However, because of the large amount of oil which may be released and ignited, oil-immersed transformers are potentially at least as dangerous and the consequences in terms of loss of power availability and pollution can be considerable.

Most discussions of transformer failure relate to interturn faults and their causes, but these cause a comparatively small number of fires, etc. Many incidents are generally associated with automatic tap-changing gear, while bushing failures, flashover and arcing at the transformer top, etc. (including some lightning damage) cause about the same number of incidents. Major transformer failures are comparatively rare events.

The main dangers are the spread of fire by the release of a very large volume of burning oil and the emission of clouds of black smoke but there may be secondary hazards such as plant being stopped by damage to cables and protection, control and alarm equipment even when the fire itself was not initially very large.

Typical failures and their causes are described below.

*Lightning and voltage transients* These may cause external flashover of bushing insulations which may shatter or split oil-filled insulators, causing fires. If the voltage surge reaches a transformer winding it may cause a flashover above the oil and damage the winding insulation.

*Internal flashover above oil* This can be caused by voltage transients as described above but there are other causes which are more easily eliminated. These are arcing caused by fractured conductors, sparking at loose connections, and badly made joints which provide ionisation above the oil level. Hot joints and connections are also suspected causes.

*Interturn faults* Whatever the cause such faults are likely to develop slowly. The volts per turn are normally quite low (say 5–20 V for transformers below 2 MVA) and will not sustain continuous arcing until a number of turns become involved but this may not apply where, in modern transformers, coils and turns are interleaved without spacers to improve surge voltage distribution. Overheating can be caused by short-circuited turns. Failures may go undetected by conventional protective relays as there is likely to be no significant change in through current. However some interturn faults can be detected by certain forms of monitoring and testing.

*Failure of the insulation of the magnetic circuit* Such failure, e.g. of core frame, or clamping bolts, or between laminations, can allow parasitic eddy currents and local heating. The former may cause sparking and the evolution of arc gases. Such faults do not lead to immediate danger but contribute to the deterioration of insulation and oil. Also an accumulation of arc gas (particularly  $H_2$  and  $C_2H_2$ ) in the airspace above or dissolved in the oil is a

concealed explosion risk. Other faults which occur from time to time are due to poor hygiene and untidiness during manufacture and maintenance. Nuts, bolts, cut-off ends of wire and even spanners have been found wedged between windings. These can cause local stress concentration and heating with possible mechanical damage to insulation.

*Overloading and 'through' faults* These will overheat the windings and cause cumulative damage to the insulation. They may not cause immediate danger unless they persist but the life of the transformer will be shortened.

There are advantages in using sealed transformer tanks. Experience indicates that in the absence of air (oxygen) the oil deteriorates much more slowly and less maintenance is necessary. There are drawbacks however. Unless there is an adequate space above the oil, which can be filled with inert gas, e.g. nitrogen, special means must be provided to allow for the expansion of the oil with rise of temperature, otherwise the tank may fail under the hydrostatic pressure developed. For this purpose internal 'bellows' or flexible diaphragms are sometimes provided.

Also, a sealed tank, unless it has a separate expansion chamber or conservator at the top, cannot be fitted with a Buchholz relay and it may be impossible to give full protection against slowly developing faults. A sealed tank should therefore be provided with a bursting disc or similar device as a major fault between phases or to earth, caused by lightning, fractured conductors, loose connections, etc., may otherwise cause the tank to rupture or the lid to be sprung before differential or overcurrent relays have time to operate the circuit-breakers.

Such faults are rare, and it may be that there are situations where the risk can be accepted, but this would not be the case for very large transformers, transformers in occupied buildings, or high fire-risk situations.

#### 24.3.2.3 Cables and installations

Traditionally, high voltage distribution cables, if they were buried in the ground, were impregnated paper (tape) insulated, lead covered, steel wire armoured and served (i.e. protected with a sheath of material resembling bitumen impregnated sacking) and frequently further protected by ceramic tiles a few inches above the cable. Modern cables comprise plastic materials with metal extruded or wire armouring. Cables often have a life measured in many decades and many cables of early style construction may be found in use, particularly on public electricity distribution systems.

Medium voltage (400/230 V) distribution cables were steel tape armoured but sometimes tough rubber or similar sheaths were used in ducts. Such cables pose a very low fire risk. Modern cables mainly use plastic insulation. The main hazards are:

- Burst cable boxes at transformers, switchgear and other joints. Link, or street mains disconnecting, boxes which use the traditional bitumen insulation have been the subject of many incidents of failure, mainly due to voids in the bitumen, water ingress and to loose connections.
- Puncture by pneumatic road drills which causes short circuits and a shower of sparks, but which is often more alarming than dangerous because the sheath and armouring provide an efficient earth-return path. There have been incidents of serious burn injuries too however, the severity of the arcing being dependent on the power fault level of the transformers feeding onto that particular circuit. In cities these fault levels are often very high.
- The spread of fire in ducts or tunnels.

The evolution of clouds of black smoke from cable oil is a serious hazard because it hampers effective fire extinguishing operations, contaminates buildings and may result in the need for extensive cleaning and renovation work.

Although plastic insulation and sheaths such as polyvinyl chloride (PVC) are now common, and difficult to ignite, they will nonetheless burn if in adequate bulk and sufficiently preheated locally. However, when ignited PVC produces clouds of dense black smoke, as do some 'rubbers'. There is then a substantial liberation of hydrogen chloride, which may corrode sensitive electrical equipment, e.g. in telephone exchanges and computer departments, and steel reinforcement bars in concrete.

Important cable tunnels should be provided with fire detection and monitoring equipment and possibly fixed fire extinguishing installations.

The relative positions of power, telecommunication, control, and alarm and safety circuits must be considered, to ensure that power short circuits and fires do not damage safety circuits.

Cable tunnels are perhaps more vulnerable to fortuitous 'external' fires than to short circuits, etc. The experience of the London Underground system shows that cable fires along the tunnels are likely to result from accumulation of rubbish ignited probably by sparks from the collector shoes of passing trains.

Inside industrial buildings, cables are usually drawn into conduit or laid in ducts or on trays. The possible spread of fire must again be considered. Attention must also be paid to the possibility of damage by vehicles such as forklift trucks and cranes.

Supply to 'island sites' in a work area presents difficulties. Under-floor ducts are subject to flooding and the entry of rubbish, flammable liquids and vapours. Overhead distribution busbars along a line of machines are frequently used, particularly where the position of machines may be changed at short notice when there is a change of product or method. The conductors are usually, but not invariably, covered with insulation, except at fixed points where provision is made for tapping off, and the whole assembly of busbars is enclosed in suspended metal trunking with provision for 'plug and socket' attachments or spur switch and fuse combinations. The construction must be considered in relation to possible damage by cranes, forklift trucks, etc., and the entry of water from a leaking roof or sprinkler systems.

It is preferable to make the connections to individual machines by cables with a flexible outer metallic screen, pliable armoured cable or by flexible conduit.

### 24.3.3 Protection against failure

#### 24.3.3.1 Earthing principles

Earthing is a complex subject. Its complexity should be apparent from a cursory reference to the current British Standard on the Code of practice for earthing which runs to 84 pages.<sup>8</sup> In the context of the safety of most electrical installations however there are three main points to be made.

- It prevents the outer conductive casing of apparatus and conductors from assuming a potential which is dangerously different from the surroundings for any appreciable length of time although if a fault does occur inside the equipment the outer casing may actually be raised to a dangerous potential momentarily.

- The earthing connections must be sufficiently robust and conductive to allow sufficient current to pass safely in order to operate overcurrent or other protective devices promptly, including those for earth-leakage protection. Protective devices must be suitably rated for the fault currents which might be expected.
- Care must be taken against the occurrence of dangerous earth-potential gradients due to fault currents flowing in the terminations made to the general mass of earth. The 'resistance areas' of the earth electrodes of different systems should not be permitted to overlap to any significant degree. The purpose of this is to prevent faults on one system imposing dangerous voltages onto the protective (earthing) conductors of other systems.

Earthing is also used for functional purposes, for signalling and draining leakage currents. The needs of these uses can sometimes conflict with the safety objectives of earthing.

#### 24.3.3.2 Interlocks and guards

Different classes of guards are described below.

*Fixed guards* By virtue of their position, these prevent access to dangerous parts.

*Automatic guards* These move in advance of each operation or stroke of a machine and sweep or push the operator's arm or person out of the way before the stroke is made, or automatically take up a position similar to a fixed guard before the danger can arise. They are sometimes used where material or blanks are fed by hand into the machine. They are best combined with trip guards, but are largely being replaced by interlocked guards.

*Interlocked guards* These guards are moveable and whose movement is interconnected with the power or control system of the machine. They must be correctly adjusted before any potentially dangerous operation can commence.

*Trip guards* These stop the machine or automatically cause other appropriate action to be taken immediately danger arises. They can often be combined to advantage with automatic guards or with positional and distance guards.

*Positional and distance guards* These are often a rather elementary form of fixed guard, so placed as to keep an operator or other person at a safe distance from a machine which cannot be enclosed because of the nature of the material being handled or the work being done.

*Electrosensitive safety devices* 'Curtains' of interlaced light beams are used extensively on machines such as power presses, bending brakes and guillotines, where the size and shape of the workpieces prevent complete enclosure with fixed guards. The risk of failure with such machines can lead to serious injuries of amputation and crushing so this demands that the design of these guards be a specialised matter with check circuitry and timing requirements to prevent failures to danger. There are international Standards which specify the safety integrity for these devices.<sup>9</sup>

#### 24.3.4 Fires and explosions

Electrical installations are often cited as the cause of fires but this is probably due in large part to the difficulty in determining the actual cause of many fires. In effect electricity is an

easy candidate for blame in cases of doubt when the more likely causes probably lie with carelessly discarded smoking materials and other banal causes. However electricity can cause fire in a number of ways.

Serious overloading is necessarily a fire risk, since most insulating materials are in some degree flammable (ceramics, minerals such as asbestos or alumina, and mica being the chief exceptions). Overloading or resistive heating at poor electrical joints and connections may also ignite other flammable material in the immediate neighbourhood, for example wooden and similar panelling over cable runs has caused disastrous fires in shops, theatres and other entertainment centres. A common cause of fires however arises through the inappropriate use of electrical heating appliances which simply radiate heat into materials until they ignite. Radiant electric fires, convector heaters, electric irons, cookers and incandescent lamps are involved.

Fires are also caused through arcing or sparking release of electrical energy. The use of electrical equipment in areas where flammable or explosive atmospheres may exist is the subject of extensive expertise and availability of specialist apparatus. Coal mines (which have firedamp, i.e. methane), oil refineries and chemical plants, are examples where this specialised apparatus is required. In the EU it is also the subject of the ATEX directive 94/9/EC.

## 25.1 A brief UK history

In the early days of coal mining (with candles or oil lamps as the only form of lighting) it was soon learnt that explosions could be caused if an accumulation of gas occurred when working a coal seam. It was also soon realised that the gas tended to collect along the top of the tunnels, so someone (the original fireman!) had the unenviable job of crawling along the tunnels in advance of the miners, carrying a candle on the end of a pole (*Figure 25.1*). They could reach to the roof and if gas was present at that level, it would hopefully be ignited and burnt off without major problem, thus rendering the area safe to work in. This system was by no means foolproof, and on occasions when a large concentration of gas was encountered there could still be a major fire or explosion. The Davey lamp was the first major step forward in this situation. Its design was such that the flame within the lamp would not propagate through the metal gauze surrounding it so it would not ignite the surrounding atmosphere. At the same time, the colour of the flame showed when the explosive gas was present, so giving a good warning to take extra precautions.

With the advent of electricity and resultant mechanisation, more thought was needed in guarding against the ignition risks from electrical or frictional sparks or hot surfaces, and a major mining disaster around 1913 served to focus attention even more on the risks. Around this time the safety in mines research establishment (SMRE) was formed, and located near the small village of Eskmeals on the Cumbrian coast, but hopefully far enough away so as not to disturb people with any test explosions which occurred.

In the mid 1920s SMRE moved its testing facilities to Buxton in Derbyshire, again placed on a hill out of town so that any explosions would not worry the neighbours. In mining, both flameproofing and intrinsic safety gained ground as accepted protection techniques, in combination with forced ventilation to keep the gas concentration below explosive levels whenever possible. At the same time as

SMRE assisted with the safety of equipment in the mines, the board of trade (BoT) looked after the safety of surface industries such as chemical works and oil refineries. As electrical installations became more complex, a system of issuing certificates for both apparatus and intrinsically safe systems was developed, to ease the job of inspectors checking an installation. The first standards used were some early British Standards such as BS 229 and BS 1259, which were very brief and general in their wording, so that they almost let the certifying officer make up his own rules for certification. At this time (the 50s and 60s) the certification was still carried out by the factory inspectorate, and gradually the proliferation of electrical installations led to increasing delays in inspecting sites. In 1967 the British Approvals Service for Electrical Equipment in Flammable Atmospheres (BASEEFA) was formed to take over the basic certification of apparatus from the factory inspectorate and so ease their load.

In the early 70s BASEEFA produced its own more detailed standards, in particular for intrinsic safety, special protection, and gas detectors using pellistors (both for explosion protection and for performance). Then in the mid 70s, the major explosion and fire at Flixborough focused attention even more on the need for safety in electrical equipment, the influence of the European Union was gaining ground, and a series of harmonised standards (the EN 50014 to EN 50020 series plus one or two others) was evolved for use by all the member states. These standards were published in 1977 in the UK by BSI, as BS 5501 Parts 1 to 7 and others.

When BASEEFA was first set up the certification went hand in hand with a licence to reproduce the BASEEFA mark, which in turn was conditional on the manufacturer having an acceptable quality control system in place to ensure the certified equipment was made correctly. Also with the advent of the EN 50014 series of standards, there was a general comment in them which placed a responsibility on manufacturers (and arguably on certification bodies too)

**Figure 25.1** Fireman igniting firedamp. Illustration courtesy of HSE

to ensure product was made correctly. The BASEEFA licence was issued in conjunction with a surveillance visit (or audit) as a third party check on production quality. Whilst such audits were common with regard to American organisations such as Factory Mutual (FMRC) or Underwriters Laboratories (UL), they tended to be the exception in Europe, with BASEEFA being possibly the only certification body carrying out such visits, and pressure mounted from some quarters for these audits to be drastically reduced if not phased out completely. However, at least one of the large user companies became very dissatisfied with the acceptability of goods it was receiving from various companies both in the UK and the rest of Europe, and so led a push to reinstate and reinforce the quality audit situation. The problem was not poor quality of equipment, but that well intentioned changes to the design to improve functionality or ease manufacture sometimes resulted in non-compliance with the strict interpretation of the standards and hence invalidation of the certificate. The worry was that sooner or later such a problem might go beyond a technical non-compliance and actually result in an unsafe piece of equipment being installed somewhere. This resulted in BASEEFA launching its conformity assurance programme for quality auditing. Now as we enter the 21st century quality control in general has achieved prominence, and the new ATEX directive legislation has introduced a clear quality module into the certification process, so that quality requirements will be recognised and enforced throughout Europe. This is mentioned again later on.

For many years various testing and certification bodies throughout the world have met at regular intervals to exchange knowledge and experiences, and this has led to a gradual convergence of the various explosion protection standards. The latest editions of the EN 50014 series of standards (now numbered by the British Standards Institution as BSEN 50014, etc.) are the basis for ATEX directive certification, and greater alignment is also being achieved with the IEC 60079 series of standards which will eventually open the way for global certification with the IECEx scheme. One immediate advantage to users of certified equipment is that the marking of apparatus will become very nearly the same anywhere in the world. These will be mentioned in more detail later in this chapter.

## 25.2 General certification requirements

Most countries in the world have government regulations, or general requirements laid down by insurance companies, or both, requiring workplace managers or owners to take reasonable precautions to ensure the safety of their employees and the general public. For example in UK there is the health and safety at work act 1974 plus the working regulations 1996 act, or in the USA, OSHA (the Occupational Safety and Health Administration) which is one of the US Government Agencies.

The need for using certified apparatus in a particular situation depends on several factors, such as the quantity of flammable material present, how the material is handled and contained, what ventilation exists, and how large the work area is in comparison to the quantity of flammable material.

The explosion triangle shows the elements needed to create an explosion (*Figure 25.2*). The first obvious means of explosion protection is to keep ignition sources away from the flammable material. The next can be to ensure that there

Figure 25.2 The explosion triangle

is plenty of ventilation, so as to keep the air fuel mixture below the lower explosive limit. Some people would suggest that ensuring air is totally excluded so that there is always 100% fuel is also a 'safe' situation to aim for, which in turn would allow invasive probes to be included directly into the process system without any need to use certified types. This is debatable; as although some countries' test authorities will accept it as a safe situation, others would argue that you could well at some time run into a potentially explosive situation if there was a problem with the process and air entered during the repair period. Then great care would be needed when refilling the system to ensure all air was flushed out before re-energising any non-certified invasive probes.

As mentioned earlier, in mining, forced ventilation is used to dilute any gas and keep the mixture well below the explosive limit. In surface industries, natural ventilation may be sufficient much of the time, especially if the work area is large compared to the amount of flammable material being handled. Another factor in siting equipment can be the density of the flammable mixture, which would determine where the mixture might concentrate most (floor or ceiling). For further guidance on assessing the disposition of hazardous areas, see BSEN 60079-10.

The probability of an explosive atmosphere being present is based on a system of zoning.

*Zone 0* is where a hazardous (or explosive) atmosphere may be present continuously or for long periods, for example within or immediately around a vessel containing a flammable liquid, or within the pipework of some process.

*Zone 1* is where the explosive atmosphere may be present in normal operation, but for a more limited period of time. This could be where (normally sealed) containers of flammable liquid are kept and at regular intervals the liquid has to be poured, thus releasing vapour into the surrounding atmosphere. A common rule of thumb is to say if the vapour is likely to be present for less than around 100 to 1000 hours per year then this constitutes a zone 1 area as opposed to zone 0.

*Zone 2* is where an explosive atmosphere is not normally present but could occur under fault conditions. This could be a storage area where the flammable material is kept in sealed containers, but spillage could occur if a container was accidentally dropped and ruptured.

In America and Canada, the area classification up to now has been by division. In this system division 2 is very similar to zone 2, but division 1 encompasses both zone 0 and zone 1.

The zoning system is beginning to be used with the advent of the latest standards discussed later, but it remains to be seen how long it takes to gain general acceptance in those countries.

### 25.3 Gas group and temperature class

The next factor which comes into play is the sensitivity of the explosive atmosphere to possible ignition sources. Materials are classified by minimum ignition energy (m.i.e.) based on how easily they will ignite due to a spark, maximum experimental safe gap (m.e.s.g.) based on how easily they will transmit a flame through a small gap, and auto ignition temperature based on how easily a hot surface can ignite them. The m.i.e. and m.e.s.g. tend to go fairly closely together. For example hydrogen is the most onerous gas in this respect, and both the permitted energy in intrinsically safe equipment and the permitted gaps in flameproof equipment are the smallest. The auto ignition temperature, however, tends to work independently. Using the hydrogen example, its ignition temperature is around 560°C, so hot surfaces are not a particular problem, whereas many other explosive mixtures could be ignited by temperatures around say 250°C or 300°C.

The gases, based on m.i.e. and m.e.s.g. are classified into subdivisions which align with the apparatus groups shown in Table 25.1. BSEN 50014 and BSEN 60079-0 both contain information on the subdivisions of many compounds, and includes IEC/TR3 60079-20 also include auto ignition temperature information for a large range of compounds. The auto ignition temperature is used to determine the suitability of apparatus for use with a particular gas, by reference to the apparatus temperature class. For compounds not listed, the health and safety laboratory or other specialist laboratories may be able to provide advice or testing to allocate the material to the appropriate group or temperature class.

In the USA and Canada the group marking usually lists all the group letters applicable, such as 'for group D' or 'for groups A, B, C and D', whereas in the group marking for European or IEC, a mark of IIC automatically implies that the apparatus is also suitable for IIB and IIA, and IIB implies suitable for IIB and IIA.

Note that acetylene is listed separately in the Table 25.1 the reason for this will be explained when discussing flameproof equipment later in this chapter.

Temperature class sometimes causes confusion, so hopefully this explanation will help to clarify things. The temperature class marked on a piece of apparatus gives indication of the likely maximum temperature which will be reached in service (either in normal operation or under certain fault conditions). In the absence of anything more than the temperature class, the implication is that this will

Table 25.1

Representative gas	Group (European or IEC)	Group (USA and Canada)
Acetylene	IIC	A
Hydrogen	IIC or IIB + H2	B
Ethylene	IIB	C
Propane	IIA	D
Methane	I	

Table 25.2

Temperature class	Temperature of apparatus (°C)
$T_1$	450
$T_2$	300
$T_3$	200
$T_4$	135
$T_5$	100
$T_6$	85

be the maximum temperature of the apparatus when located in a surrounding ambient not exceeding 40°C. For other ambient temperature ranges and extra marking such as  $(-20^{\circ}\text{C} < T_a < 60^{\circ}\text{C})$  will be included. Now the gas mixture of concern will have either a suitable temperature class or an auto ignition temperature (or both) shown, and provided the temperature class of the apparatus is equal to or 'better than' that for the gas mixture, then the apparatus is suitable. For example, if a gas mixture was shown as requiring  $T_2$ , then apparatus of  $T_2$  up to  $T_6$  would be suitable, but not  $T_1$ , or if the mixture was quoted as having an auto ignition temperature of 180°C then apparatus of  $T_4$ ,  $T_5$  or  $T_6$  would be suitable, but not  $T_1$  to  $T_3$ .

In America and Canada, when working to their earlier standards, some temperature classes may be further subdivided with a suffix, such as  $T_{2A}$  to  $T_{2D}$  which refer to intermediate temperature steps. They are omitted from this description for simplicity, but full details can be found if required on the appropriate websites.

### 25.4 Explosion protection concepts

Table 25.3 repeats the zoning mentioned earlier and shows the types protection permitted in each zone.

#### 25.4.1 Intrinsic safety 'i' (which may be subdivided into 'ia' or 'ib')

This technique is used mainly for electronic equipment such as level, density or temperature transmitters, toxic or combustible gas detectors, or proximity detectors, or portable radio transceivers. The power levels involved are relatively small, usually less than 1.3 W, but in some cases up to around 5 or 6 W. For fixed apparatus fed from a separate power source, both the hazardous area apparatus and the

Table 25.3

Zone	Division	Suitable type of protection	ATEX category
0	1	'ia' 's' when specified as being suitable for zone 0, mixed concepts covered by BSEN 50284 (only used in ATEX certificates)	1
1		'ib', 'd', 'e', 'p', 'q', 'm'	2
2	2	'n', 'N'	3

power source itself are designed so as to ensure that under fault conditions, any spark energy or surface temperature is insufficient to cause an ignition of a surrounding explosive atmosphere. The spark energy has an extra safety factor applied to it, and the temperature is assessed under worst case fault conditions to provide a safety factor there also. The power source may be a custom designed power supply or control unit, or a general purpose zener barrier or repeater power supply. 'ia' relies on a two fault analysis and is suitable for use in zone 0, and 'ib' relies on a one fault analysis and is suitable for zone 1. This type of equipment may also be self contained battery powered (*Figure 25.3*).

For the fixed installation with separate power supply, the cabling linking the two is specified in terms of capacitance, inductance and inductance to resistance ratio, but otherwise can be almost any lightweight cable, which can save on installation costs. Also the equipment tends to be very light and manageable in comparison with other protection concepts, because the enclosure is basically only required to keep the circuitry clean rather than being a vital part of the protection concept. Another advantage is that 'live maintenance' is possible, whereas with other protection concepts the equipment usually must be de-energised before any work is carried out. The consideration to be offset against this is that both the power source and the hazardous area equipment must be certified, and in general only equipment operating at 30 V or lower and 5 W or lower is available.

This equipment is sensitive to gas group, and may be certified for IIC, IIB, IIA or I. As hot surfaces may be present, the temperature class also needs checking against the gases present where it is used (*Figure 25.4*).

#### 25.4.2 Flameproof enclosure 'd'

This technique is often used for such things as luminaires, valve actuators, high powered control units and heavy duty

motors and pumps. It is also used for level, density or temperature transmitters of similar size to those certified 'i', but in situations where for various reasons the user happens to prefer the 'd' concept. In this technique the enclosure is designed to be strong enough to contain an internal explosion, and with covers, cable glands, etc. arranged such that any gaps (or flamepaths) to the outside world are small enough to ensure that the internal explosion will not be transmitted to the surrounding atmosphere. Testing for non-transmission and the pressure test both have an extra safety factor applied compared to normal operation, to give the required integrity. The obvious advantage compared to 'i' is that high powered equipment operating up to several hundred volts can be protected 'd'. To be offset against this is that even small equipment can be relatively bulky and heavy, and the cabling always needs to be well protected, either by use of armoured cable or by use of conduit or other mechanical protection (*Figure 25.5*).

Acetylene is dealt with as a separate item in the flameproof standards because it has a unique characteristic compared with other flammable or explosive mixtures which causes problems with this equipment. If the acetylene mix is very rich, it produces carbon particles, and whilst a properly dimensioned plain flange will stop normal flame propagation, it does not prevent incandescent particles being ejected. Thus acetylene requires the use of such things as spigot joints or threads to provide added integrity.

This equipment is also sensitive to gas group, and may be certified for IIC, IIB, IIA or I, and again the temperature class needs checking for suitability. With this type of equipment, the temperature of internal components may be much higher than the external surface of the enclosure, which is permissible in normal use, but can result in extra conditions being imposed when it is necessary to open the equipment, such as de-energising and waiting a specified minimum time before opening.

**Figure 25.3** An example of a battery powered hand held intrinsically safe instrument. Photograph courtesy of Ion Science Ltd

**Figure 25.4** EEx 'ia' field-cased pressure transmitter (courtesy of WIKA Instruments Ltd)

### 25.4.3 Increased safety 'e'

Typical equipment here includes luminaires, induction motors, pumps, etc. This technique relies on ensuring that all components are run well within their capabilities so as to avoid hot surfaces, and connections are arranged to be of high reliability so that they will not produce sparks. Again the advantage here is that high powered equipment can be protected this way, the weight and bulk tends to be somewhat less than 'd' equipment, but still the cabling needs to be well protected.

This equipment is not sensitive to gas group as it is essentially non-sparking, so the group marking is likely to be just II implying any gas group, however the temperature class may still vary and so need checking against the gases present in the location where it is used (*Figure 25.6*).

### 25.4.4 Purged and pressurised 'p'

This technique relies on keeping the explosive atmosphere away from the live electrical circuits, by dilution with air or inert gas. Depending on the nature of the equipment being protected, either the unit may be a sealed enclosure (with probably an air or inert gas bottle attached) with a very low leakage rate, or it may be deliberately ventilated by means of a fan bringing in air from a 'clean' location. In each case the technique relies on monitoring the internal pressure of the unit, or the flow rate, or both, and cutting off the electrical supply to the unit if the pressurisation fails. When starting up the system it is necessary to monitor the pressure and/or flow and ensure the enclosure is up to pressure and has been flushed 'clean' (or purged) before re-energising the electrical circuits. The control equipment is often used in conjunction with some 'i' or maybe 'd' circuits, to enable fully automatic start-up.

Basically while the pressurisation system is operating, neither the gas group nor the temperature class are of any consequence in respect of the items within the enclosure, but clearly any residual high temperatures will be of concern if the system fails, and any associated 'i' or 'd' equipment will need to be chosen to suit the gasses involved (*Figure 25.7*).

### 25.4.5 Quartz filled 'q'

This technique uses quartz filling around the hot or sparking components to prevent spark emerging into the surrounding atmosphere and to keep external temperatures to a suitable level. This seems to have found some favour in Germany, but has not particularly been used in the UK so far.

Again this technique is not gas group sensitive, but the temperature class needs consideration.

### 25.4.6 Oil immersion 'o'

With oil immersion, the sparking or hot parts are totally covered in an oil bath. Again this technique is not as popular as other methods of explosion protection, although there are some situations where it is the only practical alternative.

Again this technique is not gas group sensitive, but the temperature class might need consideration. One possible disadvantage is that the oil itself is flammable, and there have been incidents where the oil has ignited under severe fault conditions.

### 25.4.7 Encapsulation 'm'

This relies on the circuits being covered with a certain depth of encapsulating material. For this technique the encapsulant has to survive various tests to prove its durability, and ability to survive the possible temperatures in the encapsulated circuit.

This technique is not sensitive to gas group but always carries a temperature class.

### 25.4.8 Non sparking 'n'

This technique is suitable for zone 2 only and uses a combination of suitable enclosure, adequate rating of components, temperature limitation, and non-sparking circuits (such as sealed relays) and if necessary energy limited circuits where any spark is non-incendive, or enclosed break components (which are similar to flameproof, but accepted on the basis of passing a test for non-transmission

**Figure 25.5** Sectional illustration of an EEEx 'd' induction motor (courtesy of Invensys Brook Crompton)

of an ignition, but without any specific minimum mechanical requirements). The philosophy is that once the requirements of the standard are complied with, then the chances of a fault occurring in the apparatus at the same time as the explosive atmosphere is present are so small as to be ignored.

The gas group marking may be II or IIA, IIB or IIC depending on whether or not the equipment incorporates energy limited circuits or enclosed break components, and there will also be a temperature class.

#### 25.4.9 Special protection 's'

This standard is unlikely to be used in future. The UK version was a BASEEFA standard which contained various extra tests and guidance to enable certification of apparatus which did not exactly fit the other standards in existence at the time, but could be shown to be of 'equivalent' safety. It was a national standard, with each European test house having its own similar version, but entailed re-certification in each country where the apparatus was used. It was introduced in 1972 in the UK and updated in 1985, but since then some of the principles in it have been incorporated into later versions of the flameproof Standard BSEN 50018, and into EN 50028 for encapsulation 'm'. Also the introduction of BSEN 50284 along with ATEX has come along, so that the standard is now very close to becoming redundant, as most if not all equipment may now be covered for use throughout Europe by means of the newer harmonised standards, or directly against the EHRS of the ATEX directive.

#### 25.4.10 Mixed concepts

There are some situations where, for various reasons, a piece of equipment is protected by more than one technique. The most likely combinations which will be seen in practice are 'di' or 'id', 'd[i]', 'emi', 'de' and 'n[i]'.

The [i] combinations are often used to enable intrinsically safe barriers or repeaters to be mounted in a 'd' or 'n' enclosure. The interior of that enclosure then counts as a safe area for the barriers and the enclosure can then be located nearer to the instrumentation which the barriers feed than might be possible by relying purely on mounting them in the main safe area.

A common practice is to fit a 'd' motor with an 'e' terminal chamber, to save a little weight. In this situation, the motor and terminal chamber might each carry their own certification, or there might be just one certificate for both, coded 'de'.

The other combinations involving 'i' may occur for a variety of reasons. One example is a gas detector using a pellistor element. The pellistor element uses a catalytic effect to 'burn' the surrounding gas and usually needs to be contained in a 'd' enclosure in order to prevent the flame propagating to the surrounding atmosphere. At the same time the remainder of the circuit often can be certified 'i', so that the equipment is coded 'di' or 'id'. Other examples could be various forms of gas analysers or detectors, or maybe smoke or vapour cloud detectors, where for technical reasons sufficient power is required in the main circuits that they need to be 'd' or 'em', but for ease of maintenance the sensors themselves and maybe their calibration adjustments are 'i' so that they can be exchanged or adjusted at

**Figure 25.6** EEx 'e' Zone 1 emergency luminaire (courtesy of CEAG Crouse-Hinds)

**Figure 25.7** Main features of a pressurisation installation (courtesy of Expo Safety Systems Ltd)

**Figure 25.8** Example of a mixed concept apparatus which aids routine maintenance and adjustment. The circular threaded cover allows entry to a flameproof chamber and so must only be opened when de-energised, and under any other specific conditions which might be stated on the unit or in the associated documentation. The chamber contains only intrinsically safe circuits, thus permitting it to be opened at any time to allow access to, and live adjustment of, calibration or alarm setting controls, but subject of course to any extra operational conditions laid down by the manufacturer. Photograph courtesy of Servomex Group Ltd

any time without having to de-energise the equipment. It is worth noting here that it is possible for equipment to be coded 'dia' for example, and there can be a slight conflict of understanding here as 'd' is a zone 1 concept, whilst 'ia' can be zone 0. The general rule to apply here is that in the absence of other information, the lower zone takes preference, and the overall equipment is only suitable for zone 1. There are situations where the 'ia' part may be placed in a zone 0, or be attached to pipework containing a zone 0 sample, and this will be explained fully in the certification and/or the manufacturer's instructions for the particular equipment. (Figure 25.8)

Other combinations of codes are not precluded, but the author has not necessarily seen them in practice.

### 25.4.11 Dust protection

Historically some extra requirements for coal dust protection have been included in the standards mentioned above, to take account of mining situations. This meant that there was a fixed maximum permitted surface temperature of 150°C for any surface or component where coal dust could form a layer, or 450°C on any part where coal dust did not have access. Note that the temperatures shown here are for the very specific case of coal mining where coal dust and methane or firedamp are present. The prevention of access by coal dust was achieved by having an enclosure sealed to at least IP54.

For some time in North America, dust protection requirements have been included in the explosion protection standards for their class II and III, groups E, F and G, but with different (lower) temperatures and different enclosure sealing requirements, depending on the particular dust or fibre concerned.

In Europe, generalised dust protection was covered in various standards, but not specifically included in the explosion protection requirements until the advent of ATEX (see below). Now EN 50281-1-1, EN 50281-1-2, EN 50281-2-1 and others are being used to bring in dust protection here too. Equipment can be certified for use in dust areas only, or with dust and gas. Depending on the severity of conditions anticipated in service, enclosures may be IP5X (dust protected) or IP6X (dust sealed), and the temperature of the apparatus may be based on just a thin coating of dust, or on the possible increased temperature when covered with a thick blanket of dust. The marking used on the apparatus is dealt with under the ATEX heading.

## 25.5 ATEX certification

The European harmonised certification which came into operation during the 1980s had problems with respect to the introduction of amendments to—or new editions of—the relevant harmonised standards. The original EC directive was precise in specifying the exact issue level of each standard, so that each time a standard was changed, another modifying directive had to be issued to incorporate the new amendment level of the standard. Each country would put the standards or amendments in place ready for use, but they could not be used in the actual certificates until that modifying directive was issued. This caused confusion at times for all concerned, as manufacturers or users would obtain copies of the new standards and expect certificates to incorporate them immediately, whilst the certification bodies would have to refuse to include them until the appropriate EC directive appeared.

One of the main themes behind the ATEX directive is intended to overcome this problem. There is a phrase in the directive along the lines of 'taking account of technological advances', which means that certification bodies will use the latest published version of a standard at the time of the certification.

The ATEX directive uses a set of essential health and safety requirements, referred to at various times in other articles as ESRs or EHSRs. These are couched in general terms and cover many, if not all, aspects of hazard to persons, for example integrity of pressure systems and radiation of various types, instead of just possible ignition of explosive atmospheres. The EHSRs also effectively include mechanical as well as electrical sources of ignition, and cover protection against flammable gases or dusts.

At the present time ATEX certification can be used voluntarily as an alternative to the previous certificates of conformity, but from July 2003 any new installation will have to be in compliance with ATEX. Two situations are clear cut at that time: first, any brand new installation will have to meet ATEX; second, existing installations will be able to remain in service for the remainder of their useful lives. The area which is slightly unclear at present is that of repairs and maintenance on those installations. There is bound to be debate in some situations as to how much can be done in the name of a repair and where it becomes new equipment. Also the ATEX directive talks in terms of 'equipment placed on the market' after July 2003. At present there is a feeling that manufacturers or users could maybe 'stockpile' a reasonable number of units for repair purposes, but what is a reasonable number, and would the manufacturer be permitted to hold that stock, or would they have to be sold to the user before the due date and held by him? This is something to which there is no clear answer right now, and it remains to be seen how things develop once ATEX is fully in force.

### 25.5.1 Example of an ATEX label

AAAA is up to 4 letters identifying the notified body which issued the type examination certificate.

00 is the year of the certificate

ATEX shows it is an ATEX certificate

nnnn is the serial number of the certificate

ABC Etc Ltd  
This Road, That Town, ZZ7 2XX  
Transmitter Type ttt

AAAA00ATEXnnnn

 II 1 G  xxxx

EEx ia IIC T4 (-30°C < Ta < 60°C)

Serial Number or Batch Number  
Year of Manufacture

xxxx is the number of the notified body carrying out the quality module of the ATEX requirements. This  mark together with the four digit number may appear in addition to any other  mark which the manufacturer may need to apply for other purposes.

The G in the II 1 G signifies protection for gas, and could be replaced by D for dust, or G D for both gas and dust. If the apparatus is protected for dust, there will be two further items on the label: the enclosure degree of protection, which must be at least IP54 for category 3 and IP65 for category 1 or 2, and the maximum surface temperature of the enclosure (shown as Txxx °C).

## 25.6 Global view

Both the earlier harmonised standards and ATEX arrangements were intended to ensure acceptability of certified apparatus in any European member state without repeating the certification every time.

From the certification body and manufacturer aspect, a strong trend has already developed towards one-stop assessment and testing for several other countries. Various agreements are in place between many organisations in Europe, Canada, America, Australia and Japan among others, whereby one certification body can provide assessment and testing of the design to several standards at the same time and issue a report to the other co-operating body. The equipment still has to be finally certified or approved by the appropriate organisation in the country where it is to be used, but the initial 'combined' assessment can help in achieving a 'universal' design first time and avoid having to keep redesigning the equipment for each authority in turn, with the resultant delays and inconvenience this was likely to cause.

Historically the various standards relating to intrinsic safety all used basically the same set of ignition curves originated by SMRE in the early 70s and supplemented by more research work by PTB in Germany in the 90s. Similarly, the test gas mixtures used in both intrinsic safety and flameproof testing tend to be the same throughout all the standards. However the exact application of factors of safety applied in testing or interpretation of the curves varies from standard to standard, which is one reason why it has been necessary to have equipment certified separately in every country where it is used.

Even when the equipment itself is certified to the harmonised standards within Europe, each member state tends to have its own installation requirements which need to be taken into account. The advent of EN 60079-14 (Code of practice for installation) lays the foundation for hopefully a more universal set of installation practices.

In the long term the IECEx scheme of certification (based on the IEC 60079 series of standards) is heading in the direction of providing certificates which would be acceptable in any participating country, so eventually full global certification is a possibility. At present the scheme is still only being used on the basis of an assessment and test report (ATR) produced in one country being accepted as the basis for certification in another country. At this time there are still too many national differences compared to the IEC Standards to enable direct acceptability of any country's certificate in any other country, but the long term aim is to reach that situation. around 20 countries have so far signed up to the IECEx scheme with around a further 5 showing interest.

It is also worth mentioning again here that the style of coding similar to EEx ia IIC T4 is becoming more and more the usual arrangement to look for, which should avoid the confusions which tended to occur in the past. The variations in this coding are likely to be only such things as the EEx changing to Ex for the IECEx scheme, or AEx for American approval, but the protection concept, gas group and temperature class will be recognisable throughout.

## 25.7 Useful websites

In this technological age, there is a plethora of information available on the internet. The following is a list of useful

websites found by the author, with apologies to those not included.

## 26.1 Steam generating plant

### 26.1.1 Introduction

The production of steam at conditions suitable for supplying an engine or a turbine, or of providing steam for heating or process plant, is achieved by the transfer of heat from a primary energy source to water contained in a boiler, or steam generator, which in its most rudimentary form may be little more than a vessel heated from below. Currently, there are two major energy sources capable of supplying heat at a sufficiently high temperature and in a controlled and economically acceptable fashion. These are nuclear fission and the combustion of fossil fuels, such as coal, oil, natural gas and their derivatives. It is the latter, or 'conventional' energy source and its associated plant which are considered here.

### 26.1.2 Combustion

The combustion process for a fossil fuel is a rapid exothermic chemical reaction between the oxygen in the air and the combustible elements in the fuel. There are two such principal elements, carbon and hydrogen, which react with oxygen, thus:

The heat release for carbon is approximately 7830 kcal/kg of carbon burned, and the equivalent figure for hydrogen is 33 940 kcal/kg. The requirements for the above reactions to proceed to completion are: first, a sufficiently high temperature to ignite the constituents; second, adequate mixing of the constituents; and third, sufficient time for the reaction to be completed. With regard to the ignition temperature, *Table 26.1* gives an indication of these values for a number of fuels.

The mixing of the constituents and the reaction times are both major elements in the design of the furnace of a steam generator, which must be large enough and provide sufficient turbulence to ensure that these two requirements are met.

The absorption of heat in the boiler is achieved in two ways. In the furnace, where all the combustion takes place, heat is transferred to the water by *conduction* through the walls of its containing vessel or tubes, which receive heat by radiation from the burning fuel. At the outlet of the furnace the products of combustion are still very hot (probably in excess of 1000°C), so that they remain capable of transferring heat; this time by *convection*. This heat can be used in

non-superheating boilers to further heat the water, while in superheating boilers, as the gas passes through the convection zone, it may progressively be used to superheat the steam first produced in the furnace, and eventually the cold incoming feedwater. Finally, the gaseous products of combustion are ducted to a chimney (sometimes via flue gas clean-up devices) and so any residual heat left in these gases is lost. Nonetheless, the efficiency of steam generating plant, as defined by the ratio between the heat energy of the steam leaving the boiler and the chemical energy of the fuel entering the furnace, can be high, with typical figures in excess of 85% for coal fired plant, rising to as high as 98% for compact oil fired boilers.

With regard to efficiency definitions, care should always be taken to establish the basis of the efficiency calculation, as the heat content of the fuel is generally assessed differently in Europe and the USA. In the USA the higher heat of combustion ( $Q_H$ ) is used which incorporates the heat of vaporisation of water (that is, it is assumed that all water vapour formed by combustion is condensed). The lower heat of combustion (or lower calorific value,  $Q_L$ ) is derived by assuming that the products of combustion remain in the gaseous state. It may be shown that

$$Q_L = Q_H - 578.24W \text{ kcal/kg}$$

where  $W$  is the weight of water formed per kilogram of fuel. European practice tends to favour the use of  $Q_L$ .

Calorific values are obtained experimentally by means of a bomb calorimeter in which combustion occurs at constant volume and the derived value  $Q_H$ .  $Q_L$  is obtained from the above relationship and, in fact, refers to combustion occurring at constant pressure.

The major heat loss from a boiler has already been identified as the heat loss up the stack, or chimney. Other losses may arise due to incomplete combustion of the fuel, leaving carbon in the ash or by producing CO rather than CO<sub>2</sub>. In practical installations it is always necessary to use more than the theoretical air requirements to be sure of complete combustion. However, in order to keep the stack loss to a minimum this excess must be carefully controlled. For fuel oil fired installations, excess air is typically in the range 5–10% by weight, referred to the theoretical air requirements. Corresponding figures for a pulverised coal fired unit would be 15–20%, while for a stoker fired boiler the figures would be in the range 30–60%. The remaining inherent loss for a boiler arises due to the moisture content of the fuel and the production of water vapour in the combustion process, while the remaining avoidable loss arises from radiation from the boiler setting. This latter loss can, of course, be controlled by providing the unit with good insulation.

### 26.1.3 Sources of chemical energy

The fossil fuels available as suitable heat sources occur naturally in the earth and are the remains of organic materials once found living on the Earth's surface. It is not surprising, therefore, that the properties of individual fuels vary markedly from place to place and that the fuels contain many trace elements which can in some cases profoundly influence their combustion characteristics. It is necessary, therefore, that the boiler plant designer knows the type of fuel that will be burned and also fully understands the effects the properties of the fuel will have upon all his design parameters. In consequence, much effort has been directed towards understanding the combustion of conventional

**Table 26.1** Ignition temperatures for some common fuels in atmospheric air

Fuel	Ignition temperature (°C)
Charcoal	343
Bituminous coal	407
Anthracite	450–600
Ethane (C <sub>2</sub> H <sub>6</sub> )	470–630
Ethylene (C <sub>2</sub> H <sub>4</sub> )	480–550
Hydrogen (H <sub>2</sub> )	575–590
Methane (CH <sub>4</sub> )	630–750
Carbon monoxide (CO)	610–657

**Table 26.2** Examples of some fuel oils available

Grade of fuel	Composition (% by weight)					Gross heating value (kcal/kg)	Description
	C	H <sub>2</sub>	O <sub>2</sub> + N <sub>2</sub>	S	Ash		
Distillate (amber)	86.5	12.7	0.2	0.7	Trace	10 800	For general-purpose domestic heating
Very light residual (black)	86	12	0.5	1.5	0.02	10 500	For installations not equipped with preheating
Residual (black)	85.75	10.5	0.9	3	0.08	10 150	For installations equipped with preheating
Crude oil (Mexican)	83.3	10.9	2.2	3.6	—	9 665	
Coal-tar	89.5	6.5	3.5	0.6	—	9 020	

fuels which are commonly used, and considerable data are available on the fossil fuels (oils, natural gases and coals).

As well as fossil fuels, less important, but common, vegetable fuels such as peat, wood, wood bark, bagasse (sugar cane residue), grain hulls and residues from coffee grounds and tobacco stems are useful sources of heat. Sometimes gases, tars and chars produced as by-products in steel making or oil refining processes are used. In many instances when waste products are to be used they will be burned in conjunction with the major fuels (oil, coal and gas).

#### 26.1.3.1 Liquid fossil fuels

Fuel oil, owing to its relative ease of handling and storage, the absence of large quantities of residual ash and its high calorific values, had by 1970 become a most attractive fossil fuel. Since then, however, its relative cost with regard to other fuels and the uncertainty of its long-term availability have both tended to reduce its competitiveness. Nonetheless, particularly in the case of smaller boiler installations, oil remains a viable fuel.

The type of oil burned for steam generation can vary from light distillates having low viscosity and low specific gravity to the heaviest residual black fuel oils with very high viscosities. Occasionally, crude (or unrefined) oil may be considered for use directly in the boiler furnace; however, the presence of highly volatile fractions (normally removed in a refining process) may prove troublesome. Typical characteristic of fuel oils are shown in *Table 26.2*. Despite the low percentages of ash indicated in *Table 26.2*, trace elements such as vanadium, sodium and sulphur can be responsible for a number of operating problems.

A further source of liquid fuel is oil derived from oil-shale, which is a fine-grained, compact, sedimentary rock containing an organic material known as kerogen. Shale

oil is obtained by heating the rock to 470°C. (The yield is normally about 115.1 per tonne of rock.) Substantial reserves are known to exist in North America, in some parts of the Middle East, in China and in Australia. The use of shale oil in steam generators may be restricted by cost, but consideration is currently being given to the direct combustion of oil-shale in boilers.

#### 26.1.3.2 Gaseous fuels

In many ways gas can be considered the most easily used of all the chemical fuels. It is capable of easy transportation from the producing or gathering plant to the consumer, and the use of pipelines can eliminate storage problems, particularly for very small installations. Care is required, however, in large boilers to avoid the occurrence of explosions during unit ignition or at other times when ignition may be lost. As may be expected, for clean gases complete combustion with a low excess air requirement is possible and the combustion does not produce smoke; additionally, it is substantially free of ash. Typical analyses of gases burned in steam generators are shown in *Table 26.3*. Blast-furnace gas is included in *Table 26.3* for completeness, although it is usually available only as a by-product of a steelworks. It is normally heavily contaminated with dust, and great care must be taken to avoid plugging of fuel pipes or furnace fouling. Clean-up is usually achieved by a washing process.

#### 26.1.3.3 Solid fossil fuels

Coal is a major fossil fuel throughout the world and has been in use for many decades by the industrialised nations. It is found in many forms, ranging from anthracitic through bituminous and sub-bituminous to lignitic. With so many sources and with such variations of type and quality, it has

**Table 26.3** Examples of some gaseous fuels available

Gaseous fuel	Composition (%)							Higher heating value (kcal/kg)
	CO	H <sub>2</sub>	CH <sub>4</sub>	C <sub>n</sub> H <sub>m</sub>	CO <sub>2</sub>	N <sub>2</sub>	O <sub>2</sub>	
Coal gas	4.7	2.5	38.5	35.9	10.3	7.3	0.8	8640
Water gas	71	6.4	0.3	—	14	8.3	—	3560
Producer gas	31.3	0.9	0.2	—	8.5	59.1	—	985
Natural gas	—	—	63–88	6–29	0.5–8	0.5–7.3	—	9000–11 050
Blast-furnace gas	30	0.2	1.3	—	14	55	—	5900

**Table 26.4** Examples of some hard coals available

Country	Typical analysis (%)				Higher heating value (kcal/kg)
	Moisture	Volatile matter	Fixed carbon	Ash	
Australia	0.5–2.6	30–37	50–65	11–15	6500–7300
Canada	1.4–4.0	25–34	51–62	10–12.5	7000
China	2.5–5.4	25–30	40–45	20–31	5200–6000
Great Britain	0.7–7.5	11–36	57–85	2–4	7400–8000
Poland	4–17	21–32	40–59	6–22	4500–7500
South Africa (export)	2.0–5.5	16–27	50–70	9–16	5900–6800
USA (export)	1.5–3.5	20–40	—	5–9	7700

**Table 26.5** Examples of some non-fossil solid fuels

<i>Fuel</i>	<i>Moisture (%)</i>	<i>Volatile matter (%)</i>	<i>Ash (%)</i>	<i>Heating value (kcal/kg)</i>
Peat (air dry)	37–45	38–40	1–2	2600–3000
Bagasse	40	45	1.315	2200–4860
Wood (air dry)	10–20	75	0.5–3	4200–5400
Wood waste with bark	15	70	2	3300

been found impossible to produce any generalised analysis for this fuel which will predict its behaviour in the boiler. As opposed to oil and gas, coal contains relatively high ash levels, which in turn will contain trace compounds (such as  $\text{SiO}_2$ ,  $\text{AlO}_2$ ,  $\text{TiO}_2$ ,  $\text{Fe}_3\text{O}_4$ ,  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{Na}_2\text{O}$ ,  $\text{K}_2\text{O}$ ,  $\text{Mn}_2\text{O}_4$  and  $\text{P}_2\text{O}_5$ ) whose presence and effects need to be recognised if efficient and reliable coal combustion is to be achieved.

With these reservations in mind, however, it is possible to divide coals into certain classifications. In Europe the International System of Classification is generally used, while in the USA the ASTM System is used. Both systems have attempted to group coal together by their heating values, moisture contents and volatile matter contents.

Anthracitic coals have a high heating value, are non-agglomerating, have low volatility and very high fixed carbon content (in excess of 85%). Bituminous coals have a heating value not less than 5700 kcal/kg, and are agglomerating, while sub-bituminous coals can have heating values as low as 4600 kcal/kg. Lignitic coals are characterised by high moisture contents (up to 60%) and heating values lower than 4600 kcal/kg.

To provide an indication of the variations of coals worldwide, some of the more significant producers are listed in *Table 26.4*, together with corresponding typical hard coal properties.

#### 26.1.3.4 Other solid fuels

Other fuels, mainly vegetable or vegetable waste, have been found to be useful. Peat is, in fact, burned by certain public utilities. Wood and wood wastes as well as bagasse waste are also well-known fuels, while, more recently, trials have been conducted into the use of industrial and domestic refuse as a boiler fuel. Some indication of the properties of these fuels is given in *Table 26.5*.

#### 26.1.4 Thermodynamics and hydrodynamics of steam generating plant

In a conventional steam generator the working fluid (water) receives heat from the chemical reactions occurring between

its fuel and the air, and in an ideal situation the working fluid is at constant pressure. In a real boiler there is a pressure drop between inlet and outlet due to the effects of friction; however, the process can reasonably be represented by the line bcde in *Figures 26.1* and *26.2*. Initially, the incoming water or feedwater to the boiler has to be pumped into the boiler and this is represented by the line ab. At inlet to the boiler (b) the water enthalpy will be subcooled and will first need to be heated to saturation at c. At c its mass quality ( $x$ ) is zero. Mass quality may be defined as,

$$x = W_{\text{g}}/(W_{\text{g}} + W_{\text{f}}) \quad (26.1)\Leftarrow$$

where  $W_g$  and  $W_f$  are the flow rates of steam and water, respectively. A mass quality definition can also be stated as

$$x = (h - h_f)/h_{fg} \quad (26.2)\Leftarrow$$

**Figure 26.1** The temperature–entropy diagram

Figure 26.2 The Mollier or enthalpy-entropy diagram

where  $h$  is the enthalpy of the working fluid,  $h_f$  the enthalpy of saturated water at the same pressure and temperature, and  $h_{fg}$  the latent heat at the same conditions.

In equation (26.1)  $x$  can vary between zero and unity, while in equation (26.2)  $x$  can assume negative values if the fluid is subcooled and values greater than unity when the fluid is superheated. In the range  $0 \leq x \leq 1$ , the values of  $x$  derived from equations (26.1) and (26.2) are identical if thermodynamic equilibrium exists.

Between c and d the mass quality increases from zero to unity as steam is produced, until at d the working fluid is completely transformed into dry-saturated steam. If the boiler is equipped with superheaters, further heat can be added, to achieve a final condition at e. The processes between c and d occur at an essentially constant temperature (the saturation temperature equivalent to the pressure in the boiler), while in the superheat region the added heat causes the steam temperature to rise.

At point d or e the steam can be used to provide heat for process plant or be used to drive a work producing engine or turbine. If steam leaves the boiler at d, which is a dry-saturated condition, it is evident that the removal of energy from it by heat transfer or by work in an engine will cause it to start to condense, and  $x$  will fall. However, if the steam is initially superheated to e, it can provide an amount of work approximately equivalent to the drop in enthalpy ( $h_e - h_f$ ) before any moisture is formed: this is the great advantage of superheat. Nonetheless, many applications, particularly in the process industries, require only heat and the added complications of providing large amounts of superheat are avoided, providing that process temperature demands are compatible with available boiler pressures.

By contrast, in cases of power generation, high pressure and temperatures are thermodynamically attractive, as in the expansion of the steam to vacuum in a condenser (point f' in Figures 26.1 and 26.2), so making the term ( $h_e - h_f$ ) as large as possible. The boiler may then be said to be working as part of a regenerative cycle with steam under vacuum at f' being condensed along f'a to a pump at a, where it is pressurised and returned to the boiler at b.

Mixtures of these two systems are common, particularly in industry, where some electrical power as well as process steam is required. However, in all cases the steam generator must provide the steam at the desired conditions, and to achieve this the boiler designer must be fully aware of the

processes involved within the working fluid as it moves from b to e.

For the simplest type of industrial boiler, the shell or fire tube boiler, where only modest steam pressures are available and little or no superheat is produced, the combustion occurs in furnace and fire tubes and the products of combustion pass down further tubes (called smoke tubes). The tubes are contained within a vessel (or shell) which contains essentially non-flowing water, heated by the tubes passing through it. The rate at which heat can be transferred to the water is controlled essentially by the properties of the water. If the rate of heat transfer is poor or a very high flux is provided by the furnace, overheating of the tubes may occur and the material may fail. Information on these heat transfer rates, either by experience or by experiment, are therefore required by the designer.

For higher pressures and capacities and for applications calling for appreciable amounts of superheat, the roles are reversed, in that water occupies the tubes, which now form the enclosure of the furnace. Such a boiler is known as a water tube boiler. In such designs, water flows in the tubes and it is induced to do so either by means of a pump or by the 'natural' effects induced by heating water in inclined or vertical tubes so that the steam so formed is free to rise.

## 26.2 Steam turbine plant

The steam turbine is a prime-mover well suited to the direct drive of two- or four-pole high-speed a.c. generators for power-supply networks. The associated steam-raising plant can be fired by a wide variety of fuels—fossil, nuclear and such unusual fuels as city refuse, sawdust and sugar waste. The turbine can accept a low exhaust temperature (making possible a reasonable thermal efficiency) and a moderate inlet temperature (permitting a long life, e.g. 200 000 h). The turbine is best suited to high power ratings, as parasitic losses tend to be independent of size; further, output ratings can be raised without a pro-rata increase in materials, so giving a higher power cost ratio.

Steam turbines are constructed in the range 5–1300 MW. At the highest ratings the only comparable prime-mover is the hydraulic turbine, while at the lower end of the range the steam turbine competes with the diesel engine and the gas turbine.

Besides generator drive, the steam turbine is applied to ship propulsion and to rotary compressors. This section deals exclusively with electric power generator drive applications.

### 26.2.1 Cycles and types

#### 26.2.1.1 Reheat cycle

Most fossil-fuel-fired generating stations use the reheat cycle. Currently, outputs span the range 200–1300 MW. Common steam conditions are 16 MPa, 540°C (2350 lbf/in.<sup>2</sup>, 1000°F). Occasionally supercritical conditions, e.g. 22 MPa and above, are met, and sometimes there are two stages of reheat; but the one-stage reheat subcritical cycle here described is more common. The British advanced gas-cooled nuclear-reactor plant also uses this cycle, with outputs currently of 660 MW.

In Figure 26.3, ABCD shows the conditions of steam throughout the cycle, and Figure 26.4(a) gives the plant arrangement. Steam is expanded in the high-pressure (h.p.) stage down to near-saturation and is then returned to the

**Figure 26.3** Cycles on a Mollier chart

boiler for reheat to the original temperature but at lower pressure. It then expands in the low-pressure (l.p.) stage until it becomes as wet (usually not more than 13% wet) as the final blades can tolerate.

The cycle is efficient and eases the design of last blading, which is usually the critical problem in turbine development. By using reheat, less steam per megawatt-hour is needed and this means shorter blades at exhaust. The cycle usually gives an exhaust somewhat drier than others, reducing the blade erosion hazard. However, all this is at the expense of some complication and extra boiler size and the smaller units—say under 100 or 200 MW—use the simpler non-reheat cycle.

#### 26.2.1.2 Non-reheat cycle

This is shown by the line EF, in *Figure 26.3*, and the plant layout in *Figure 26.4(b)*. Steam usually at 5–8.5 MPa (900–1250 lbf/in<sup>2</sup>) is expanded through the turbine to exhaust from the condenser without return to the boiler. This simple and compact machine is usually constructed in a single cylinder. The plant has a lower first cost than that for reheat, but is 8% or more higher in fuel consumption.

#### 26.2.1.3 Pressurised-water and boiling water reactor cycle

The steam conditions are given by line GHJF and the layout in *Figure 26.4(c)*. Water-cooled reactors require a special cycle because steam is supplied at an unusually low temperature, about 280°C (540°F). The steam is saturated and when expanded, quickly becomes wet. Water in the

h.p. stages can cause damage, so the steam is taken out of the turbine after the h.p. stage and put through a drier—usually a device that uses the motion of the steam to separate water from it. It is then reheated by steam bled from the main supply to a surface heat exchanger alongside the turbine.

The cycle is not efficient and turbine design must take care of the potentially damaging effects of water in the steam. However, it suits the pressurised-water boiling-water reactors and their economics. Machines of up to 1300 MW are in service using such cycles.

#### 26.2.1.4 Extraction cycle

This cycle, line EKF in *Figure 26.3* with layout in *Figure 26.4(d)*, is particularly economical where steam is used to supply a process as well as to generate: a typical example is the desalination plant fed with steam from a turbogenerator, an arrangement in demand in countries where industry and population develop in desert areas. Here, power units of 20–120 MW are in operation, and pass-out steam feeds multi-flash sea-water desalination plants.

Steam is expanded in the h.p. stage of a turbine and is then withdrawn. A control system acts to take off as much steam as the process requires. The steam that the process does not need is then returned to the turbine to expand and do work in the l.p. stages and ultimately to exhaust to the condenser under vacuum.

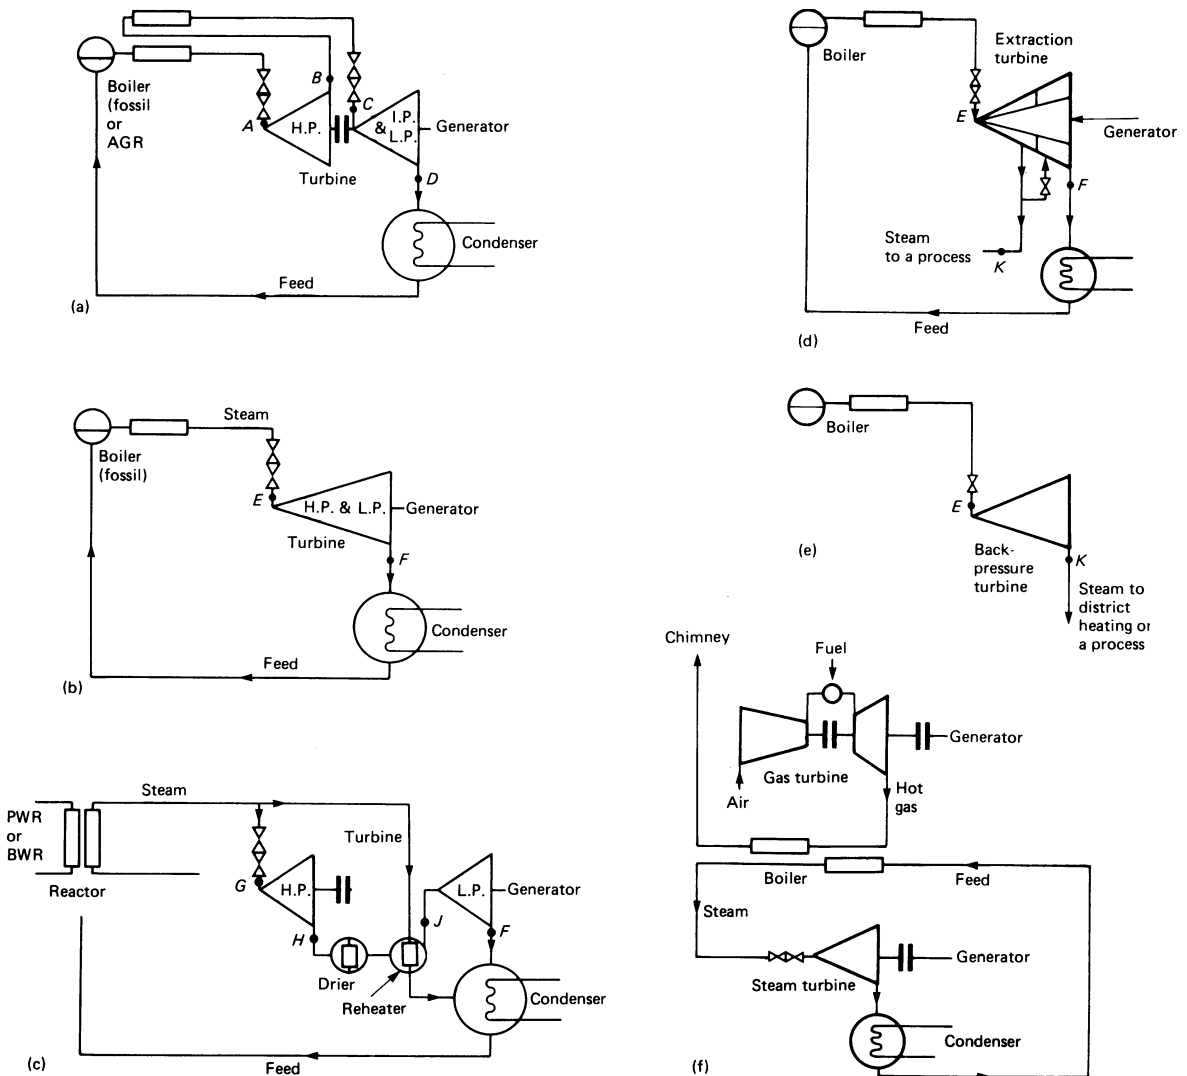

#### 26.2.1.5 Back-pressure ('total energy') cycle

*Figure 26.3* shows the cycle by line EK, and *Figure 26.4(e)* shows the plant diagram. While the turbine is efficient in itself, with stage efficiencies of around 80%, the basic cycle has a much lower efficiency (usually 30–38% overall for power stations), mainly because over half the energy in the steam is lost in the exhaust. With the exhaust pressure usually as low as 5 kPa (0.75 lbf/in<sup>2</sup>) the steam is at only 33°C (92°F). It is difficult to find ways to use energy at such a relatively low temperature and so the very considerable heat in the exhaust is discarded to a condenser.

Some factories need steam for process work, e.g. at upwards of 150°C and at a pressure useful enough to drive the steam to and through the process plant—say 350–1000 kPa. District heating schemes usually require water at 65°C and obtain it from steam at around these conditions.

The turbine can be arranged to exhaust at these higher pressures and to pass all its exhaust steam to the process or to the district-heating scheme. Although the higher back pressure of, say, 700 kPa makes the machine much less efficient than with a more normal condensing turbine, the cycle as a whole is efficient because the turbine exhaust heat is not lost. Thus, a back-pressure plant generating electricity and exhausting to a factory process can have a thermal efficiency of 70% compared with 35% for a normal power station.

The basic problem with back-pressure units is that the heat required near to the turbine-generator rarely keeps pace with the electrical power required locally. Basically, it is easier to distribute electricity to more distant parts than to send heat: back-pressure units are therefore usually small. Confining their power and heat output to nearby use, they are rarely of more than 20 MW rating and often much less. There may well be a future for such cycles in the conservation of increasingly costly fuel, and the potential of such 'total energy' schemes must inevitably attract more attention.

**Figure 26.4** Various turbine cycles. (a) Reheat cycle, commonly used in fossil fuel and AGR power stations; (b) Non-reheat cycle, used for lower power; (c) Cycle for pressurised-water and boiling-water nuclear reactors; (d) Extraction cycle; (e) Back-pressure or 'total energy' cycle; (f) Combined cycle, one of various steam and gas turbine arrangements

#### 26.2.1.6 Combined cycle

The ideal engine has a high inlet thermodynamic (absolute) temperature  $T_1$  and a low exhaust temperature  $T_2$ . The highest attainable Carnot efficiency is  $(T_1 - T_2)/T_1$ . The steam turbine has only a moderate  $T_1$  but a very low  $T_2$ , so that its efficiency is normally higher than that of the gas turbine, for which  $T_1$  is high but so is  $T_2$ .

The combined cycle aims to optimise conditions with a cycle that uses the high  $T_1$  of the gas turbine and the cool exhaust of the steam turbine, *Figure 26.4(f)*. The cycle works as follows.

Fuel is burnt in the combustion chamber of a gas turbine, which generates electricity and exhausts to a heat exchanger. Here the hot gases boil water to raise steam which then drives a steam turbine which also generates electricity. The steam turbine exhaust is changed to boiler feed water in a condenser.

A number of such plants are in service and more are being built because of their high efficiency. They also have the quick-starting ability that the straight steam turbine lacks. Also they can offer power early in the building programme by installing the gas turbine first and the steam turbine later.

They have as yet a reliability somewhat lower than that of simple steam plant, and the gas turbine has a shorter life. The availability is more acceptable if natural gas is used rather than oil. A common arrangement is to take about two-thirds of the power output from the gas turbines and one-third from the steam turbine; say, two gas turbines and one steam turbine per unit.

While this cycle is as yet limited to gas and carefully prepared oil, there are prospects of its use with coal. The pollution problem is creating so strong an emphasis on clean burning that new combustion methods are being developed for coal. Pressurised, fluidised bed combustion

is one; gasification is another. Such arrangements promise to produce a gas clean enough for gas turbines to use. So there is a prospect of using the combined cycle to give thermal efficiencies of around 45% using coal, which is the most profuse fossil fuel.

Combined cycles are not necessarily arranged as in *Figure 26.4(f)*. For instance, fuel can also be burnt in the gas-turbine exhaust to raise more steam (see also Section 26.3.3).

### 26.2.1.7 Alternative fluids

From time to time research is done into fluids alternative to steam. The physical properties of freon and ammonia have certain advantages, but so far the disadvantages have over-ruled them. Energy costs, however, may yet impose a change from the steam cycle.

## 26.2.2 Turbine technology

### 26.2.2.1 Blade types

There are two basic types of blade—impulse and reaction. In the impulse type (*Figure 26.5(a)*) all the expansion of steam is done in fixed nozzles and the high-velocity jets so created drive the rotor blade. In most machines the expansion is in successive stages, of which there are usually as many as 20 from inlet to exhaust, each comprising a row of nozzles and a row of moving blades.

Some turbines use a 'Curtiss' stage (*Figure 26.5(b)*) to drop the temperature quickly at inlet or to shorten the machine. This stage takes a more than usual pressure drop. An exceptionally high jet velocity results and this is converted to work by driving two or more rows of blades from the one jet. The sketch shows how this is done using guide blades to re-direct the steam leaving the first row.

In reaction blading (*Figure 26.5(c)*) the moving blades are driven not only by the steam jets from preceding nozzles: they act as nozzles themselves and the jet they create helps to propel them. Therefore, pressure is lost both in the fixed and moving blades and power is produced both by impulse and jet reaction.

In practice, few machines are purely impulse and none are purely reaction. In the modern so-called impulse machine all blades have a degree of reaction and generally this increases towards the exhaust. In some designs the amount of reaction is more marked, depending on the background experience of the manufacturer. Properly designed, there is little difference in efficiency between the impulse and reaction types.

In all but a few small machines, the steam flows along the shaft, parallel to the axis. There are two unusual designs in which this is not so. One is the Ljungström turbine, in which steam flows radially outwards through concentric rings of counter-rotating blades. The other is the Terry turbine where the steam jets travel at an angle inwards to drive against hollows in a rotating disc. The Ljungström turbine is confined to medium outputs, while the Terry turbine is used only for very low powers, e.g. for driving small auxiliaries.

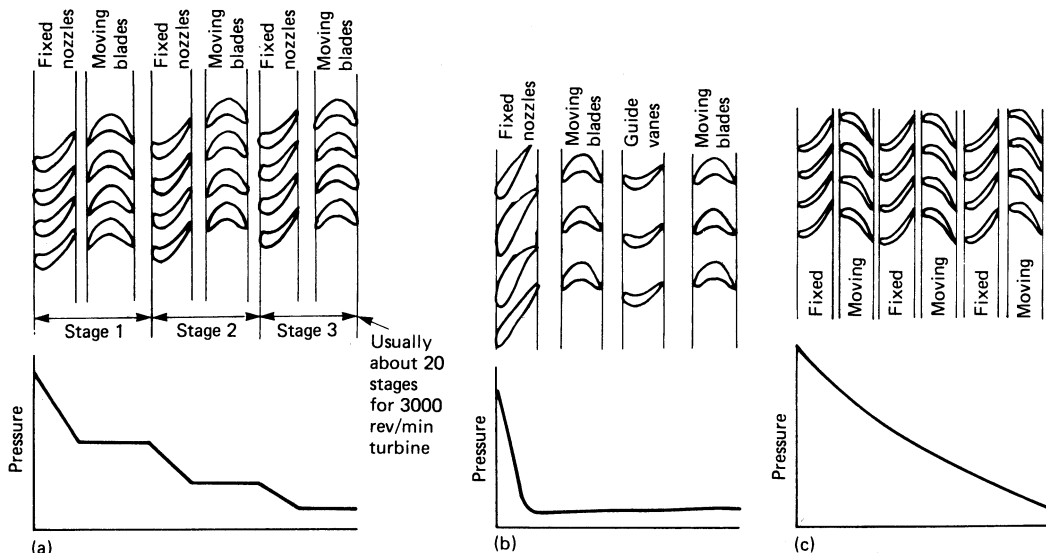

Both these types are now rare. Most modern machines have axial flow with either reaction blading or a combination using h.p. stages of mainly impulse and l.p. stages of mainly reaction design.

### 26.2.2.2 Size effects

The steam turbine is notable in that higher outputs can be achieved without a pro-rata increase in mass and cost. A power increase of 20% is achieved by using blades 20% longer and this increases the mass of the machine by much less than 20%. So the mass/output ratio is a curve such as that shown in *Figure 26.6*. Also, parasitic losses such as gland loss, etc., do not increase at the same rate as power does when greater outputs are used. Thus, increased size produces some gain in efficiency (*Figure 26.7*).

Taking these two factors together there is a financial gain to be got from increased size (*Figure 26.8*). Two important points to be noted, however, are:

- (1) If size is achieved at the expense of reliability, the financial gain may well become a loss; and

**Figure 26.5** Blade types: (a) impulse, pressure compounded; (b) Curtiss stage; (c) reaction

Figure 26.6 Weight of turbines of higher output

Figure 26.7 Trend of efficiency as outputs grow

Figure 26.8 Power/weight and cost/unit power trends

- (2) The gain due to higher outputs is best achieved if blades are lengthened and the change confined to this and to directly related issues. It will be only partially realised if, say, increased exhaust area is achieved by using more exhausts and hence more cylinders, rather than if the change is confined to longer blades.

### 26.2.2.3 Part load

The steam turbine performs best at full load, where the whole system of nozzles and blades operates with proper steam velocities, with minimal throttle losses in valves. It will be less efficient on part load: energy is wasted by throttling down the pressure in valves. The steam jets are slow and do not strike the blades at the right angle, and the exhaust is too hot. If a turbine has to be used frequently at part load, it can pay to adopt nozzle rather than throttle control. The arrangement shown in Figure 26.9 could show advantage over that shown in Figure 26.10.

In nozzle control, part load is achieved by using fewer nozzles and unthrottled steam. The technique is more common overseas than in the UK, though mechanical difficulty tends to make it less suitable for large machines.

## 26.2.3 Turbine construction

### 26.2.3.1 Form and arrangement

It would be ideal to have all turbines as simple as the single-cylinder machine, this is shown diagrammatically in Figure 26.11(a). In fact, these are built for outputs up to 80 or 90 MW. Above these, the longer blades make two or more exhausts necessary and these need a separate shaft. The next step is to Figure 26.11(b), which in the non-reheat form provides outputs of 250 MW or more.

When reheat is adopted there are two hot inlet flows, one at high pressure and a second at an intermediate pressure.

Figure 26.9 Steam inlet for nozzle control

Figure 26.10 Steam inlet arrangement for throttle control

**Figure 26.11** Forms of turbine: (a) simple cylinder, non-reheat; (b) two cylinder, non-reheat; (c) three cylinder, reheat; (d) four cylinder, reheat; (e) reheat with combined high power and interim power; (f) reheat with combined high power and interim power; (g) nuclear tandem for pressurised-water reactor

Some makers mount each on a separate shaft, giving the h.p., intermediate-pressure (i.p.) and l.p. arrangement of *Figure 26.11(c)*. Others take both inlets to a common h.p.–i.p. rotor, *Figure 26.11(e)*. The latter is common American practice.

The arrangements so far described are for rated speeds of 3000 or 3600 rev/min. An important design factor concerns the last blade size: increase in blade height permits the number of exhausts to be reduced. Current UK designs for 3000 rev/min turbines include blading heights up to 0.95 m on a mean diameter of 2.65 m. For 300 MW these use two exhausts as in *Figure 26.11(c)* and four for 600 MW, as in (d), or alternatively six where the higher efficiency obtained is economically justified.

Developments may lead to even longer blades, capable of 600 MW with two exhausts as in *Figure 26.11(c)* provided that low coolant temperatures are feasible. In some areas of the world these cannot be obtained, and only low area exhausts are justified.

Where the power rating is such that the exhaust area is beyond the capacity of the largest blades, the necessary area can be provided by a two-shaft or cross-compound arrangement, e.g. *Figure 26.11(f)*, or by halving the speed as in the 1800 rev/min 1300 MW machines such as that in *Figure 26.11(g)*. These arrangements accept, as most do, that eight exhausts on a single high-speed shaft line would not be a preferred solution.

There is a compromise between the two methods shown by using a cross-compound with a high-speed, h.p.–i.p., line and a low-speed, low-pressure line, either 3000/1500 or 3600/1800 rev/min depending on grid frequency. Inherent in these schemes is the fact that the lower speeds make it possible to use much longer blades and so enlarge the exhaust area and machine output. However, they do so at the expense of more metal for the low-speed rotors and casings, which are massive in comparison with those for a high-speed set.

Engineering solutions to the problem of increased output are always evolving and much larger turbine sizes than the current 1300 MW units could, no doubt, be devised. The limit tends to be imposed not by technical aspects of turbines, but by economics and by factors other than the turbine itself. An influence that the turbine contributes to this limiting of growth, however, is that the return tends to level off as size increases and can easily be nullified or even reversed if availabilities of the large machines fall even slightly beneath those of the smaller ones.

### 26.2.3.2 Foundations

The large turbine generator is supported some 10–12 m above the basement, a space that accommodates pipes, condensers and drainage. Supports were formerly mostly of reinforced concrete, but steel supports are increasingly preferred. They can be accommodated more readily into a building programme and are more predictable in their dynamic characteristics.

The block usually takes the form of an entablature supported on columns. It must be designed so that the shaft runs smoothly even though it may be slightly out of balance. The foundations must sometimes accommodate earth tremors. Both these requirements are better served if the structure is in steel than in concrete, because with steel the stresses, loadings and masses commercially used give a lower and more predictable and natural frequency. Vertical frequencies of about 10 Hz and sway frequencies somewhat lower are typical of such designs. These frequencies are

substantially less than the shaft frequency of 50 Hz or half-shaft frequency of 25 Hz, both of which must be avoided if resonance is not to occur.

Concrete foundations tend to give calculated frequencies nearer 50 Hz, either above or below it. If the softness of the earth beneath the foundations is allowed for, these fundamental frequencies fall usually to well below 50 Hz, but not so low as with steel. While concrete foundations have given good service, their response is more difficult to predict and they are less likely to accommodate shaft and earth dynamics so acceptably as do steel foundations. Also, steel is usually more amenable to a quick station-building programme. However, in many countries concrete may be more economic and the choice has to be made on the circumstances.

### 26.2.3.3 Lubrication

The security of the turbine depends on a continuity of oil supply to its bearings and on the safe functioning of its hydraulic control gear. Further, the fire record in power stations shows that the oil system may play a part in starting or aggravating a fire. It pays to invest thought and money to make the oil system completely reliable and safe. Oil systems involve quite large flows with large turbines, partly because the bearings (especially the thrust block) have turbulent conditions in them unlike the less power-absorbent laminar conditions in former 30 MW sets. Special measures aim to reduce these power losses but they can still reach 3.5 MW for a 660 MW set.

Most machines have shaft-driven main oil pumps, usually centrifugal, primed by jet pumps or pumps driven by a hydraulic motor. The main pumps are backed by a.c. full-duty pumps and by a battery-operated d.c. emergency pump to provide oil until the shaft stops should there be an a.c. failure. Sometimes a small a.c. pump is fitted for use on barring. Shafts are generally jacked by h.p. oil to help starting.

In many arrangements the main oil pump also supplies the control gear with fluid; in others, separate pumps are used and feed control gear at much higher pressures than are used in the lubrication system. A fire-resistant fluid is sometimes used for control but is rarely considered for lubrication. The lubricant fluid is still oil, which can burn: it is therefore essential to design the oil system and fire-fighting plant to reduce fire risk. Attention is needed especially to pipe flange and coupling design. Any item that may fracture or leak oil should be eliminated or designed to reduce risk.

### 26.2.3.4 Governing

The governing and protection system operates control valves both to keep the speed steady within narrow limits and to prevent overspeed on sudden loss. The large turbine has stop and throttle valves at its inlet, and stop and interceptor valves at the i.p. inlet from the reheater. Usually, speed control is by adjusting the h.p. throttles. Overspeed on sudden load loss is prevented, first by closing the throttle valves and interceptors and then, should speed still rise, closing the h.p. and i.p. stop valves. Overspeed prevention requires fast valve action, usually well under 0.5 s closure and in some cases down to 0.15 s. The modern large machine has a high power/mass ratio and a sudden loss of full load can cause accelerations of 10–15% of full speed per second. This allows only a short time to cut off the steam supply, a situation aggravated by the stored energy of steam

already in the pipes and spaces downstream of the valves. It is an important aspect of machine arrangement to minimise such spaces, e.g. using short steam loop pipes.

Other protective circuits besides overspeed operate the valves. The list usually includes low bearing-oil pressure, high vibration and poor vacuum.

Mechanical governors of large machines operate the steam control valves via hydraulic relays and power amplifiers and, eventually, by a servo-motor whose position is determined by speed level and held by a pilot valve and feedback. There are variations on this theme, some having an acceleration element.

Electric governing is becoming more general. Speed accelerations are sensed electrically and translated to an error signal in some adjustable way within the electric governor. The final movement and positioning of the steam valve is still hydraulic.

Some small machines use mechanical relays between speed sensor and valve, but most use hydraulics or electrical signalling and hydraulic power for valve movement. Lubricating oil is normally used, with pressures taken from the main oil pump at 0.35–2 MPa (59–300 lbf/in<sup>2</sup>) but occasionally separate pumps are used for control and with pressures as high as 17 MPa. Fire-resistant fluids are used in the control systems of some large machines. In US practice, double piping is often called for if lubricating oil is used. The reason is that oil leaks are retained within the pipes rather than spill to atmosphere and cause a fire hazard.

## 26.2.4 Turbine support plant

### 26.2.4.1 Condensing plant

The condenser itself is large and costly consisting essentially of tubes through which cooling water is pumped and about which steam and air move. The steam is condensed and the air extracted. The condensate is drawn out by extraction pumps and in an efficient condenser it is nearly at the same temperature as the steam. It is returned to the boiler to use again. For every 1 °C by which the exhaust temperature is lowered in a typical 100 MW set, up to 0.5% extra fuel is burnt. Thus, a larger surface area of tubing allows the exhaust to be brought down more nearly to the coolant temperature; but, of course, this means a higher plant cost.

Having decided the surface area, however, it is important to use it properly. A particular offender is air, which can increase the exhaust temperature if it enters the condenser in large quantities, blanketing the tubes from steam. Excluding air is important: the condenser must extract such air as does enter without its forming pockets and blankets.

In the past, tubes have usually been made of brass. Where there is a severe corrosion risk, cupro-nickel is sometimes used. Dosing is usually employed, e.g. by ferrous sulphate injections, especially where there is a risk of corrosion or of erosion. Sometimes a cleaning gear is used in which shoals of floating balls pass through the tubes, are recollected and put back into the tubes.

Thin tubes of titanium are now becoming more usual. The evidence so far is that they offer much greater resistance to corrosion and erosion and often promise economic advantage.

With the high-steam conditions now used, it is vital to keep salts from the boiler and tube fixtures usually involve expansion or welding. Packings are rare. Sometimes anti-leak measures extend to the use of double tubeplates, with pressurised distilled water filling the space between the two

plates. This ensures that, if there is a leak into the steam space, it will be of clean water and can be monitored. Large condensers usually have arrangements for on-load cleaning.

Ejectors are used to remove air from the condenser. Currently, steam-jet ejectors appear to be in favour but there are various alternative electrically driven ejectors.

The cooling water system can be quite elaborate and usually involves a considerable amount of both mechanical and civil engineering. In a typical British coastal 660 MW unit, for every 1 kg of steam that enters the condenser, about 30 kg of cooling water must be pumped through it. This means a flow of some 1000 m<sup>3</sup>/min. A 1300 MW nuclear unit on the Californian coast uses as much as 3000 m<sup>3</sup>/min of cooling water.

There is no standard cooling system using sea-water: the arrangement and equipment are made to suit the circumstances. Most have one or all of the elements shown in *Figure 26.12*. The system shown is elaborate because it is designed for the extreme conditions met, for instance, in the Mediterranean, where pollution causes growth of sea-grass. Periodic disturbance by storm can bring large quantities of this into the cooling system of a power station. The choking which results can take the turbines off load and is always a worry as regards chemical attack of the tubes. The weed has to be trapped and extracted before the condenser is reached if trouble is to be avoided.

Sand can also be a hazard, especially if it is hard and sharp. Settling tanks are often used to take sand out of the system.

In such systems the water inlet is taken well out to sea. This usually avoids the areas of higher weed density. The inlet is kept well above the seabed to avoid intake of sand, yet well beneath the surface to avoid oil slick. Water inlet positions must be planned most carefully with all these factors in mind and with others, such as avoiding warm water from the discharge re-entering the system. The work involves a careful on-the-spot survey with seasonal observations. It usually entails a hydraulic model.

Power stations are often sited on rivers. In some estuaries the water may be seriously short of oxygen or have aggressive pollutants, which promote tube damage. In others, the water is warm through use by other power stations or may be in seasonal short supply. Cooling towers then become necessary. Their essential principle is shown in *Figure 26.13*. Warm cooling water is sprayed into the atmosphere within the tower and passes its heat to the air, which in turn

becomes warm and rises. The tower is thus filled with air which is warmer than that outside and the thermal syphon effect creates a through-draught. Wind across the top of the tower can stimulate the process.

In a sea-water system the turbine exhaust temperature is set by the temperature of the sea plus the temperature difference required by the condenser to transfer heat. In cooling-tower plants a further temperature rise occurs because the air is normally warmer than the sea; thus the station efficiency is lower and the cooling plant more costly.

Some water is lost by a wet cooling tower. About 1.4% of the total throughput is carried away by the air—about 27 000 t/day for a 660 MW plant. At some sites a reasonable source of water is too remote for economic use and a dry cooling system must be adopted.

*Figure 26.14* shows the principle of the dry cooling tower. There is no direct contact between the water coolant and air, so no water is lost. Cooling takes place in large heat exchangers at the base of the tower across which air is drawn either by natural draught or by fans. The cooled water, which must be pure enough to use in the boiler, is sprayed into the steam entering a jet condenser. Such a system was installed at Rugeley in England in 1961 as an experiment at 120 MW and others have been built overseas since. An alternative arrangement is to use a surface condenser instead of a jet condenser. Raw water is then used as a coolant instead of feed water.

The dry-tower system is less efficient than the wet because the terminal temperature differences are higher so poorer vacua are obtained. Also the tower itself is much larger and so the system costs more. It can, however, enable large amounts of power to be produced in a dry terrain.

Where lower-power units are required, an air-cooled condenser (*Figure 26.15*) may be more economical than a dry tower. In the air-cooled condenser, the turbine exhausts to a heat exchanger mounted some distance above it. Steam goes through tubes and is condensed by air drawn or blown across them. The choice between air condensers and dry towers depends on many factors, but currently the former is used below about 100 MW and dry towers above about 200 MW.

#### 26.2.4.2 Feed plant

The feed water produced in the condenser is taken back to the boiler through a train of devices. First the extraction pump raises it to well above atmospheric pressure and

**Figure 26.12** Sea-water cooling system where weed and sand are a problem

Figure 26.13 Principle of wet cooling tower system

Figure 26.14 Dry cooling tower with jet condenser

Figure 26.15 Air-cooled condenser

drives the water through a series of l.p. heaters, which warm it with steam drawn from the turbine. The heaters are usually of tubular type, the direct contact type is out of favour after accidents in which water spilled back into the turbine.

After leaving the l.p. heaters, the feed water is lifted to the deaerator where it is mixed with more steam bled from the turbine, and releasing dissolved air that would otherwise appear in the boiler. Sometimes the deaerator is incorporated in the condenser itself.

Water is then passed through a network of further tubular heaters and the feed pump, before passing to the boiler via flow-regulating valves. A typical arrangement is shown in Figure 26.16.

The feed-heating system is complicated, expensive and often takes up almost as much station space as the turbine itself. In spite of the fuel saved by it (and even for a small station and medium steam conditions this can amount to over 10%) there is a trend to simplify by reducing the number of feed heating stages, more particularly on stations for developing countries where simple robustness is desirable and where fuel is not expensive.

The feed pumps of a large power station absorb considerable power—up to about 15 MW for a 600 MW generator. There is much to be gained by driving them in an economical way.

### 26.2.5 Turbine operation and control

There are two basic ways of arranging and controlling the steam supply. Where boilers have substantial storage volume in their drums, the steam is arranged to pass direct from the boiler to the turbine (Figure 26.17(a)). This is common practice in Britain. A system more frequently met overseas is Figure 26.17(b), which uses bypasses. This is essential for supercritical boilers, for no drum is used and the boiler has but little steam storage capacity. But the bypass system is also advantageous where only small drums are used. It allows the boiler to operate on part-load and pass steam via the bypass system to the condenser without its going through the turbine. Thus, should the turbine

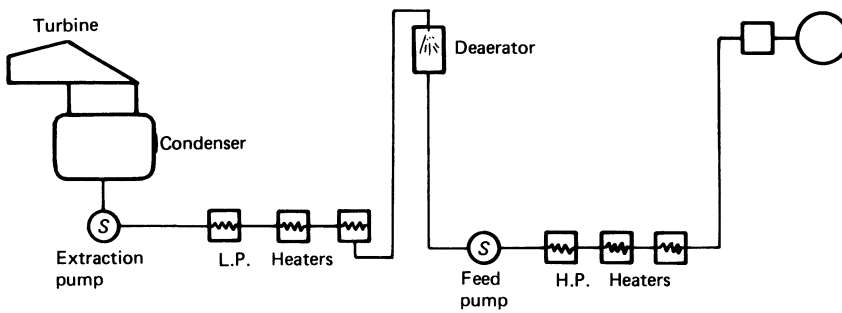

Figure 26.16 Typical feed system

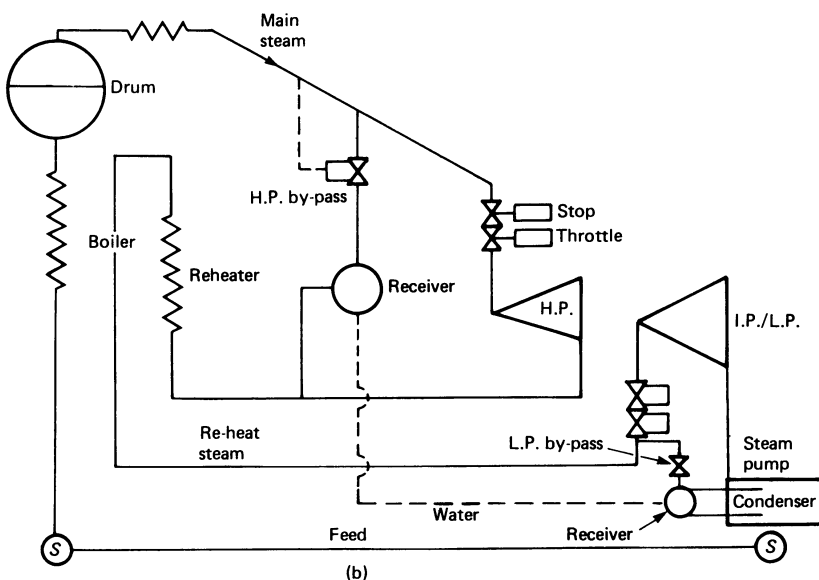

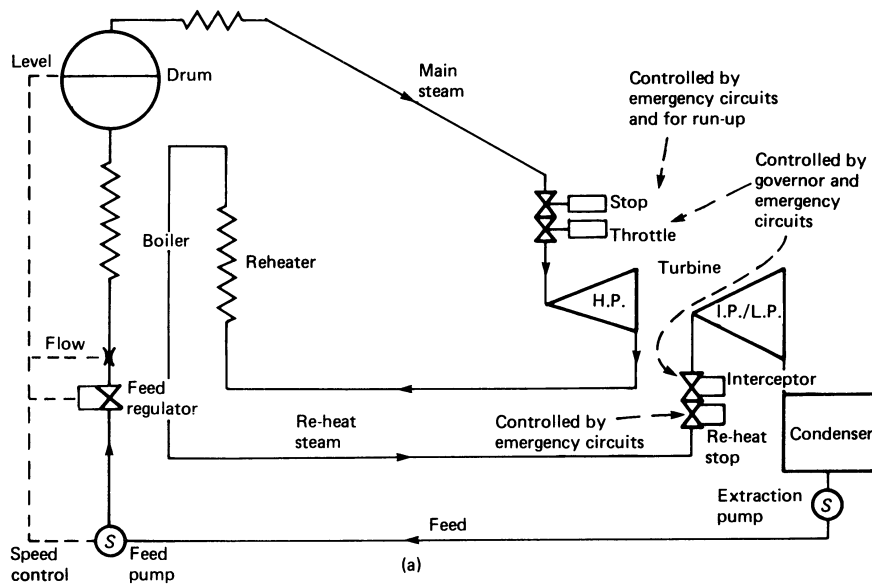

Figure 26.17 (a) Basic steam supply and control system; (b) system with steam bypass

lose full load, rather than blow the safety valves the bypass will open and take steam from the boiler until the furnace heat has been adjusted to the load condition.

The bypass system has other advantages. For instance, the i.p. stage can be warmed through in parallel with the h.p. rather than in series with it, so applying hot steam sooner to the large i.p. cylinder and quickening the start of the unit as a whole.

When on-load in either system, the control of the turbine is by the governing system operating the throttle valves. Emergency signals of overspeed, oil loss, vibration, vacuum loss, etc., can close or reduce both stop and throttle valves by over-riding or acting through the governor. Instruments record the more important parameters of steam pressure, temperature, eccentricity, sliding, differential expansion, etc., and alarms operate from selected parameters.

Starting the machine is mostly automatic, or can be made so. There is a set sequence for taking each action, starting the oil system, barring the shaft, raising vacuum, etc. The most difficult operation and the one that requires most judgement is the admission of steam. The walls of the turbine valve chests and cylinders are thick and steam must not be admitted so quickly that severe thermal stresses develop. Many machines are equipped with instruments to measure the temperature difference across critical sections of chest or casing and so guide the operator on whether the warming through and starting is proceeding safely.

The operator must watch other factors too during a start. Most machines require special care to ensure that axial clearances are not taken up and these and the ease of sliding of the critical guidance and expansion surface are shown by appropriate instrumentation.

## 26.3 Gas turbine plant

During recent years many electric supply authorities have installed gas turbines, in unit sizes up to 150 MW, primarily for peak load or stand-by, but occasionally (where fuel is cheap) for base-load operation. Many industrial plants have also used gas turbines in connection with total energy schemes.

The major advantages of a gas turbine over steam plant are low capital cost, quick starting, small erection time and the facility for using a wide range of fuels from heavy oil to natural gas; also remote control or fully automatic operation is readily achieved. The disadvantages are the low thermal efficiencies (typically 25–30%) unless considerable complication is involved; the use of suitable materials to withstand very high temperatures combined with attack from undesirable elements in the combustion products is still a critical issue.

In the *open-cycle* plant, air is taken from the atmosphere, burnt with the fuel in a combustion chamber, passed through the turbine and finally exhausted to the atmosphere. In the *closed-cycle* plant air (or gas) is circulated around a closed circuit, heat being supplied to the air through a heat exchanger from an external combustion chamber. The former is the more common; its lower capital cost and adaptability to the relative importance of capital cost and efficiency are cogent factors.

### 26.3.1 Open-cycle plant

The simplest form of gas turbine consists of a compressor, a combustion chamber and a turbine as shown in *Figure 26.18*. This is the 'single shaft' gas turbine which is generally

**Figure 26.18** Simple open-cycle single-shaft gas turbine. Note that the turbine may also be split into high-pressure and low-pressure elements to form a two-shaft gas turbine

used for electricity generation applications. Driven by the turbine, the compressor delivers compressed air to the combustion chamber where there is continuous combustion of the injected fuel at constant pressure. In order that the temperature after combustion may not be too high, the ratio of fuel to air, by weight, is of the order of 0.017. This ratio is too low for combustion, so the air from the compressor is divided at entry to the combustion chamber. Part of it is used in the combustion zone and part acts as a coolant. The two streams are thoroughly mixed before entering the nozzles of the turbine at the permissible temperature. *Figure 26.19* shows the outline of a gas turbine combustion chamber. The combustion of the fuel must be as nearly 100% efficient as possible to ensure a high plant efficiency and to reduce carryover of carbon matter to the turbine blades. The quantity of fuel injected controls the output of the plant but it is essential that flame stability shall be maintained over a wide range of fuel injection rates.

The heated air from the combustion chamber, including the products of combustion, is expanded in the turbine and is then exhausted to the atmosphere. Approximately two-thirds of the power developed by the turbine is used up in driving the compressor, the balance is used for producing the net output power for the generation of electricity or other purposes.

#### 26.3.1.1 Simple power relations

*Figure 26.20* shows the ideal pressure–volume diagram representing the ideal cycle work derived from the turbine and the ideal work necessary to drive the compressor. In practice the work done in the turbine is less than that for the 'ideal', i.e. the isentropic efficiency  $\eta_t$  of the turbine is less than unity. Similarly the work done in the compressor is greater than for the ideal case, i.e. the isentropic efficiency  $\eta_c$  is also less than unity. The useful work per unit mass of air is the difference between the work done by the turbine and the work required by the compressor, namely

$$W = \dot{m}_p [T_2(1 - 4/k)\eta_t - T_1(k - 4)/\eta_c] \leftarrow$$

**Figure 26.19** Scheme to show the layout of a combustion chamber

Figure 26.20 Pressure/volume diagram for an ideal gas turbine cycle

where  $k = \frac{c_p(\gamma - 1)}{\gamma}$ ;  $r$  is the pressure ratio of compression and expansion,  $\gamma$  is the ratio of specific heats,  $c_p$  is the specific heat at constant pressure,  $T_1$  is the absolute temperature at compressor inlet, and  $T_2$  is the absolute temperature of the air after combustion and before entry to the turbine.

It is evident that if  $\eta_t$ ,  $\eta_c$  and  $T_2$  are too low this expression could have a negative value. The turbine output would not be sufficient to drive the compressor and there would be no useful work. Hence the success of the gas turbine depends on the attainment of high isentropic efficiencies in the compressor and turbine and the ability to operate at a high turbine inlet temperature.

The gas turbine must operate at very high temperatures to develop efficiencies comparable with those attained in steam turbines and diesel engines. The turbine blades must withstand both high stresses due to rotation and the high temperature of the combustion gases passing over them. The success of the gas turbine has been made possible by the development of steels which will permit stressing at high temperatures without excessive creep. To allow the use of higher gas temperatures the turbine blades are often cooled by fluid circulating through passages in them. The designed maximum temperature of operation is determined by the required 'life' of the turbine. A lower temperature of operation will reduce the creep rate of the stressed parts and increase the number of hours of running life of the turbine. Temperature gradients in rotors and blades also induce stresses and alternating stresses due to blade vibration could cause failure by fatigue. With the materials and design experience now available, efficient and reliable gas turbine plants are being built and many are in successful operation.

The gas turbine is not a self-starting machine; it must be brought up to speed by a starting motor until the compressor is running fast enough to attain an adequate pressure ratio and component efficiencies for a self-sustaining or viable cycle. After ignition of the fuel the machine will increase in speed until the turbine drives the compressor and provides the useful output. If the gas turbine drives a generator with separate exciter, the exciter may be used as a starting motor.

As in the operation of a steam turbine, starting up and shutting down must take place with due precaution to avoid excessive temperature gradients, particularly in the rotors.

Contemporary gas turbines have compressor pressure ratios (delivery pressure/inlet pressure) of as much as 30:1 resulting in combustion chamber pressures up to 3000 kN/m<sup>2</sup> (435 lbf/in<sup>2</sup> gauge).

### 26.3.1.2 More complex plant

The efficiency of the plant described above is somewhat low (25–30%). It has advantages of simplicity, low cost and independence of water. Higher efficiencies (30–40%) may be attained at the expense of greater complication and cost.

The addition of an efficient heat exchanger has a most pronounced beneficial effect on efficiency. Figure 26.21 shows a gas turbine plant in which a heat exchanger is included. Heat in the turbine exhaust is transferred to the air delivered by the compressor so that less heat is required from the combustion of fuel. The output of the plant is not increased but the reduction in the amount of fuel burned improves the efficiency. To justify its space, weight and cost the heat exchanger must have a high thermal ratio. It usually consists of a shell containing nests of small-bore tubes over which the turbine exhaust passes giving up heat to the compressor delivery air passing through the tubes on its way to the combustion chamber; however, heat exchangers have not been adopted widely for reasons of cost, bulk and reliability.

For electric power generation the gas turbine is essentially a constant-speed machine. The simple, single-shaft open-cycle gas turbine is not generally flexible as it needs to operate at full load at constant speed to give its highest thermal efficiency. Some flexibility is possible by adopting a 'split shaft' (sometimes known as a 'two-shaft') machine, but much better flexibility and performance can be obtained at the cost and inconvenience of complexity. There are many possible combinations of compressors, intercoolers, turbines, combustion chambers and heat exchangers. Figure 26.21 shows a plant in which the compressor and turbine are each in two stages. Interstage cooling of the compressed air increases the efficiency of compression. Another combustion chamber may be interposed between the h.p. turbine and l.p. turbine to increase the output of the plant. The separation of the turbine producing useful output from that driving the compressors makes the plant more adaptable to load variations with less reduction of efficiency at part load. The cost of more complex plant is, of course, justified only when the load factor and fuel costs are high.

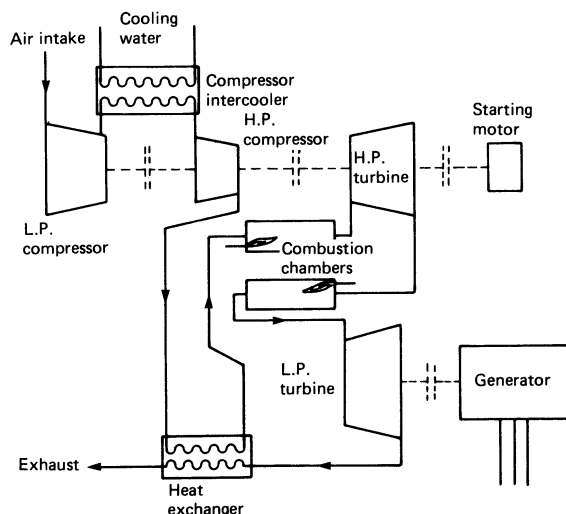

Figure 26.21 Compound-cycle gas turbine

### 26.3.1.3 Aircraft-type gas turbines

Since the 1960s there has been widespread application of aerojet gas turbines in which the propulsion jet is coupled to a heavy duty power turbine. The development of this type of turbine makes use of the extensive research carried out by the aero-engine industry and employs one or more aircraft jet engines to discharge into a gas turbine. Such units are reasonably inexpensive, compact and have exceptionally quick starting properties, e.g. full load from a cold start in 2 min.

The jet engine on aircraft has frequent skilled maintenance and normally operates at a high altitude with low atmospheric pressure. By de-rating the engine and incorporating certain small modifications it can be operated successfully at sea level at a power between its normal flight and take-off ratings and can give 20 000–25 000 h operation between overhauls. Its compactness also makes it suitable for mobile power plants.

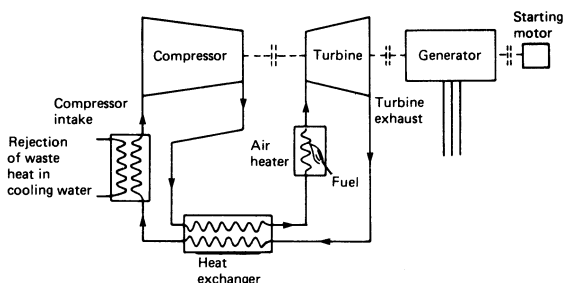

### 26.3.1.4 Free-piston gas generator

Instead of the compressor and combustion chamber of the conventional gas turbine, one or more free-piston gas generators may be used to produce the hot gas for discharge into the turbine. This comprises a cylinder containing two free pistons; fuel is admitted between the pistons and, by compression ignition and appropriate operation of valves, hot gas is emitted from the exhaust ports. The chief advantage is a higher overall efficiency (30–35%) than the conventional gas turbine, but cost and maintenance requirements are generally greater so that applications are limited. A few successful plants of between 1 and 10 MW are, however, in operation.

## 26.3.2 Closed-cycle plant

In the open-cycle plant a continuous supply of air from the atmosphere is drawn into the compressor. The intake pressure and density of the air are, therefore, fixed at atmospheric conditions. By using the closed system shown in *Figure 26.22*, in which the same air is circulated continuously, the pressure and density of the air may be increased. More power is obtained from a given size of plant and output may be varied by changing the pressure and mass flow of air, the pressure ratio and speed being retained at the optimum values.

Combustion must be external to the air stream and the heat transferred to the air in an air heater. Waste heat is extracted from the system in a cooler placed before the compressor intake.

**Figure 26.22** Closed-cycle gas turbine

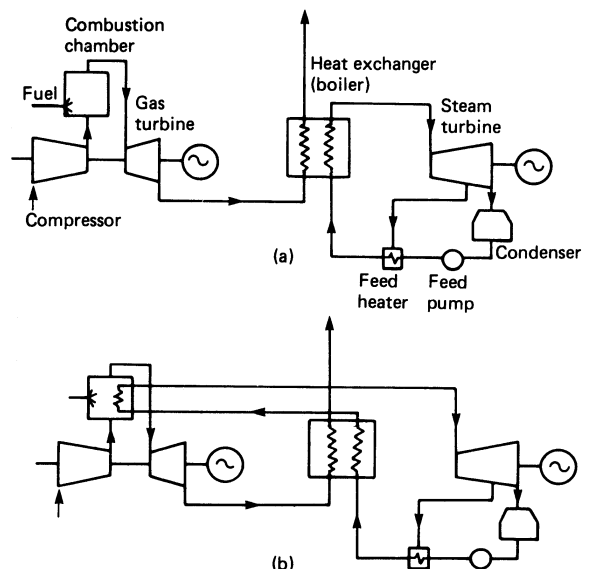

A further advantage of the closed-cycle plant is that the air is not contaminated by products of combustion and dust drawn in from the atmosphere. Other gases than air might be used if their physical properties were superior for the purpose, e.g. helium has been used for nuclear reactor cycles.

The main disadvantage of the closed cycle is the air heater. It is very difficult to attain high rates of heat transfer to a gaseous fluid like air, and excessively high tube temperatures are easily developed with consequent failure. Increasing the air velocity through the tubes improves the heat transfer but increases the pressure drop of the air in passing through the tubes. A similar problem occurs in the design of heat exchangers where improvements in heat transfer by higher velocities and greater turbulence result in excessive pressure drop. The solution is always a compromise between these conflicting factors.

## 26.3.3 Combined-cycle plant

The combined cycle, in its conventional power generation form, recovers much of the gas turbine's unutilised exhaust heat in a heat recovery steam generator (h.r.s.g.). The h.p. steam generated by the h.r.s.g. is used in a conventional Rankine cycle where the steam is expanded in a condensing steam turbine/generator set to provide an additional conversion of fuel energy to electrical energy. Unfortunately, because not all the exhaust energy can be recovered by the h.r.s.g. and the efficiency of the Rankine cycle is unlikely to exceed 38%, considerable energy is still eventually lost to atmosphere as low temperature heat, principally from the condenser. (The Rankine cycle thus acts as a bottoming cycle for the gas turbine's higher temperature cycle.) Two typical arrangements are shown in *Figure 26.23*.

*Figure 26.24(b)* illustrates the use of a high efficiency simple gas turbine in combined cycle mode. The situation has considerably improved and overall power generation efficiencies in the range 44–55% are currently available. Application is, however, still restricted due to the need for

**Figure 26.23** Gas/steam cycles: (a) simple cycle; (b) additional evaporator in the combustion chamber

Figure 26.24 Energy usage in various gas turbine systems

clean but expensive fuels such as distillates and natural gas. However, the above-mentioned application of fluidised bed combustion systems capable of burning all coal types, peat, refinery bottoms and cokes, is anticipated to change this. The increasing influence of emission controls also favour

fluidised bed combustors which can absorb sulphur oxides ( $\text{SO}_x$ ) and produce inherently low-nitrogen oxides ( $\text{NO}_x$ ) without performance penalties. The addition of flue-gas scrubbers to conventional steam plant to absorb  $\text{SO}_x$  and  $\text{NO}_x$  causes a reduction in plant efficiency of 2–3 percentage points and 25–30% increases in capital cost. This will give a considerable incentive to utilities to give serious consideration to the new generation of fluidised bed combined cycles that are now available.

#### 26.3.4 Cogeneration/CHP plant (see also Section 26.5.10)

If instead of using recovered exhaust heat solely for additional power generation in a bottoming cycle, it is used directly as heat for a process requirement, further substantial improvements in energy utilisation can be achieved. This is known as 'cogeneration' (of both heat and power), or sometimes as 'combined' heat and power (c.p.h.).

Figure 26.25 shows diagrammatically some of the heat utilisation forms that are possible with gas turbine cogeneration plant. In each case exhaust heat is used to eliminate, or significantly reduce the requirements for additional combustion of fuel in separate heat generation plant (boilers, kilns, combustors, fired heaters, etc.). In addition, since a number of the applications involve eventual heat rejection at temperatures close to ambient, most (if not all) of the exhaust heat can be credited to the overall thermal efficiency of the cogeneration plant. Accordingly, cogeneration installations can achieve very high overall efficiencies, up to 90%, depending on the nature of the heat utilisation.

From the point of view of economically effective plant installations, the two most interesting forms of heat use shown in Figure 26.25 are the direct use of the gas turbine exhaust gases and the use of exhaust heat for steam generation. The first is of interest because no expensive intermediate heat exchange equipment is required to recover the exhaust heat; this possibility arises because the gas turbine exhaust gases are relatively clean, particularly when the gas turbine is operating on high-quality natural gas, and they contain a large percentage of oxygen which can be used in further combustion processes downstream of the gas turbine.

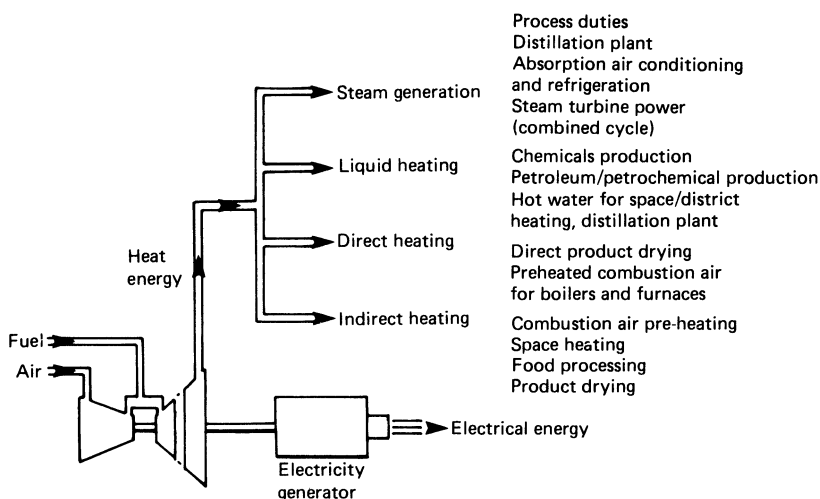

Figure 26.25 Gas turbine cogeneration utilisation

Accordingly, the exhaust heat can be used directly for duties such as product drying or preheating of combustion air for product heating in fired heaters (petrochemical industry), kilns (brick and ceramics industry), coke ovens (steel industry), etc.

The steam generation function is of interest because it is often found that the steam is required at relatively low process pressures, say at an absolute pressure of 274–620 kPa. Since it is economic to generate steam in an h.r.s.g. at much higher pressures, say 1825–6310 kPa, the opportunity arises to expand the steam from its generation pressure to the required process pressures using a back-pressure steam turbine, with steam extraction for intermediate pressure requirements. Thus, valuable extra electrical megawatts can be generated, thereby improving the economics of an installation, while serving the process steam requirement. Such plant would be properly referred to as combined cycle cogeneration equipment, although frequently only the cogeneration term is applied.

Figure 26.24(c) shows the energy utilisation of a typical combined cycle cogeneration plant. The figure shows that overall energy utilisation efficiencies well in excess of 80% can be achieved with this plant configuration. The performances of typical systems are shown in Table 26.6.

## 26.4 Hydroelectric plant

### 26.4.1 General

Hydroelectric plants convert potential energy of water into an electrical output. Rivers, upland lakes, coupled with their catchment areas, estuarial tidal cycles and upper reservoirs of pumped storage plants can provide the source of

energy to be converted. The process involves flow of water from the source to the turbine tailrace, which acts as a sink. In the process of conversion, use is made of water turbines, of associated civil structures and of rotating electrical machinery.

The power supplied to the turbine,  $P_d$  (kilowatts) is given by the product of the rate of mass flow  $\zeta Q$  (tonne per second) and of the net head across the turbine  $H_n$  (meters) corresponding to this flow:

$$P_d = 9.81 \zeta Q H_n \quad (26.3) \Leftarrow$$

where  $\zeta$  is specific mass (tonne per cubic metre) and  $Q$  is the volumetric discharge (cubic metres per second).

The net head ( $H_n$ ) represents only a fraction, however large, of the total or gross head ( $H_g$ ) which for all types of hydroelectric plant is defined as the difference in elevation between the water levels at the upstream (intake) and downstream (tailwater) limits of the installation, when there is no flow. The difference between these two heads represents the losses within the plant, but outside the confines of the water turbine. These losses are either due to flow related phenomena or arise because of the need to set certain types of impulse turbines well clear of the tailwater level. The ratio  $H_n/H_g$  is designated as the hydraulic plant efficiency ( $\eta_p$ ) which, as will be shown later, can represent a significant parameter when evaluating the worth of alternative designs of the civil works.

While hydroelectric projects are normally considered in terms of the gross heads they create, water turbines are invariably designed bearing in mind the need to maximise the weighted efficiency at a number of net heads. Exploitable heads vary from a few metres to 2000 m.

It will be apparent that, even at the highest heads, the available energy levels per unit of mass flow, are sub-

**Table 26.6** TYPICAL SYSTEMS (simple-cycle, combined cycle and cogeneration)

Performance at power turbine coupling.

Steam production figures assume 98% boiler efficiency.

Cogeneration systems are tailored for specific projects and the above examples are typical.

stantially lower than those associated with thermal plants. Typically a conventional 660 MW thermal unit would require a water mass flow of 2000 t/h to achieve its full output. A similar rate of flow in a hydroelectric unit, operating at 2000 m head would produce an output of under 10 MW. At this flow, and at a head of 20 m, the output would be below 100 kW, the capability of a small mini hydroelectric unit. However, notwithstanding the very low levels of specific energy, high output per unit can be achieved, even at moderate heads. This clearly involves very high rates of mass flow.

The greatest outputs, on modern units, have been achieved at net heads of around 120 m where flow rates of 700 t/s yield outputs of 715 MW. Similar rates of flow have recently been considered on some very low head, tidal installations, currently under study. These would result in outputs of 40 MW or so. In the former case, the diameter of the water turbine runner is 8.5 m; in the latter case a 9.0 m runner is envisaged. The largest runner diameter already in service is believed to be 9.3 m. It will be appreciated that machines of these sizes would operate at very low rotational speeds. The 715 MW units operate at 90.9 and 93.3 rev/min on the 50 and 60 Hz systems of Paraguay and Brazil, respectively.

The proposed synchronous speed of tidal units amount to only 50 rev/min and even that speed represents a compromise between the optimum speed of the turbine for energy capture (47 rev/min) and the need to ensure that the generator design parameters, such as the number of poles and the rating, could be achieved without recourse to the use of an uneconomical, oversized rotor. It is the quest for higher rotational speeds and for higher turbine efficiencies which provides the motivation for the continuing development of turbine designs.

#### 26.4.2 Types of plant

The very wide range of possible operating conditions has led to the development of a number of diverse designs of rotodynamic machinery. However, as far as the conceptual design of plant is concerned, there are in the main only two basic types of arrangement of the powerhouse within the scheme; there are, of course, some variations on the theme.

One of these arrangements is known as a 'run of the river' plant (see Figure 26.26). Here the powerhouse is either incorporated in the dam, or is located alongside it, i.e. is local to the dam. In such an installation, the gross head is determined by the difference in levels across the dam. The majority of such installations operate at heads of less than 100 m. However, even substantially higher heads, amounting to 200 m or so can be accommodated with this arrangement, as evidenced by the example of the Boulder Dam in the USA. This arrangement is also employed on tidal schemes, where the gross heads involved are well under 10 m.

The alternative arrangement is known as a 'diversion' plant (see Figure 26.27). Here the supply is taken from a dammed river or lake, from which water flows through a head race canal to a head pond or forebay in the vicinity of the remote powerhouse. From the forebay, the water flows to the turbine through a system of pressurised pipes, known as penstocks. The purposes of the forebay is to ensure that sudden changes in rates of flow, dictated by turbine controls, can be accommodated without producing unacceptable changes of the levels in the canal. In a variation on this design, the canal is replaced by a low pressure tunnel. In such a case, when control considerations justify it, a surge chamber or surge tank is provided.

**Figure 26.26** A 'run of the river' plant (Boguchauy hydroproject).

(a) Layout: 1, powerhouse; 2, spillway; 3, rockfill dam; 4, switchyard.  
(b) Section through the dam and centre line of a unit

The purpose of either of these devices is to protect the low-pressure tunnels from water hammer caused by turbine controls and to permit quick starts of the turbine, without producing significant loss of head, caused by the need to accelerate quickly the water column within the tunnels.

The powerhouse in a diversion-type plant may occasionally be located underground. Here, the tailrace may take the form of a tunnel. In cases where the tunnel runs full and is of sufficient length for the effect of the inertia of the water column to become significant a surge chamber may have to be provided downstream of the turbine draft tube. Thus it is possible to have plants of this type with no surge protection or with one surge chamber upstream or downstream of the plant or, alternatively, with two surge chambers or tanks.

Finally, in micro units which, because local demand for power is limited, may take only a fraction of the total discharge of a river, it is often possible to divert sufficient flow without the use of a dam, simply by providing a parallel channel.

Thus, it will be noted that in diversion plants the gross head is either only partly or not at all dependent on the level above the toe of a dam. In any case, a large proportion of the gross head, even in a system containing a dam may be due to the geodetic head difference between the toe of the dam and the tailwater level. Thus a diversion type of plant makes it possible to create high heads without the need to build tall dams.

Another important aspect in the consideration of the design of hydroelectric plant is concerned with the question of how best to develop the potential of a river or a basin. Given the statistical information concerning the 'run off' over a period of many years, the designer must consider the various ways in which the potential can best be exploited. The local load demand and its probable rate of growth must also be taken into consideration.

Where the hydraulic potential is large but the local demand is small or even non-existent, the designer must

Figure 26.27 A diversion plant (Collierville)

consider the viability of transmitting large amounts of power to distant load centres, as was done in the cases of Churchill Falls in Labrador (the power output of which is exported to the USA) and Cabora Bassa in Mozambique (which was constructed on the assumption that it would export power to South Africa). Yet another possibility is presented when a substantial load such as an aluminium smelter can be brought to the vicinity of the plant, as was the case on the Volta River in Ghana.

Where a scheme is to meet a demand which is expected to grow substantially with time, economic considerations dictate that, if at all possible, the scheme should be built in stages. Where damming of the source of power is involved, this of course must be done before any power at all is produced. It is possible, however, to install only the amount of machinery commensurate with the initial demand. Alternatively, a scheme may be evolved for using only a portion of the total potential head by dividing the overall scheme into a number of stations to be developed sequentially.

Another aspect of conceptual design concerns the case of a potential site where the available gross head is substantial, the site topology favourable, but the 'run off' insufficient to support the required levels of output. In such a case, diversion of 'run off' from neighbouring catchment areas through low-pressure tunnels is often employed. Only when the flow-duration data including normal seasonal variations and effects of unusual dry and wet years has been established and the storage capacity determined can the most economic mode of operation be considered. In addition, the existing load demand and its anticipated rate of growth must be taken into consideration.

Where there is no storage capacity or where the storage capacity is only small, the output, up to the rated capability

of the plant, will tend to be in step with the flow. At times of flood, excess of flow over that used for generation must be spilt over the dam. Even in such a plant, it may often be economical to increase the capability of the rotating plant well in excess of the rating based on time averaged rates of flow. This is so because the cost of the civil works represents a major component of costs and the marginal increase in costs arising as a result of the use of oversized rotating plant could be more than compensated for by the value of the additional energy recovered during the period of floods.

Where the inflow to a scheme is seasonal, as is typically the case where melting of snow or of glaciers is the source of water, provision of storage capacity is essential. Where storage capacity is provided, it is not only possible, but often very desirable, to increase the capability of the plant well beyond that corresponding to a plant that would operate on a base-load principle. This is due to the fact that hydroelectric plants are inherently suitable for use as peak-loading plants. Where pondage is small, this type of operation can be achieved by providing a pumping facility for replenishing the stored energy. On any but the very high-head plants using impulse machines, the ability to operate both as a pump or as a turbine can be achieved in a single reversible pump-turbine unit. During pump operation the generators would operate in the motor mode. From the foregoing it will be clear that in the majority of hydroelectric plants the rated capability of the plant does not relate directly to the firm volume of output. While steps can be taken to reduce seasonal variations by provision of storage, the main uncertainty stems from variations in precipitation, be it in the form of rain or snow.

It is therefore desirable to install either a suitable mix of schemes or to ensure a certain level of stand-by capacity in thermal plant. Only very occasionally, on small schemes,

taking their supply from large natural lakes, can the rated capacity, with suitable allowances for outages, be taken as firm power.

### 26.4.3 Power station

Depending on the layout of a scheme, the turbines, their auxiliaries and the electrical plant may be housed either at or below ground level. Run of the river situations are invariably housed at ground level and are located either inside or alongside the dam. On very low head schemes they may be housed within the structure of a submerged weir, with provisions for spilling excess flow, over the roof and side of the station. In diversion schemes, the power station is housed either in a purpose-built structure at ground level or in an underground cavern.

By comparison with thermal stations, the number of auxiliary systems that must be housed either within, or in the vicinity of, a hydroelectric power station is fairly limited. Such systems that are essential include the following:

- (1) Gates and/or valves used for isolating the turbine, together with the associated pumping sets and pressure receivers. Note that closure must be effected either under the action of gravity or by utilising stored energy.
- (2) Governors, actuators and servomotors and a power oil system containing sufficient stored energy for operation of a closing-opening-closing cycle.
- (3) Duplicated de-watering system with a proportion of the de-watering pumps supplied from a secure battery based supply.
- (4) A compressed-air system capable of charging and topping up the pressure receivers under (1) and (2). Where synchronous condenser operation is involved or where pump turbines are employed, the compressed air system should have sufficient stored capacity to permit the blow down of one unit at a time and have the additional capacity to make up air losses following the blow down.
- (5) Cooling systems for generators, transformers, pumping sets and for thrust and journal bearings of the turbo-generator.
- (6) A heating and ventilating plant capable of maintaining the required degree of comfort.
- (7) Voltage regulators and controllers.
- (8) Instrumentation and controls for monitoring and operating the units and their auxiliaries, including automatic synchronising equipment.

In addition to the generators, the electrical plant housed within or in the neighbourhood of the plant consists of low- and high-voltage switchgear, transformers and generator bus-bars. In connection with the latter it should be noted that, as the generator voltages employed in hydroelectric sets tend to lie in the range 8–15 kV, considerations of the cost of bus-bars dictate that the main transformers must be placed in close proximity to the generators. Thus in underground stations the main transformers are normally housed in galleries running alongside the turbine hall.

On installations on which large pump turbines are employed, pump-starting equipment has to be housed within the stations. This equipment operates on the variable-frequency principle and comprises transformers, converters and inverters, together with the associated switchgear, controls and bus-bar connections. The use of a de-watered pump turbine ensures a soft start prior to synchronising with no significant surge currents.

## 26.4.4 Turbines

### 26.4.4.1 General principles

Consideration of hydraulic conditions at the turbine runner leads to the division of water turbines into two main groups: the impulse turbines represented in modern turbine practice mainly by Pelton wheels; and reaction turbines, a group covering both mixed flow and axial flow machines.

Impulse turbines are driven by jets of water issuing from one or more nozzles distributed tangentially around the periphery of the wheel. The power output is controlled by adjusting the opening of the nozzles. As such adjustment does not affect the direction of the jet, the part-load performance of such machines is on a par with that at the design point.

With a few exceptions, reaction turbines are normally equipped with movable guide vanes. These are disposed symmetrically around the runner and control both the velocity of flow and its direction at the entry to the runner. The majority of reaction turbines have runners whose geometry is fixed and invariable. Modern, mixed flow machines, equipped with such runners are known as 'Francis' turbines. The flow at inlet is invariably inward and the flow at exit is usually axial. The axial-flow machine with a fixed geometry runner is known as a 'propeller'. Turbines in which the guides are movable but the runner blades are fixed are said to have 'single regulation'. Part-load performance of such machines (see *Figure 26.28*) tends to be poor. In order to improve performance, machines with both movable guide and movable runner blades have been introduced. Such machines are said to have 'double regulation'.

Axial-flow turbines with double regulation have been employed since the 1920s. They are known as 'Kaplan turbines', after their inventor. Double regulated mixed-flow turbines have been used since the 1950s. This type of turbine is now designated as either a 'diagonal' or a 'Deriaz' turbine, after its inventor. It may be of interest to note that the Deriaz turbine was first developed in Rugby, England. Perusal of *Figure 26.28* will show the degree of improvement, of part-load performance, resulting from the use of double regulation, on both axial- and mixed-flow machines. It will be appreciated that double regulation increases both the size of a machine and its costs. However, the resulting improvement in performance under a range of operating conditions can make their use economically justified, either where single or very few machines are installed, or where substantial head variations are encountered.

The range of heads for which the various reaction machines operating as turbines and as pump turbines are suitable is shown in *Figure 26.29*. This figure also indicates the outlines and the proportions of the runners of such machines. The shape of runners corresponding to progressively higher heads are shown from left to right.

Figure 26.28 Comparative turbine efficiency curves

Figure 26.29 Heads under which single-stage pumps and turbines can operate

With the advent of physically large units operating at very low and varying heads, as encountered on some run of river schemes and on tidal applications, yet another variation on the design of an axial flow turbine has been introduced. This type of turbine, known as a 'Kapeller', has fixed guide vanes but the runner is equipped with movable runner blades. Such a combination produces a plateau of relatively high turbine efficiencies, along the line of maximum output for a substantial range of heads.

In an impulse turbine all the available energy is converted into velocity, before the water enters the runner, while in a reaction turbine the process of conversion takes place partly before and partly after the water has entered the runner. The division of water turbines into these two groups is based on general usage and does not imply any difference in the method of energy transfer between the water and the runner. At its simplest the principle of a water turbine is that of a rotating duct, through which flows a stream of water. The stream and the duct interact; the stream is deflected and, as a result, a force is exerted on the duct. The moment of this force, about the axis of rotation of the duct is equal and opposite to the change in the moment of momentum of the stream. If the mass of water, flowing in a unit of time is  $\dot{Q}$ , the driving torque  $M$  is given by

$$M = \dot{Q}(r_1 C_{u1} - r_2 C_{u2}) \quad (26.4) \Leftarrow$$

where  $C_{u1}$  and  $C_{u2}$  are the whirl velocities at the inlet and exit, and  $r_1$  and  $r_2$  are the corresponding radii. Note that only the whirl components of the absolute velocities of flow contribute to the driving torque.

The driving torque can also be determined from considerations of power output from the turbine and of angular velocity  $\omega$ . Hence it can be shown that

$$\begin{aligned} H_n \eta_t &= (r_1 C_{u1} - r_2 C_{u2}) \omega / g \\ &= (u_1 C_{u1} - u_2 C_{u2}) / g \end{aligned} \quad (26.5) \Leftarrow$$

where  $u_1$  and  $u_2$  are the peripheral velocities of the runners at the inlet and exit, and  $\eta_t$  is the turbine efficiency.

If the effect of the small mechanical and volumetric losses on turbine efficiency is neglected and the concept of effective head  $H_e = H_n \eta_t$  is introduced, we get the Euler turbine equation in its canonical form

$$H_e = u_1 C_{u1} / g - u_2 C_{u2} / g \quad (26.6) \Leftarrow$$

This equation demonstrates the interdependence between head, velocities and the geometry of the turbine, at entry and exit from the runner.

It should be noted that, although equations (26.4) to (26.6) are constantly used in the literature to describe the performance of water turbines, they are only strictly applicable to machines in which the flow can be fully described by a single representative stream line.

#### 26.4.4.2 Fundamental similarity

Turbine characteristics are normally established on the basis of tests carried out in hydraulic laboratories on homologous models of the machine and of certain associated water passages, be it distributor pipework and nozzles in the case of a Pelton wheel, or a portion of the inlet pipe, the spiral casing and the draft tube in the case of a reaction machine. For the model to be homologous it must be:

- (1) *geometrically similar*—the requirements are that if any representative dimensions defining a water passage are in a given ratio, then all the dimensions of the units must be in the same ratio, i.e.  $D_a/D_b = D_{ma}/D_{mb} = \text{constant}$ ; and

- (2) *kinematically similar*—i.e. it is necessary for all the fluid velocities to change in a given ratio when going from one system to a corresponding point of another. This requirement can be expressed mathematically as

$$\begin{aligned}\text{Flow coefficient} &= \phi = \frac{\text{velocity of flow}}{\text{rotational velocity}} \\ &= \frac{V_a}{u_a} = \frac{V_m}{u_m} = \text{constant} \quad (26.7)\end{aligned}$$

The above relationships can be expressed in the form

$$\phi = (Q/D^2)/nD = Q/nD^3 = \text{constant} \quad (26.8)$$

where  $n$  is the rotational velocity and  $D$  is the diameter of the runner. In addition all the fluid velocities must have the same direction at similarly located points. These two conditions can be summarised by stating that all the velocity triangles at all corresponding points must be summarised by stating that all the velocity triangles at all corresponding points must be similar.

- (3) *dynamically similar*—i.e. any forces, be they inertia, viscous in origin or those arising out of cavitation phenomena, acting at similar points of fluid should have corresponding magnitudes and should be so arranged that the ensuing flow can satisfy the conditions of kinematic similarity and follow similar paths.

In order to meet these conditions, in machines operating at speeds which are inversely proportional to size it is necessary to ensure that Reynolds numbers for both the model and the prototype are sufficiently high to assure similarity of viscous forces. In addition, the consistency of head coefficients ( ) at corresponding points must be assured. This last requirement can be expressed mathematically as

$$= u^2/2gH_n = \text{constant} \quad (26.9)$$

Using the relationships established above, and if small differences in the respective prototype and model efficiencies are disregarded, it is possible to derive a number of parameters in terms of which the performance of a whole family of homologous machines, of various sizes and operating at differing heads can be reduced to just a single diagram, applicable to the whole range of similar turbines. This is achieved by reducing all the data to those appertaining to a turbine with a runner of unit diameter, operating under unit head. These parameters are:

$$\text{Unit speed} \quad N_{11} = nD/\sqrt{H_n} \quad (26.10)$$

$$\text{Unit quantity} \quad Q_{11} = Q/D^2\sqrt{H_n} \quad (26.11)$$

$$\text{Unit torque} \quad M_{11} = M/D^3H_n \quad (26.12)$$

$$\text{Unit power} \quad P_{11} = P/D^2H_n^{3/2} \quad (26.13)$$

In the case of turbines, the performance is nowadays most commonly expressed in terms of unit speed against unit quantity, with efficiency curves (mussel curves) superimposed on the diagram. Occasionally, cavitation data are also superimposed. In the case of pump turbines the above

diagrams would normally be extended to cover both turbine and pump operation. In addition, a four-quadrant plot of unit speed against unit torque is often given.

Typical turbine characteristics for a high-head Francis and a propeller turbine are shown in Figures 26.30 and 26.31. Figure 26.32 shows a four-quadrant characteristic for a reversible pump turbine.

#### 26.4.4.3 Specific speed

In order to extend codification of hydraulic performance from that covering just one family of homologous turbines at a time to all turbines at large, it was found necessary to introduce yet another parameter. Theoretically, this parameter, known as 'specific speed' ( $N_s$ ), should be obtained by combining unit speed and unit power at the point of best efficiency (b.e.p.) in such a manner as to eliminate the size of the unit from the resulting expression

$$N_s = N_{10}\sqrt{P_{10}} = \frac{n\sqrt{P}}{H_n^{5/4}} \quad (26.14)$$

However, the published data are more often than not based on the value of this parameter for the rated output rather than the b.e.p.

It should be noted that specific speed is a dimensional quantity and, therefore, the system of units must be specified. Thus in SI units, speed ( $n$ ) is in revolutions per minute, power ( $P$ ) is in kilowatts and head ( $H_n$ ) is in metres. Unfortunately most of the available data are classified in terms of specific speed expressed either in metric or British units. In both systems, the horse power is taken on the reference unit and heads are in metres or feet, as appropriate.

Figure 26.30 Typical high-head Francis characteristic (mussel curves)

Figure 26.31 Typical propeller characteristic (mussel curves)

Thus, when referring to such data, it should be borne in mind, that

$$1.165(N_s)_{\text{SI}} = (N_s)_{\text{metric}} = 4.65(N_s)_{\text{British}}$$

Whichever system of units is used, the numerical value of the specific speed represents the rotational speed at which a homologous machine would operate if it were designed to give an output of unit power, under unit head, when operating in the same fluid and at the same efficiency.

At this point, it should be mentioned that, while machines having different specific speeds cannot be geometrically similar, it is possible for machines of the same specific speed to be geometrically different, because the same hydraulic conditions can be met by different designs. Thus at certain ranges of specific speed there are overlaps between machine types. The two such ranges of interest concern the overlaps between Francis and multi-jet Pelton wheels at the lowest specific speeds and between Francis and propeller turbines at the highest specific speeds corresponding to the Francis range.

In selecting an appropriate specific speed for large reaction turbines of a particular installation, use may be made of a number of empirical expressions which summarise the current achievements world-wide. These expressions are normally given in the form

$$N_s = A/\sqrt{H_n} \quad (26.15) \Leftarrow$$

where  $A$  is a constant whose magnitude has been steadily increasing with the passage of time, following the adoption of higher specific speeds.

In the case of major reaction machines this constant is now taken as 2400 or so. Some 25 years ago, on Francis units

Figure 26.32 Characteristic curve of a Francis reversible pump turbine

Figure 26.33 Application ranges of water turbines (After Eiseher Wyss)

US practice was based on half of this value. This improvement was made possible by better understanding reached through research and testing of the conditions at the turbine runner, where the danger of damage by cavitation represented the major risk. The steady increase in the magnitude of this constant represents a substantial economic benefit because the higher specific speed leads to smaller runner diameters and higher running speeds.

In the case of impulse machines the specific speed is based on a per-jet principle. Thus if a wheel is equipped with four jets its specific speed would be twice that of a wheel with just one jet. The range of specific speeds covered by Pelton wheels equipped with a single jet extends approximately from 10 to 80 rev/min, the lower figure corresponding to the highest available heads.

Because of the overlap between Pelton wheels and Francis turbines, the choice of machine type for a given combination of head and flow becomes too complicated to be expressed by a simple formula. Instead, the reader is referred to Figure 26.33 which demonstrates the design trends.

For many years specific speed has been used as a general guide to the shape, relative size and speed of machines. It also provides access to information regarding typical efficiencies, flow and head coefficients as well as to values of runaway speeds appropriate to a given class of machinery. The relevant information is summarised in Figure 26.34.

#### 26.4.5 Hydrogenerators

Because of the system frequency, the maximum design speeds encountered in practice are not greater than 1000 or 1200 rev/min and salient-pole generators are almost universally employed. Small induction generators of up to 5 MW are used in isolated cases. The two requirements specific to hydroelectric installations are the need to take into consideration the very high runaway speeds and the need to provide sufficient rotary inertia to assure both the quality of speed control of the turbine and the stability of the electrical system. In the case of vertical-shaft units the specification often calls for the bore of the generator stator to be of sufficient size that the turbine runner can be withdrawn without the need to remove the stator. Thrust bearings are normally provided on the generator shaft. It is thus necessary for the generator designer to be acquainted with the magnitudes of

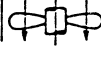

Head (m)	Low 4–50	Medium 20–700	High 200–2000
Storage	Pondage or run-of-river	Storage or pondage	Ample storage
Turbine type	Propeller or Kaplan	Francis	Impulse (Pelton)
Speed (rev/min)	50–250	150–600	200–1200
Runner			
Specific speed (kW·m)	300–1000	60–450	10–80
Peripheral speed of runner	2–3	0.75–0.9	0.5
Water speed			
Runaway speed Normal speed	2–2.2	1.8–2.1	1.8

Figure 26.34 Data for basic types of water turbine

hydraulic thrusts appertaining to a range of operational conditions.

As a result of the restrictions on size and weight due to consideration of transport and access to remote sites, generator rotors and stators are often assembled on site using preformed, transportable components. In the case of major schemes it is often economic to construct a dedicated factory at the site of the scheme, rather than to transport large components and subassemblies to the site.

#### 26.4.6 Economics

The capital costs per unit output of hydroelectric schemes are normally very much higher than comparable costs for thermal stations. This is due to the cost of the extensive civil-engineering works involved and to the very long periods of construction, during which costs are incurred and interest has to be paid, without receipt of any compensating income. However, the civil works are permanent and the life of much of the plant may well be 60 years between major overhauls, partly because of its durability and partly because the problem presented by obsolescence hardly arises. Operating costs are very low, comprising only taxes, wages and salaries of the staff and low levels of expenditure arising from the need for maintenance of the plant. Because a very large portion of the lifetime costs is incurred before a scheme is operational the cost of borrowing is one of the major parameters to be considered when assessing the viability of any scheme. As a result, the construction of many power-producing schemes can only be justified by incorporating them within larger schemes producing additional benefits such as irrigation, flood control or navigation.

The cost of the environmental effects of a scheme cannot be easily assessed. Hydroelectric schemes often provide excellent recreational facilities, first-class roads and river crossings. However, they lead to drowning of valleys, interfere with the migration of fish and can lead to the deposition of substantial amounts of silt upstream of dams. Tidal schemes can badly affect the ecology of an estuary, especially during the construction period, and on any future schemes it will be necessary to ensure that at no time will a

tidal reach of a river be turned into a temporary sweet water or brackish lake.

Notwithstanding the difficulties arising from the need to assess the ecological consequences of major power schemes, their effects must be seen to have been taken into account in any assessment of the viability of any future scheme. Otherwise, major costs will be incurred by the population at large rather than the polluter.

## 26.4.7 Pumped storage

### 26.4.7.1 Historical development

In many countries the available water-power resources are becoming fully utilised and, as environmental considerations lead to resistance to further encroachment by developments leading to the inundation of large tracts of land, modern hydroelectric practice is tending towards construction of pumped storage schemes. Currently some 20% of the world's largest turbines are used in this mode.

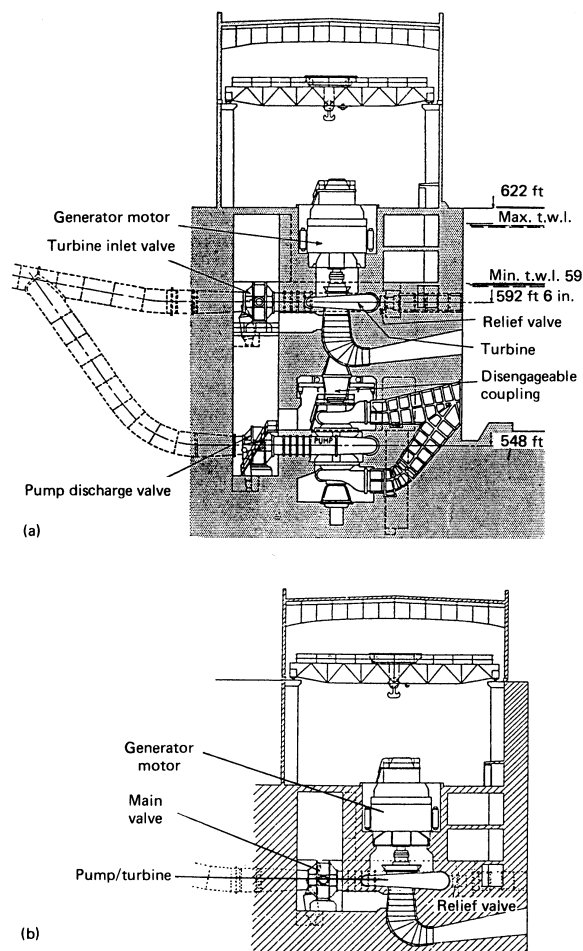

The location of such installations is not critically dependent on the quality of the catchment area, but there must be sufficient water to fill and make good any losses due to seepage and evaporation. However, any natural inflow to the upper reservoir produces a bonus in output.

As the cost of machinery per unit output depends on the available head, there is an incentive to construct such schemes at sites providing potential heads in the range 300–600 m. Should such sites not be available, lower heads could still be exploited, but at a greater cost. The pump turbines employed on schemes with heads of up to 600 m would nowadays invariably be of the single stage, reversible type. Where higher heads are encountered, the pump turbines would employ several stages of runners/impellers. Alternatively, the scheme itself can be based on the use of two or more pump turbines operating in series. However, such a solution would involve substantial additional costs.

Wherever possible, the existing storage capacity of conventional hydroelectric plant is used as the base for the pumped-storage plant. In the absence of such facilities, large existing underground excavations may be used as the lower reservoir with the pump turbines installed in a deep shaft, well below the free level of the underground reservoir.

Historically, on pumped-storage schemes separate pumps and turbines were employed with the generator doubling up as a motor in the pumping mode. The four 90 MW units operating at a maximum head of 320 m installed at Ffestiniog, North Wales, are typical of this type of installation. All the machinery is arranged in line and the length of the main shaft is around 30 m. When pumping, the turbine is run in the dry and the thrust load is supported on two separate thrust bearings, one of which is located within the generator and the other under the pump. A coupling is provided between the turbine and the pump. Separate water conduits lead to the turbine and the pump and these are guarded by separate sets of valves (see Figure 26.35(a)). In 1960, when the scheme was commissioned, Ffestiniog was the largest pumped-storage project in the world. Even at the time, the design concept was already obsolescent. The next generation of pumped-storage plants depended on the use of reversible pump turbines which were developed at that time. Figure 26.35(b) demonstrates the simplification of layout arising out of the use of reversible units.

In Great Britain, because of constraints imposed by the terrain, conventional hydroelectric installations provide a very small fraction of the electrical output. Such schemes as are in existence are invariably small and are mainly

**Figure 26.35** (a) Section through the pumped-storage station of the Ffestiniog site, North Wales. (b) Possible arrangement of a reversible installation based on the Ffestiniog site

located in the north of Scotland. However, there is a substantial investment in pumped storage. In addition to the 360 MW installation at Ffestiniog, there is a four 100 MW turbine installation at Loch Awe, operating at a maximum head of 365 m; a two 150 MW turbine installation at Foyers, Loch Ness, operating at a head of 180 m and the six 300 MW turbine station at Dinorwig, North Wales, operating at a maximum head of 545 m.

At the time of writing, the reversible pump turbines giving the largest output are installed at Bath County, USA, where six 457 MW units operate at a maximum head of 329 m. Next in terms of output come the units at Helms, USA, operating at heads of up to 540 m with an output of 400 MW per unit. Comparable outputs are obtained at Raccoon Mountain, USA, where the operating heads are 310 m.

At the heads beyond the range of Francis turbines, where Pelton wheels are employed, application of pumped storage involves the use of multistage centrifugal pumps. Because of the need to ensure that the Pelton wheels are set above tailwater level, while high-head pumps require substantial submergence, the generator can no longer be used to drive the pump.

The Roncovalgrande plant in Hago Delio, Italy, operating at a maximum head of 747 m is equipped with eight Pelton wheels and a single pump. Similar arrangements have also been used at San Fiorano, Italy, where four Pelton wheels and one pump are installed. These operate at heads in excess of 1400 m.

Yet another solution to the problem presented by pumped storage at high head is presented by the use of multistage reversible pump turbines. An example of such an application is provided by the Edolo plant in Italy where eight such machines each rated at 132 MW operate at a head of 1287 m. In connection with the use of such machines it should be mentioned that, while their performance at or about the design point can be excellent, their output cannot be varied other than by natural changes in head. However, with eight units installed, the output of the scheme can of course be varied in stepwise fashion between 12.5 and 100%.

#### 26.4.7.2 Mode of operation

Pumped storage plants provide the means for system regulation, peak lopping capacity and spinning reserve. Where a correct mix of thermal stations and pumped-storage plant has been installed, the system operator can maintain continuous output from base-load plant even at times of low-load demand. At times of high-load demand, the pump turbines provide additional output, and when operated in the spinning reserve mode they are capable of very quick response to system demands. Their use, unlike that of conventional hydroelectric units, does not in the main introduce the utilisation of renewable energy. Their economic and operational benefits arise mainly from a reduction of the high costs incurred in both fuel and in the consequences of physical damage incurred by thermal stations when operated in a cycling mode, such as 'two shifting', so common in the UK and elsewhere. They also ensure that the uneconomic use of gas turbines in their peak-logging mode of operation is no longer necessary, thus removing the need for the provision of such facilities.

The rapid response capacity of pumped storage plant can be seen from consideration of the operating times, under automatic control, achieved at the Dinorwig power station:

- |  |        |
|--|--------|
| (1) standstill to no-load generation             | 90 s;  |
| (2) no-load generation to 1320 MW station output | 10 s;  |
| (3) full load to no load but still synchronised  | 10 s;  |
| (4) pump synchronised to full pump discharge     |        |
| for a single pump                                | 80 s;  |
| for six pumps                                    | 220 s. |

Modern reversible pump turbines when starting in the pump mode are nowadays run up to speed and synchronised while the generator that acts as a motor is under the control of static, variable-frequency convertors. These convert the fixed voltage, mains frequency supply into a variable voltage, variable frequency output. Fixed-blade machines are normally started with the runner operating in the dry, in compressed air. Movable-blade runners are normally started with the unit watered, but with the blades fully feathered, to minimise resistance.

Starting a set for generation simply involves, after starting the essential auxiliaries, admitting water to the turbine. Where separate pump and turbine units are installed, like at Ffestiniog, the start of pumping involves: running the set up to speed by the turbine and then synchronising; closing the turbine guide and inlet valves so that the set is motoring; dewatering the turbine casing using compressed air; and opening the pump discharge valve. At Dinorwig changeover

times from pumping to turbinning under normal procedures take just under 10 min. In an emergency this time can be reduced substantially. It is claimed that at Dinorwig under an emergency procedure the changeover can be achieved in 90 s. The changeover from turbinning to pumping is much slower, mainly because the rates of acceleration of the unit in the pump start mode are controlled by the capability of the static, variable-frequency converter. However, as already pointed out, the initial reduction in load, from full to no load, is only a matter of 10 s or so.

#### 26.4.7.3 Economics of pumped storage

The overall energy efficiency of a modern pumped-storage scheme is usually about 75%; the losses arise chiefly from the need for double energy conversion and from loss of water from the upper reservoir due to seepage and evaporation.

The running costs of the station comprise the cost of the energy used in pumping (including the above losses), wages and maintenance, and the costs of transmission losses arising from the remoteness of the station. Pumping energy can be purchased at off-peak times at between one-half to two-thirds of the price at which it can be sold at times of high demand.

Capital costs depend critically on the topography of the site and on the availability of efficient turbo-machinery of sufficiently high specific speed. The latter determines the size of the power station and the cost of generators.

Availability of pumped storage increases the efficiency of operation of the whole interconnected system and, because of its rapid response capability, removes the need for investment in gas-turbine based peak-logging units and of operation of thermal units in the spinning reserve mode. Given the correct mix of pumped storage and thermal stations, the need for two shifting is largely eliminated.

In Europe, the USA and Japan, many pumped-storage plants have been built. Many more are projected or are in the course of construction. Pumped plants comprise the single most important area of growth of hydroelectric power generation.

## 26.5 Diesel-engine plant

Generators powered by diesel engines are employed in three main roles:

- (1) on primary or base-load duty in locations where there is no utility supply or as an independent power source to ensure security of supply where a public supply system is available;
- (2) for peak-logging (or peak-shaving) duty to supplement and/or reduce the cost of supply from a utility source; and
- (3) as stand-by to a power supply from a utility.

The speed of crankshaft rotation basically determines the weight, size and cost of an engine in relation to its output power. Engines are generally accepted as being divided into three classes:

High speed	>1000 rev/min,
Medium speed	400–1000 rev/min,
Low speed	<400 rev/min.

The maximum size of diesel plant for primary power generation is for all practical purposes between 150 and 200 MW per station. Output ratings available are in unit sizes from 1 kW to 30 MW. The most significant range for generating plant in all three utilisation categories

(continuous, peaking and stand-by) lies between 250 kW and 3.5 MW unit sizes, in the medium- and high-speed classes.

The choice between low, medium or high speed engines must be related to evaluation of power supply security against operational economy. Security of supply is essentially a function of the availability of engines and the number of units and spare capacity installed in relation to the average load demand.

## 26.5.1 Theory and general principles

### 26.5.1.1 Working cycles

The compression ignition engine operating on liquid fuels, or in the dual-fuel mode, works on the principle of fuel being injected into a charge of compressed air and spontaneously ignited by the high temperature of the induced air by the heat of compression. The process converts the heat energy of the fuel into mechanical work.

The two basic working cycles are four-stroke and two-stroke. These are represented diagrammatically in *Figures 26.36* and *26.37* together with the appropriate indicator diagrams, which portray the events within the engine cylinder during each cycle.

In the two-stroke engine the working stroke occurs in each revolution of the crankshaft, whereas in the four-stroke engine it occurs once in every two revolutions. It does not follow that, because the two-stroke engine has twice as many power strokes as the four-cycle engine it will produce twice the power. The down stroke of the two-cycle engine (*Figure 26.37*) combines both power and exhaust strokes. As the intake and exhaust ports are cleared by the piston some mixing of fresh air charge and burned gases takes place (scavenging). Not all the burned gases are exhausted, which prevents a larger fresh charge of air being induced into the cylinder. The resulting power stroke has, therefore, less thrust.

In the four-stroke engine, however, nearly all the burned gases are forced out of the combustion chamber by the up-stroking piston. This allows almost a full air/fuel mixture to enter the cylinder since a complete piston stroke is devoted to induction of the mixture. The power stroke therefore produces relatively more power than its two-cycle counterpart.

### 26.5.1.2 Combustion

The major advantage of the reciprocating internal combustion engine is that its design is not limited by the properties of the materials of its construction, since none of its parts is required to work continuously at maximum-cycle temperature. This allows high maximum-cycle temperatures to be used, which results in a high thermal efficiency—this is a measure of the efficiency with which the fuel is burned during the combustion process to produce engine power.

Whilst compression-ignition engines are generally about 5% more efficient than their prime-mover competitors, there is appreciable variation amongst them in thermal efficiency. Much depends on the size of engine and the type of combustion chamber.

Combustion chambers are basically of two types: those designed for indirect injection and those for direct injection. The former employ pre-combustion chambers in the cylinder head into which a relatively coarse fuel spray is injected at low pressure. They are popular with European and American engine manufacturers and have the advantage of being able successfully to handle a wide range of fuels.

Figure 26.36 Four-stroke cycle

When required to operate over a wide band of environmental conditions, however, they compare unfavourably with direct-injection chambers on fuel-consumption performance. Also, since heat loss from the pre-combustion chamber is high, cold starting can be difficult without prolonged cranking or recourse to external heating (such as glow plugs).

In direct-injection systems the underside of the cylinder head is usually flat and clearance volume on compression is mainly contained within the piston crown. Crown depressions are so shaped as to effectively induce swirled air

Figure 26.37 Two-stroke cycle (valveless form)

turbulence, as the piston rises on its compression stroke. Fuel is then injected in the same direction as this flow of swirling air. The direct-injection principle is almost universally employed in modern medium-speed and on many high-speed engines.

Small-bore engines tend to have lower thermal efficiencies because their high surface-area/cylinder volume ratios give larger heat losses. Again, the greater heat losses from the larger exposed surfaces of indirect-injection systems means that they give lower thermal efficiencies than direct-injection ones. For these reasons, small indirect-injection engines may have thermal efficiencies as low as 28% whilst larger engines, particularly those using direct-injection techniques, may have efficiencies as high as 40%.

### 26.5.1.3 Pressure charging and inter-cooling

In the naturally aspirated four-stroke engine the working cylinder is almost (but not fully) charged with fresh air at atmospheric temperature and pressure at the end of the suction stroke. The density of this aspirated air regulates the weight of fuel which can be burned during the working

stroke and this in turn determines the maximum power that can be developed. If a compressor were to be employed to supply the engine with intake air at a pressure higher than atmospheric, the mean effective pressure (and, therefore, the power output) of the engine would be increased without altering crankshaft speed or cylinder volume. This is effectively what pressure charging does. It can increase output by as much as 50% over an equivalent naturally aspirated engine of similar speed and dimensions. Furthermore, appreciable reductions are achieved at all loads in specific fuel consumption rates and the less arduous working conditions at the cylinders give increased engine reliability and reduced maintenance. On the debit side, however, it is impractical to expect a pressure charged engine to accept more than about 85% of its full load capability in one step in less than 10 s from crank initiation.

Several types of compressor (driven by chain or gearing from the crankshaft) are available, but since they deprive the engine of a portion of its shaft output, they are not as economical as the turbocharger which utilises the otherwise wasted energy of the engine's exhaust gases. The turbocharger very simply consists of a gas turbine, driven by the exhaust gas flow, mounted on a common spindle with a blower or compressor placed in the air intake path. Figure 26.38 illustrates in schematic form the application of the turbocharger to a four-stroke engine. Further engine upratings are now being achieved in some medium-speed, four-stroke engines by employing two-stage turbocharging to give higher air intake densities.

The full potential of this increase in air inlet density by pressure charging is, however, marginally offset by an increase of air temperature due to adiabatic compression in the turboblower. This loss is recoverable by the use of charge air coolers (inter-coolers) placed downstream of the turboblower, which have the effect of increasing the fuel/air ratio, allowing more fuel to be injected into the cylinder and so raising the engine's power output. The lower air intake temperature has the further effect of reducing not only the maximum cylinder pressure but also the exhaust temperature, and with it the engine's thermal loading. Increase in engine power over a straight turbocharged model is usually of the order of 20–25% and thermal efficiencies of over 40% are obtainable.

Figure 26.38 Four-stroke engine with exhaust-gas-operated turbocharger

Air-to-air charge cooling is usually carried out in a section of the engine's radiator. An alternative water-cooled arrangement uses either a separate radiator circuit for charge-air cooling water or, in marine installations, sea-water-cooled heat exchangers with finned tubes carrying the sea-water and over which the charge air passes.

## 26.5.2 Engine features

### 26.5.2.1 Basic classification

In generator drives, the compression-ignition engine is usually a multi-cylinder unit classified by the synchronous speed required, the type of fuel to be used, and the mechanical arrangement (i.e. the geometric arrangement of the cylinders).

### 26.5.2.2 Synchronous speed

Consistent with the output power required, the operating speed  $N$  (revolutions per minute) is determined by the frequency  $f$  (hertz) and the number  $p$  of generator pole-pairs in accordance with the relation  $N = 60f/p$ . Thus a two-pole generator must be driven at 3000 rev/min for 50 Hz or 3600 rev/min for 60 Hz; and for an eight-pole generator 750 or 900 rev/min.

### 26.5.2.3 Fuels and operating modes

(1) In its compression-ignition form the internal combustion (i.c.) engine may be run on liquid fuels using either distillate or light or heavy residual oils.

(2) As a high compression unit in its compression-ignition form, the i.c. engine may operate in a dual-fuel mode using a mixture of gas and air ignited in the cylinders by the injection of a small pilot charge of liquid distillate fuel. The pilot fuel consumption is between 5 and 10% of the normal full load quantity required for straight diesel operation and it remains fairly constant throughout the load range unless there is a gas shortage, in which case any input energy shortfall is made up by an increase in liquid fuel injected. Should the gas supply at any time fail or become inadequate for the load demanded, the engine automatically reverts to the straight diesel mode. Because of the need to modulate both oil and gas flows, the control and protection system needed is more complex than for straight diesel or gas engines.

The engine may be switched at any load from dual-fuel to diesel operation, and vice versa. The same output rating must therefore be selected for both diesel and gas operation.

(3) As a spark ignition unit the i.c. engine may operate on gaseous fuels such as natural gas, propane or sewage gas.

(4) Finally, in an alternative-fuel form, an i.c. engine may be designed to incorporate both fuel-injection and spark-ignition systems to give operation on either liquid or gaseous fuels. More often than not change to either type of fuel requires engine stoppage, but link mechanisms can be fitted to disconnect the fuel pump drive and close the air intake whilst simultaneously energising the electrical ignition and turning on the gas input. Changeover may then be effected with the engine running, much as in the dual-fuel mode described above. It must be appreciated that output rating will vary with the type of fuel used; it will be lower for gas operation owing to the change in compression ratio.

### 26.5.2.4 Mechanical arrangements

Perhaps the most widely applied engine format is the vertical design in which the cylinder axes are perpendicular and in-line. In the medium-speed range vee-form engines offering high power in a small bulk are attractive, particularly for trailer-mounted and transportable generator plants. The included angle of the vee may range from about  $35^\circ$  to  $90^\circ$ . Other arrangements occasionally used are horizontal designs, opposed piston engines of various forms and vertical twin crankshaft or double-bank engines.

## 26.5.3 Engine primary systems

### 26.5.3.1 Fuel injection

Most modern compression ignition engines have a mechanical or airless fuel injection system embodying jerk-pumps. Medium-speed engines tend to use individual camshaft-actuated pumps for each cylinder. Higher-speed engines employ block pumps within which all the jerk-pump elements are incorporated and driven from a self-contained camshaft which, in turn, is coupled to an auxiliary drive from the engine. Certain two-stroke engines use the common rail system, wherein fuel is maintained at a constant pressure by a pump and a hydraulic accumulator. A fuel valve at each cylinder, driven and timed from the main camshaft, delivers the fuel to the engine.

The injector, the device that introduces the fuel by spray into the combustion space, is in essence a spring-loaded needle valve, whose tip covers the injector nozzle hole(s). The number of holes, their angles and the angles of spray are largely dependent upon the shape of the combustion chamber. Since fuel systems must have small passages and nozzle holes, it is of paramount importance that the fuel within these systems is well filtered.

### 26.5.3.2 Lubrication

The lubricant in an engine performs many tasks. In addition to reducing friction (and the potentially considerable power loss due to it) and minimising wear, its purpose is to provide:

- (1) cooling (either under-crown and/or in piston ring areas);
- (2) cleaning and flushing of impurities; and
- (3) absorption of shocks and impacts between bearings and other engine parts.

It also affords a seal between piston rings and cylinder walls to reduce the seepage of gas that passes between the piston and cylinder walls from the combustion chamber into the crankcase.

Most engines use a pressurised or force-fed system to circulate the lubricant from an external drain tank or from a sump in the base of the crankcase. The main components of any system are: the circulating pump, which may be either of the gear or the multi-lobed rotor type; a pressure relief valve; oil filter(s) and an oil-to-engine coolant heat exchanger fitted between the feed pump and the filters. Delivery pressure is normally in the range of 50–200 kPa (0.5–2 kg/cm<sup>2</sup>) but it may even be as much as 400 kPa in high-speed engines.

In the so-called dry-sump system two pumps are employed. Oil that has circulated through the engine oilways returns by gravity to the crankcase pan. The task of the first pump is to transfer this oil from the pan to a reservoir tank external to the engine. The second pump draws oil from this tank and delivers it via the heat exchanger and filters to the bearings, etc.

The arrangement, mainly used on high-speed engines, in which the crankcase oil pan is in itself the reservoir is known as a wet-sump system.

Probably the most severe cylinder wear conditions occur just after an engine has been started, when piston lubrication is at its poorest. For this reason pre-priming systems are incorporated into both the manual start procedures and automatic start controls of low-speed and higher-rated medium-speed engines. It is also advisable to use periodic priming of lubricant on the larger high-speed engines, when these are operating in the automatic stand-by mode. Oil fed from a separate electric-motor-driven pump is circulated at periodic intervals through the oilways to flush the liners and generally wet the engine moving parts in readiness for an automatic start. Periodic priming also has the advantage of reducing the severe wear that can occur on cylinders due to condensed combustion products when an engine is at standstill.

### 26.5.3.3 Cooling

Engines may be either air cooled, using a mixture of air and oil as cooling medium, or water cooled with water and oil as the cooling media. Air cooling is simpler and is satisfactorily applied to high-speed engines up to approximately 400 kW output. Air is drawn into an impeller (usually secured to the engine flywheel or vee-belt—driven off the crankshaft) and discharged through shrouding across the finned external surfaces of the cylinder and cylinder heads. Whilst very low output engines may not require separate oil-to-air lubricating oil heat exchangers, they are standard features on larger engines.

Good installation of air-cooled engines is critical especially in high ambient conditions and in confined spaces. Care must be taken with the design and application of air intake and hot air outlet trunking to avoid, in particular, the possibility of hot discharged air being recirculated within the generator housing.

Water-cooling by circulation of water through cylinder jackets is the cooling method most frequently applied to engines in generating plants. Detailed arrangements vary considerably but most installations employ some form of closed-circuit jacket cooling system to transfer the engine heat to a heat exchanger. This may be a fan-cooled radiator or a shell-and-tube type heat exchanger. Thermostatic elements are incorporated within the systems to bypass the heat exchanger when starting from cold so as to allow the engine to attain its operating temperature more quickly.

Radiators may either be mounted on the same baseframe as their engine-generator assemblies, or remote mounted. Set-mounted radiators usually have engine-driven cooling fans, whilst remote units incorporate single or multiple fans driven by electric motors. At ratings below 1 MW,

single or double sectioned radiators are employed. On larger engines multi-sectioned units are used to provide separate circuits for jacket water, lubricating oil and charge air cooling.

Since most modern medium- and high-speed engines are designed for high-temperature coolant conditions they employ pressurised closed circuit cooling systems. System pressures vary between 30 and 70 kPa ( $0.3\text{--}0.7\text{ kg/cm}^2$ ) in practice. They equate to system boiling points at sea level of  $107^\circ\text{C}$  and  $115^\circ\text{C}$ , respectively, so that engine makers may design for corresponding maximum operating temperatures at engine outlet of  $80^\circ\text{C}$  and  $90^\circ\text{C}$ .

Where a plentiful and cheap raw water supply of good quality is available at less than  $30^\circ\text{C}$ , it may be used as a secondary fluid to circulate through an engine's tubular heat exchangers before it is run to waste. Pre-knowledge of the character and quality of the water is necessary to ensure that correct selection of materials for the tubes and shells of the heat exchangers is made.

Where a raw water supply is of dubious quality, clean (or treated) water may be used in a secondary closed circuit, which is in its turn cooled by the raw water in, for example, a cooling tower. Figure 26.39 illustrates diagrammatically an arrangement for a system of this kind. Whatever the system, it is advisable to use a high rate of jacket circulation with a small temperature difference between engine inlet and outlet, rather than a slow circulation and a large temperature rise.

### 26.5.3.4 Induction

Every engine should have air-intake filtration/silencing equipment. The induction system must be designed to supply clean dry air to the engine at as near ambient temperature as is possible and with the minimum of restriction. Engine makers stipulate the maximum permissible restriction at induction manifold or turbocharge inlet. The quality and quantity of the air supply has a direct bearing upon the engine output, fuel consumption and life.

Choice of filter depends upon the plant environment and the service life required. The following suggest the duty category in which the various filter types may be applied. The engine maker's recommendations should be sought and complied with.

- (1) For plant installed in sheltered and low dust concentration conditions: oil bath or paper element (dry) type filters, both types without pre-cleaner stages.
- (2) For installations in temperate, relatively dry and moderately dusty conditions: oil bath or dry element filters with centrifugal pre-cleaner stages and with greater dust holding capacity than those in (1).
- (3) For severe dust concentration applications or where regular maintenance is not always possible: heavy-duty paper element filters with highly efficient (90–95%)

Figure 26.39 A typical closed-circuit secondary cooling circuit

centrifugal pre-cleaner stages and preferably with self-emptying or dust unloading arrangements. Filters of this type usually offer safety elements as an optional feature. Their purpose is to protect the engine in the event of main element perforation or act as temporary substitutes when the main elements are being serviced.

It is good practice to fit air restriction indicators to dry type filters to warn when the elements have reached a pre-set limit of fouling.

## 26.5.4 Engine ancillaries

### 26.5.4.1 Starting equipment

The two main energy sources for engine starting are batteries for electric-start systems and air receivers for air-start systems. On small high-speed engines hydraulic energy or spring type inertia systems are occasionally employed. The simplest method of starting is of course manual cranking, but it is practicable only with the smallest engines. On the very largest low-speed engines small pony i.c. engines are sometimes employed to give crankshaft rotation at starting through a clutched pinion engaging with the engine flywheel gear ring.

Most electric-starting systems use motors fitted with Bendix-type pinions on their armature shafts to mesh with a toothed rim on the engine flywheel. Lower output engines in the high-speed range may require only one such motor whereas larger engines in that range, and medium-speed engines, need two motors with a common synchronising control.

Starter motors are either of the axial or co-axial type. In the former the complete armature assembly and pinion move forward axially to engage with the flywheel teeth. On the latter type only the pinion dome moves forward to engage under reduced power. This minimises engagement shock and reduces wear on the gear teeth. Starter windings may be of the 'hold-on' or 'non-hold-on' type. The non-hold variety is usually applied to motors for remotely or automatically started engines. The most frequently used voltages are 12 and 24 V, but 6 V for small engines and 32, 48 or 64 V for the top end of the electrically started range of engines are not unusual.

A cost-effective alternative to starter motors may be applied on generating sets below 15 kW rating, making use of a special d.c. starting winding within the generator to motor the engine. The same winding is used for charging the starter battery when the engine is running.

Starter batteries are either of the heavy-duty lead-acid type or alkaline type. The latter, in its nickel-cadmium form, has been favoured for stand-by generators because it retains its charge better over longer periods without use. Disadvantages are: that it is bulkier than the lead-acid battery of similar capacity; it is more expensive; and it tends to have a larger terminal voltage drop with heavy starting current drain. Maintenance-free, sealed storage batteries, using gas recombination technology, have been increasingly applied on stand-by plants in the last 5 years.

As a typical illustration the capacity of a lead-acid battery required to give six consecutive 20 s cranking periods with 5 s rest periods between each at ambient temperatures down to  $-7^{\circ}\text{C}$  on an eight-cylinder vee-form engine rated at 600 kW is 236 A-h at the 5 h rate for a 25% discharged condition. At this temperature the steady cranking current demand at 80 rev/min is of the order of 1 kA corresponding to an engine cranking torque of 1 kN-m. Breakaway current and torque figures are as much as 150% above these values.

Starting difficulties, particularly in low ambient temperatures, are more usual on the smaller high-speed engines because their large surface area-to-cylinder volume ratios tend to dissipate the heat of compression. Moreover, restrictions on the size and weight of starting equipment limit the amount of starting torque available. Various proprietary starting aids are available: devices such as electric glow plugs or those using ether-air mixtures pumped into the air inlet manifolds to give access to the engine combustion chambers to promote combustion. Decompression mechanisms may also be used to hold off either the inlet or the exhaust valve on each cylinder, during the initial starting period. Once the engine is up to steady cranking speed, full compression is restored. The engine should then fire and run up to self-sustaining speed.

Compressed air for engine starting may be expanded either in an air motor engaging with the flywheel or directly within the engine cylinders, to move the pistons downwards on their working strokes until firing occurs. As in the electric starter the drive of the air motor is through a sliding pinion. Air motors may be applied to the range of engines that otherwise uses electric starter motors.

Direct air starting applies to the larger medium-speed engines and to low-speed units. Air is directed to each of the engine cylinders, in their proper firing sequence, through non-return valves either from a camshaft driven distributor or through mechanically operated valves.

Compressed air for either form of starting is stored in one or more receivers at pressures between 100 and 300 kPa ( $1\text{--}3\text{ kg/cm}^2$ ). Air charge is maintained by a small single-stage auxiliary compressor driven by an electric motor, an i.c. engine or by the main engine itself. On large or critical installations it is usual to provide back-up auxiliaries; the primary compressor being perhaps electric-motor-driven with an i.c. engine-driven stand-by unit.

### 26.5.4.2 Governors

Diesel generators use variable speed governors set to operate at the predetermined synchronous speed. Choice of governor is dictated by:

- (1) The engine type and its application. For example: independent operation feeding an isolated load or parallel operation with similar generators or with a utility supply.
- (2) The standard of governing required, i.e. defining the limits for speed regulation (speed droop), steady-state stability and dynamic behaviour. (Classes of governing accuracy and their parameters are defined in BSS 5514: Part 4 and its corresponding International Standard ISO 3046: Part 4.)
- (3) The available inertia or flywheel effect of the combined engine and generator. It may be possible to employ a relatively simple mechanical governor in conjunction with a higher inertia flywheel to meet a tight governing specification in an economical manner without recourse to a more sophisticated and expensive governing system. Engine makers will calculate the minimum generating set inertia required for each eligible type of governor to fulfil the requirements of any governing system.

Governors vary from the simple all-speed mechanical type through various forms of mechanical-hydraulic and electro-hydraulic types to all-electric or electronic types.

The mechanical types use rotating flyweights to measure engine speed. The weights move radially and assume a position related to the speed of the engine. In the straight

mechanical governor this position is directly translated to the fuel pump rack. Speed setting is usually fixed (or adjustable through only a very narrow speed range) and speed droop is non-adjustable. Pre-selection of speeder springs provides a choice of droop settings—between 4 and 12%. Most high-speed diesel generators up to 1 MW capacity use block type fuel pumps with an all-speed mechanical governor fitted to one end of the injector pump housing. Mechanical-hydraulic governors amplify flyweight movement through a hydraulic servo system to the fuel rack(s). Droop is readily adjustable from 0 to about 8%.

In the electronic governor, engine speed is measured through a magnetic pick-up usually mounted in the flywheel housing to detect the gear teeth on the flywheel rim. The signal so derived is compared with a potentiometer-set speed reference. Any detected difference is amplified within a control unit to adjust the signal to an hydraulic or electrical actuator fitted to the engine fuel rack to correct the fuel and return the engine to its preset speed. Response to speed changes is much faster than with the mechanical-hydraulic types and fully isochronous load sharing is possible on parallel generators with these types of governor. Moreover, they may be used with a wide selection of control modules to provide fully automated and integrated multi-generator installations.

Where a governor is independently mounted from fuel injector pump(s) it is critical that the engine be fitted with some form of overspeed shutdown device, either acting directly on the fuel pump rack(s) or completely cutting off the intake air flow to the engine. This is necessary to prevent over-fuelling of the engine should any casual jamming of racks and fuel control levers take place or should any of the elements within the governing system fail.

#### 26.5.4.3 Engine monitoring

It is essential that the strategic temperature, pressure, speed and flow parameters of an engine system are regularly monitored to interpret its behaviour and performance and relay this information to planned maintenance operations.

Maker's instruction books give a good indication of the degree of instrumentation required. Much also depends upon the build specification for the particular engine but parameters such as those listed below may be monitored by instruments, wherever applicable.

- (1) Jacket and raw water temperatures, pressures and flows.
- (2) Lubricating oil temperature and pressure.
- (3) Differential pressures across fuel and lubricating oil filters.
- (4) Jacket water temperature at outlets from individual cylinders.
- (5) Exhaust temperatures at individual cylinders and before or after turbochargers.
- (6) Charge air temperatures and pressures.
- (7) Starting air pressure.
- (8) Engine, pumps, compressors, and other relevant speeds.
- (9) Fuel temperature and pressure.
- (10) Fuel and lubricating oil tank levels.
- (11) Mechanically driven or transducer operated cylinder pressure indicators.

Abnormal operating conditions may be detected by sensors whose output signals are fed into alarm/shutdown logic controls. Various combinations of indicative and protective action are possible:

- (1) two-stage alarm and shutdown;
- (2) simultaneous alarm and shutdown; and
- (3) alarm only (visible and audible).

The conditions to be covered may include:

- (1) high jacket and raw water temperatures;
- (2) low lubricating oil pressure;
- (3) high exhaust temperature before turbocharger;
- (4) high differential pressure across both fuel and lubricating oil filters;
- (5) high charge air temperature;
- (6) excessive vibration; and
- (7) engine overspeed.

This list is by no means exhaustive and the engine maker's advice should be sought on the extent of protective insurance to be taken.

#### 26.5.5 A.c. generators

Generator technology is dealt with in Chapter 20. Engine-driven generators for outputs of 20 kVA and above have direct-compound or brushless excitation.

*Compounded* generators use the load current to provide part of the excitation. They have good overload capacity and rapid voltage recovery, and may be preferred for marine application where large induction motors have to be started.

*Brushless* excitation is common for diesel-generator plant. The exciter is a three-phase machine connected to a shaft-mounted rectifier diode assembly the output from which is fed to the main generator field. The brushless machine may be self-excited from its output terminals through a solid-state automatic voltage regulator (a.v.r.). The d.c. output from the a.v.r. feeds the stator field of the a.c. exciter to control the output voltage of the main generator. Alternatively, the exciter may obtain its field supply from a shaft-mounted permanent-magnet pilot exciter in combination with an a.v.r.

For medium- and low-speed generators the rotor is usually of laminated form with fully interconnected damper windings. In some high-speed sets the poles have solid bolted-on shoes, which provide eddy-current damping.

##### 26.5.5.1 Construction

Types of construction and mounting arrangements are designated in BS 4999: Part 107 (IEC 34-7).

Almost all diesel-generator sets employ direct coupling of the prime-mover and generator. The latter may be treated either as a separate machine flexibly or solidly coupled to the engine, or flange-mounted to the flywheel housing and close coupled.

Most two-, four- and six-pole machines incorporate end-shield-mounted, grease-lubricated ball and roller bearings. Above about 3 MW, plain bearings are sometimes employed, self- or oil-scavenge lubricated. The large slow running machines tend to use single or dual pedestal outer bearings, mounted on a common baseframe with the generator stator casing.

##### 26.5.5.2 Protection

Where generators are housed in buildings or canopies and enclosures, protection to IP23 of BS 4999: Part 105 is sufficient. (The technically equivalent standard is IEC 34-5.) Ventilation is provided by an internal shaft-mounted fan

drawing air from the non-driving end and discharging it at the driving end. Dust filters may be fitted to this type of enclosure when the inlet air contains fine dust, sand, moisture or oil vapour. An output power reduction factor of about 0.95 should be applied to compensate for the resulting restricted cooling air flow. It is advisable to use thermistor temperature-sensing probes, either embedded in the stator windings or placed in the cooling air flow, to guard against damage by overheating, if the filters are not cleaned at regular intervals. For operation in extremely dirty conditions and on outdoor sites such as quarries, a totally enclosed construction, using closed-air-circuit ventilation, should be specified. The closed-circuit air is directly cooled by air-to-air (TECACA) or air-to-water (TECACW) heat exchangers, which may be attached to the generator casing. These enclosures are defined as IP45.

### 26.5.5.3 Voltage

In the UK the preferred output voltages for three-phase 50 Hz supply, and the appropriate ratings of engine-driven generators, are:

Voltage (kV)	0.415	3.3	6.6	11
Rating (MVA)	≤1.5	0.5–6	0.8–10	1–20

Voltages of 2.4, 4.2, 6.9, 13.2, 13.8 and 15 kV are encountered in American and European practice.

BS 4999 requires the output voltage to be held to within  $\pm 5\%$ , but most a.v.r.s will control to  $\pm 2\frac{1}{2}\%$  over the load range. Regulation down to  $\pm 1\%$  is possible with solid-state devices in closed-loop control systems.

Standard classification for insulating materials is given in Chapter 7. Most machines up to 3 MVA employ class E or F insulation, or combinations thereof, for stator and rotor windings.

### 26.5.5.4 Parallel operation

Active power load-sharing is a function of the engine and its governing system. The sharing of reactive power is determined by excitation and synchronous impedance: proper sharing is obtained by applying quadrature current compensation (q.c.c.) to give automatic controlled droop of the output-voltage/reactive-current relation. The amount of droop should be the same for each generator paralleled into a power system: it is typically about 5%.

### 26.5.5.5 Short-circuit performance

Fast-response brushless and compounded machines can have subtransient short-circuit current levels of 6 to 10 times full-load current. But where excitation is derived from the output voltage, a short-circuit removes the excitation supply and the generator voltage collapses.

In distribution networks it is essential that an adequate 'permanent' short-circuit current is maintained by the energy source in order to allow discriminative operation between protective devices such as circuit-breakers, fuses and overcurrent releases. This is necessary if faults on final circuits are to be cleared as quickly as possible. Maintenance of short-circuit current at a level 2 to 3 times full-load current may be achieved by excitation power derived from current transformers in series with the generator output leads. This power is fed to the exciter field

through a relay which closes when the output voltage collapses.

### 26.5.5.6 Generator selection

In selecting the right size of generator for a specific application the following factors, all influencing the rating, should be considered.

- (1) *Application*: the mode of operation, e.g. stand-by or continuous; single running or paralleled with a utility supply or with similar generators; load power factors.
- (2) *Location*: altitude, ambient temperature, humidity and other environmental conditions.
- (3) *Dynamic loading*: any limitations imposed on voltage transient performance in the starting of large induction motors or on waveform characteristics where static converter equipments or thyristor drives form part of the load.

## 26.5.6 Switchgear and controls

### 26.5.6.1 Planning

Factors affecting the choice and design of switchgear will be:

- (1) The size and nature of initial and future loads. For example, spare panel positions should be considered in an initial switchgear layout, to cater for future extensions.
- (2) In-service condition. These relate to such aspects as temperature, humidity, air conditioning and ventilation, dust, corrosion or pollution conditions and affect not only choice of components but also enclosure design.
- (3) Foreknowledge of standard equipment available in the market. Custom-built equipment is not justified when standard and competitive units may be readily adapted.
- (4) Requirements for reliability and security of supply. For example, the degree of security required influences the choice of bus-bar systems both in terms of numbers installed and their sectionalising.
- (5) Requirements for maintenance and safety, consistent with the skills of operating personnel.

### 26.5.6.2 Fault considerations

Overcurrent protective devices must operate to isolate short-circuit faults safely, minimise damage to circuit elements and avoid, if possible, shutdown of plant. An accurate knowledge of prospective fault currents throughout the system is essential for the correct application of protective devices and the design of bus-bars and terminal arrangements to withstand consequential mechanical and thermal stresses.

Generator short-circuit fault current decreases from a high initial value determined by the subtransient reactance  $X''_d$  of the machine, through a lower value determined by the transient reactance  $X'_d$ , settling after 0.6–2.0 s to a steady-state level determined by the synchronous reactance  $X_d$ . Circuit-breakers and fuses should operate before the steady-short-circuit condition is reached.

System faults are also fed by synchronous and induction motors, which may generate by release of kinetic energy by their rotating masses. The fault contribution from an induction motor ceases after a few periods. Typical values of subtransient and transient reactance, in per-unit on a machine-rating base, are:

	$x''_d$	$x'_d$
Salient-pole generators:		
up to 12-pole	0.16	0.33
14 poles and upwards	0.21	0.33
Synchronous motors:		
4 and 6 poles	0.15	0.25
Induction motors (low-voltage)	0.20	—

In the calculation of system fault levels it is sufficient to employ reactances only, except that in low-voltage (l.v.) systems the resistance of cables cannot be ignored. Arcing impedances should be included in l.v. system calculations. Typical values of per-unit arcing-fault current on 0.415 kV three-phase systems are: 0.70 for a three-phase arc, 0.57 for line-line and 0.14 for line-neutral.

### 26.5.6.3 Instrumentation and metering

Single running sets require an ammeter in each line (or an ammeter and a selector switch), a frequency indicator and a wattmeter. Optionally, a watt-hour meter and a power recorder may be fitted.

The instrumentation on each of any parallel running sets should include: an ammeter in each line (or a single ammeter with selector switch) a wattmeter and a reactive volt-ampere (var) meter. Power-factor meters may sometimes be substituted for var meters but as they develop low torque at low load they are prone to reading errors below 25% of rated current. The power factor calculated from kilowatt and kilovar values provides a more reliable and accurate indicator. Additionally, a set of synchronising instruments, perhaps mounted on a swivelling frame, is required, comprising a synchroscope, a double movement voltmeter and a double movement frequency indicator. Any incoming generator before being paralleled to the bus-bar should be connected by plug or switch to the 'incomer' movements of this voltmeter and frequency indicator, the second movements of both instruments being permanently connected to the bus-bars.

Recording instruments provide useful information for reconstruction of events, for registering operational patterns and indicating trends. In their multi-channelled form they give a time-sequenced record of events during disturbances and faults, particularly when they simultaneously monitor closing and tripping of key circuit breakers in the system.

### 26.5.6.4 Protection

The parameters to be monitored on the prime-mover have been dealt with in the preceding text. Protection related to the generator for which provision should be made, might in addition to system-fitted protective devices safeguarding against external short circuits and overcurrent, include the following:

- (1) Restricted-earth-fault protection, combined if necessary with overcurrent protection in the one relay.
- (2) Differential (circulating current) protection, where access is possible to the stator windings before the star point. Where a generator and step-up transformer are directly connected, an overall-biased differential protection scheme could be considered.
- (3) Stator earth-fault protection. It is possible to combine this with differential protection in the one relay.

- (4) Rotor earth-fault protection, by field or stator monitoring.
- (5) Generated overvoltage and overfrequency protection.
- (6) Unbalanced loading protection, with negative-phase sequence protective gear.
- (7) Load-shedding protection.

In addition, for generators running in parallel:

- (8) Reverse-power protection.
- (9) Relays should be set to operate at about 10% reverse and be time delayed.
- (10) Check synchronising relays.

Voltage surge protection should be considered where vacuum breakers or contactors are used, particularly with larger and higher voltage rated generators, if surges induced by lightning discharges on lines external to the diesel generator plant or initiated by switching are likely.

### 26.5.6.5 Control gear

Control gear should be designed to give a comprehensive indication of the state of a generator plant at all times and provide the means for modifying that state. Equipment for this purpose would include: measuring instruments, condition indicators, alarm annunciators, prime-mover and generator regulating controls and command signalling devices to engines and switchgear.

On the simplest single-generator installations, instrumentation and logic controls are usually incorporated within the switchgear cubicle(s) to give convenient operation of the plant from one location. On the more complex multi-generator plants, since adjustments on one machine affect all others in parallel with it, simultaneous observation of all the effects of any one action is essential. Where only two or three generators are involved, individual switchboards arranged as for the single generator may suffice, provided that they are placed as close together as possible and preferably in a quiet location away from the noise of running machinery.

But where adequate observation of a greater number of switchboards is difficult from one vantage point, it is advisable to use a control desk placed some distance in front of the composite switchboard. This may be used to house the generator regulating and control equipments whilst instrumentation and switchgear indicators are retained on the individual switchboards. Where size and cost of an installation warrants, a mimic diagram, representative of the complete generator plant and its feeder networks, may be incorporated into this control desk. Alternatively, it may be fitted into a separate diagram panel surmounting the composite switchboards. The diagram should incorporate pilot lights and semaphores to represent circuit-breakers, bus couplers, isolators and selector switches with miniature indicating instruments to cover feeders and generator output conditions.

## 26.5.7 Operational aspects

### 26.5.7.1 Engine ratings

Since the i.c. engine is an air-aspirating machine its output is affected by changes in the temperature and the pressure of the air it breathes. Power ratings should be quoted to the Standard Reference Conditions (S.R.C.) contained in the applicable National Standards of the engine maker concerned. For British built engines this is BS 5514: Part 1,

which is equivalent to ISO 3046/1. Although corresponding German (DIN 6270), American (SAE J-243) and Japanese National Standards cover the same technical subject matter, their treatment of it differs, particularly with regard to the standard reference conditions adopted and definitions of kinds of power.

BS 5514, which covers reciprocating i.c. engines using both liquid and gaseous fuels, applies the following standard reference conditions:

Total barometric pressure	100 kPa (750 mmHg)
Air temperature	298 K (25°C)
Relative humidity	30%
Charge air coolant temperature	298 K (25°C)

The ISO standard power rating of the engine has to be adjusted for ambient conditions falling outside the standard reference condition, to arrive at a predicted on-site or service power rating. Section 10 of BS 5514: Part 1:1987 sets out the method for re-rating RIC engines. It lists the formulae to be applied for this purpose; and Annexes B to G offer tables and examples to help simplify and explain the methods of calculation. Since the calculations are fairly complex (see Annex G of BS 5514: Part 1), most engine manufacturers reduce the formulae to simplified forms stating: the percentage reduction in power for a certain increase in temperature and altitude, above the BS 5514 SRC levels. As it is rare, in any part of the world, for high humidity to be combined with very high temperature, a de-rating exceeding 6% for humidity is seldom, if ever, warranted.

The power categories of importance to the diesel generator user are 'continuous power' and 'overload power', as defined in BS 5514: a footnote states that it is customary to permit an overload of 110% power 'for periods and speed corresponding to the engine application'. Engine makers almost universally permit 10% overload for 1 h in any 12 of continuous operation on generator application. In so doing they rightly perpetuate a requirement of BS 649, which was withdrawn on publication of BS 5514 in 1977.

Prospective engine users should be wary of rating classifications other than those above, for generator applications, e.g. stand-by rating, continuous duty with time-limitation rating, reserve rating, intermittent rating and maximum rating, to name but a few of those cited. American, European and Japanese manufacturers will usually declare ISO standard power ratings, when asked.

#### 26.5.7.2 Fuel oils

Liquid fuels used in compression-ignition engines are categorised as either distillate fuels or residual (blended) fuels. These are further subdivided into classes based upon viscosity, measured in seconds, using either the Redwood or the Saybolt systems. A fuel with a viscosity greater than 150 s Redwood No. 1 (expressed as 150 SRI) at 37.8°C is normally considered to be a residual oil.

BS 2869 lists nine classes of fuel oil, two of which, classes A and B, are specifically produced as engine fuels. Of the remaining seven, classes E, F, G and H are classified as industrial and marine fuels: E and F are light residuals or boiler fuels, G and H are heavy residuals or bunker fuels. The distillates, class A (gas oil) and class B (diesel oil), are the most widely used fuels on medium- and high-speed engines. Their American ASTM diesel fuel classification equivalents are D 975-66T Nos 1-D and 2-D. Grade 4-D

of ASTM.D 975-66T, although considered a distillate oil, is intolerable to some high-speed engines and is best suited to low- and medium-speed units.

Almost all medium-speed engines will operate on the class E and F light residual fuels, whilst crosshead two-stroke low-speed engines and some of the slower running medium-speed four-stroke engines can successfully operate on class G and, to a lesser extent, class H heavy residual fuels. Residual fuels must be pre-treated, i.e. settled, heated, separated by centrifuge and filtered or waterwashed before being transferred to an engine fuel system. Heavy fuels should not be mixed with gas, distillate or light residual fuels.

The effects that fuel constituents have on engine performance and their influence on maintenance may be briefly summarised as follows:

**Viscosity** The lubricating property of the fuel falls as the viscosity reduces. Fuel injection equipment is most affected by any reduction in fuel lubricity or excessive water content in the fuel. Special precautions are necessary when 'dry' fuels such as Avtar, Avtag and Avcat are used with high-speed engines.

**Sulphur content** Sulphur in a fuel forms a corrosive acid when it combines with exhaust gas condensates. This is wear-inducing and may be minimised by ensuring that high jacket-water temperatures are maintained.

**Conradson carbon residue value** This is a measure of the tendency of a fuel to form 'coke' when heated. A fuel with high Conradson value reduces combustion efficiency whilst increasing the rate of carbon build-up in the engine. This, if coincident with a high sulphur content, greatly increases wear rate.

**Ash content** The effect on the engine is similar to that described for the Conradson value.

**Vanadium or sodium content** Their presence in any appreciable quantity affects engine exhaust valves and turbochargers. Contents below 50 ppm are recommended if frequent incidences of valve seat burning and turbine blade failure are to be avoided.

#### 26.5.7.3 Lubricating oil

Selection of lubricant depends on whether the engine has separately lubricated bearings and cylinders (low-speed and some medium-speed engines) or whether it has combined lubrication of bearings and cylinders (all high-speed and most medium-speed engines).

Where separate lubrication is used, specially formulated and refined mineral oils containing anti-oxidant additives are specified for bearings. Some engine operators favour detergent additives despite their tendency to thicken relatively rapidly. Cylinder lubrication calls for a heavier oil than that suitable for bearings, but on many engines the same viscosity grade is satisfactorily applied to both.

For combined lubrication, oils need: a viscosity applicable to both cylinders and bearings; high oxidation stability; sufficient detergency and corrosion inhibition properties. A big proportion of medium- and high-speed engines use a straight mineral oil of the type applied to separately lubricated bearings; but others, especially the highly rated high-speed engines, require heavy duty oils with detergent and contaminant dispersive properties, e.g. MIL-L-46152

specification for naturally aspirated engines and MIL-L-2104C for turbocharged units. If there is any possibility of an engine being subjected to prolonged light-load running, such as on many telecommunication transmitter applications, it is advisable to employ a heavy duty oil even though the engine might not normally require it.

Engine makers will always specify the oil to be used consistent with the duty and rating of an application and the fuel which it is intended to use. Mono-grade oils are normally recommended but makers will countenance the use of multi-grade types, provided that the operator obtains the oil supplier's assurance that the type proposed meets the certified performance level of the equivalent and acceptable mono-grade oil.

#### 26.5.7.4 Maintenance

The diesel engine and the gas turbine are both i.c. heat engines but since the former employs reciprocating motion it is mechanically the more complex machine and demands a greater skill in its maintenance. Also its wear rate is higher. However, repair services for diesel engines are more readily available world-wide than they are for gas turbines.

Plant operating personnel should be fully familiar with all its component parts and be capable of maintaining it in its optimum condition. Operation must be continuously monitored and accurate records kept so that incipient faults are detected and repair effected before major, unscheduled and costly stoppages occur.

The starting point of any preventive maintenance programme must be the manufacturer's operator and service manuals. They indicate what needs to be checked and how frequently. Planned schedules should at first rigidly adhere to the maker's recommended frequencies for inspection checks and maintenance tasks. Only after sufficient operational experience has been accumulated should one contemplate any modification to fit the particular installation and its operating conditions, and certainly not before the first general overhaul (stripping to crankshaft bearing level) has been undertaken. This gives the opportunity to assess achievement against the maker's wear and renewal limit schedules.

Whilst the service intervals recommended by manufacturers are conservative and based on average experience and temperate conditions, periodicity of inspection and service may have to be increased where, for instance, the quality of fuel is in question or where corrosive and very dusty environments pertain, or where less than 50% loading conditions are initially expected. Over the last decade, engine and component manufacturers have achieved impressive improvements in times between overhauls. Typically, major overhauls on well-maintained high-speed engines may now occur at 15 000 h intervals, whilst those on medium-speed engines could be at between 20 000 and 30 000 h—the longer interval applying to the slower running engines.

Careful consideration must be given to plant spares stocks. A more comprehensive holding of both non-consumable and consumable items would be necessary at remote sites or in certain developing countries, where there are no local accredited spares stockists. At locations where there is ready access to good stockists, a much-reduced inventory on consumables is justified.

Even with the most vigilant monitoring, problems can arise at any time. Running plants are usually most vulnerable immediately after commissioning and after general overhauls. Table 26.7 based on 4 years of analyses of the

**Table 26.7** The major classes of failure at diesel and gas engined plants

<i>Class of failure</i>	<i>Percentage of total stoppages</i>
Fuel injection equipment and fuel supply	26
Water leakages and cooling	16

Turbocharger/lubrication/piston assemblies/gearing and drives	4 each

excellent *Annual Working Cost and Operational Reports* published by the Institution of Diesel and Gas Turbine Engineers, shows the major classes of failure (expressed as rounded-off percentages of total unscheduled stoppages) reported by over 100 diesel and gas engined plants, world-wide.

#### 26.5.8 Plant layout

The size of a plant room is largely determined by the number and rating of the generators installed and by their requirements for ancillary equipment. In addition to the engine-generator assemblies there will be switchgear, distribution and control gear, engine starting equipment, fuel service tanks, provisions for fuel and lubricating oil storage, engine cooling systems, exhaust silencing equipments, and (on the larger engines) lubrication and fuel systems external to the engine.

The internal layout should be such that the basic requirement is to construct a station building around the machinery. It is prudent to provide for future expansion. Growth may be in the form of a larger generator unit to replace the original or additional units, in multi-generator plant, to cater for increased load demand. A removable end wall offers one way of providing for future plant room expansion.

A minimum space of 2 m should be allowed around each set to facilitate maintenance. On multi-engined stations there should be sufficient headroom for overhead, installation and servicing cranes—one for large lifts of 10–30 tonne capacity and a smaller unit of about 2–3 tonne. Height to the underside of the common crane rail girder should be such that the distance between the bottom of the hook on the larger crane, when fully raised, and the floor level, is about 6 m for the biggest engines installed.

Most generator-set manufacturers provide an advisory service on foundation requirements. Where sets are not supplied with anti-vibration mountings a concrete foundation block, preferably 'isolated' from the main building structure to minimise vibration (and therefore noise) transmission, is necessary. A good empirical estimate for foundation mass is that it should be at least 1.5 times the dynamic mass of the associated diesel alternator. On new civil works a basement can be provided at little extra cost to house engine auxiliaries. Similarly, a gallery can be constructed to accommodate fuel service and water make-up tanks. This reduces the need for pipework trenches within the generator hall itself. Access to basement auxiliaries for replacement or maintenance could be by removable open-mesh gratings.

Where radiators are fitted to generating sets they should have pusher fans and be installed near to and facing an outside wall, with air ductwork and control louvers to regulate

the plant room temperatures. Space between the rear wall and the generator end of each set should be sufficient to allow for end-removal of major components, as required.

For ventilation purposes it can be assumed that approximately 8% of a generator nameplate kilowatt rating is radiated as heat from the engine and generator carcasses. The combustion air required by an engine may be taken to be approximately  $9.5 \text{ m}^3/\text{h}$  per nameplate kilowatt. Plant-room air exchange required is then the sum of the ventilation air and engine combustion air requirements. Exhaust gases should be piped to atmosphere through insulant-caulked apertures in an outside wall and silencers should be mounted external to the plant room, if at all possible.

Figure 26.40 gives floor area and height requirements, recommended by the Building Services Research and Information Association (BSRIA) in their *Technical Note TN4/79*, for individual stand-by generators in the range 50–625 kV-A.

Where noise is likely to be a community problem it is necessary to identify all the noise contributors in the plant and obtain octave-band frequency analyses for each so as to calculate the total generated noise level, in worst-case conditions. This must then be related to any noise level limits imposed by communal interests or local legislation in order to determine the noise reduction required. The appropriate noise control treatments should then be selected to restrict the noise transmitted and radiated from the plant room to a value below the promulgated level. Acoustic barriers, partial enclosures, vibration damping materials, vibration isolation, inertial blocks, lined duct work and splitter silencers in ventilation inlets and hot air discharge outlets are but some of the noise control techniques that could be considered. Any treatment applied should not prejudice the operation, maintenance and safety of the plant.

### 26.5.9 Economic factors

When considering the installation of private generating plant it is important that proposals are not only technically suitable for purpose but are also economically defensible. The actual or predicted costs of purchased power should be compared with the projected costs of privately generated power for clearly defined electrical and heat load cycles, before any management decision is sought.

Factors to be considered are:

- (1) Capital costs, embracing land; site preparation and access; foundations; buildings; workshops and tools; fuel storage; the power plant and its ancillary equip-

ments; cranes; stores and non-consumable spares and heat recovery equipment (if applicable).

- (2) Installation costs.
- (3) Operating costs; fuel; lubricating oil; service spares; wages of operating and maintenance staff; insurance; depreciation, interest on capital and rates.
- (4) Costs of any consequent supply outages.
- (5) The size of the installation and its mode of operation:
  - (a) *Base load*: independent of utility supply, supplemented by utility, with utility as stand-by, and total energy.
  - (b) *Peak lopping*: independent of utility, and in parallel with utility.
  - (c) *Stand-by to utility supply*.

Running costs are related to the pattern of operation, the number, rating and type of engines, the fuel type used, the overhaul intervals and the hours of maintenance per year. The following cost indicators will enable reasonable estimates to be made at the first stage of any appraisal, when alternative schemes are being investigated.

#### 26.5.9.1 Fuel costs

The cost of fuel to generate electricity only can be estimated as one-eighth of the cost of purchased electricity expressed in unit currency per kilocalorie (e.g. p/kal, where  $1 \text{ kW-h} = 0.863 \text{ kcal}$ ). Assume a consumer purchased 150 000 kW-h of electricity over a given period at a total price of 1.5 p/kW-h ( $= 4.74 \text{ p/kcal}$ ). This would equate to a cost of purchased power of £2610 over the period. The cost of fuel to privately generate 150 000 kW-h would then be £326.

#### 26.5.9.2 Lubricant costs

Lubricating oil consumption may be taken to be 1.5% of the fuel-oil consumption at full load. To this must be added the quantities representative of any oil changes at routine service intervals. This may vary from between 250 h to every 5000 h of running, depending upon the size and speed of the engine. The sump capacity of a 1.2 MW engine is of the order of 800 l. For first estimates of lubricating oil costs, one may work on the basis of 5% of fuel costs for the same period.

#### 26.5.9.3 Maintenance costs

Estimate on the basis of 5% of the combined costs of fuel and lubricating oil over the given period. This covers spares and labour.

#### 26.5.9.4 Depreciation, interest, insurance and rates

Engineers do not always appreciate how substantial these costs can be. A recent economic appraisal for a private generating scheme, employing two 1.2 MW sets (with a third in reserve) operating at a 92% load factor and written down over a 7-year period, revealed that the annual sum of these costs was 70% of the combined total of the other running costs, i.e. those attributable to fuel, lubricant, maintenance, spares and labour.

#### 26.5.9.5 Capital costs

Table 26.8 offers a very rough guide for first estimates on capital costs (including installation), using the cost of the engine generator and its auxiliaries as base 100.

Figure 26.40 Floor area and height for stand-by generators

**Table 26.8** Estimates of capital costs

Cost item	Size of unit (MW)		
	1	2	4
Engine-generator and auxiliaries	100	100	100
Civil works	20	19.5	16.5
Cranes and services in station	15.5	13.5	10
Installation	18.5	16.5	12.5

**26.5.10 Cogeneration/CHP** (see also Section 26.3.4)

A total energy system implies on-site power generation in which the energy input from either liquid fuel (diesel engines) or a combination of gaseous and liquid fuels (dual-fuel engines) is maximised by recovering the waste heat from the generating process. By so doing the overall thermal efficiency of generation may be raised from 37% to about 80%.

Compared with gas turbines the quality of waste heat is of a relatively low grade. Nevertheless, sizeable combined heat and power installations have been commissioned both in the UK and in Europe in recent years, most favouring multi-engined systems employing 1.5–2 MW unit sizes with dual-fuel operation.

Table 26.9 shows typical heat balances for a 2 MW 750 rev/min diesel-generator giving 1.8 MW in the dual-fuel mode.

Engines of this type and size give about 1 MW of recoverable heat from jacket water and lubricating oil in the form of low pressure water at 80 °C and another 1 MW recovered from the exhaust gases to give about 1400 kg/h of steam at 850 kPa.

Recoverable heat from a diesel engine is of the order of 250 000 kcal/h/MW from the exhaust gases and 350 000 kcal/h/MW from the jacket water.

Using exhaust heat recovery alone, 0.5 kg of steam at 850 kPa/kW-h is possible. With full jacket, oil and exhaust heat recovery this figure doubles to 1 kg of steam per kilowatt-hour and can be raised still further to 2.5 kg/kW-h if pre-heating of the jacket water into an automatic boiler, using the same fuel as the engine, is employed.

Whilst it was once considered uneconomical to employ heat-recovery systems on generators below 500 kW, the Electricity Act of 1989 has stimulated interest in small-scale combined heat and power (CHP). A UK potential of 3.5 GW of small-scale co-generation has been estimated, for the next 10 years. The majority of these plants will use engines operating on gaseous fuels; and applications will include:

- (1) hotels;
- (2) hospitals;
- (3) leisure centres;
- (4) small-scale district heating;
- (5) sewage treatment farms; and
- (6) industrial processes.

Recommendations for the electrical, mechanical and thermal protection of plants of this type are contained in publications such as:

## 27.1 Introduction

The development of electricity generation from energy sources which are alternatives to hydrocarbons has become a major objective in Europe and elsewhere both for environmental reasons, principally the limitation of carbon dioxide emissions and, latterly, for the longer-term sustainability of energy supplies. The advent of major contributions from such sources is not without significant consequences, however, for the design and operation of electricity supply systems. Secure and low cost power supplies of high quality have been achieved based on historic energy supply patterns, network infrastructures, economies afforded by large-scale generating plant, system protection and control practices all of which would be affected by substantial levels of new distributed generation.

### 27.1.1 Embedded generation issues

At present virtually all small generating plants such as arising in most CHP and renewable power stations are connected to low voltage distribution networks not high voltage transmission grids. Individually most small embedded generating stations are not subject to central system control, partly because the high cost of conventional telemetry means that in the UK, for example, system control and data acquisition (SCADA) has only low penetration at voltages below 132 kV. At these levels, therefore, distribution networks operate largely with incomplete and uncertain information. In the main, any network problems caused by renewable generators arise either because of the intermittent nature of their output or their point of connection to the network, and not particularly because they are renewable energy sources. In fact some (e.g. biomass, landfill gas, etc.) are indistinguishable from conventional generators. Others (such as windfarms, tidal schemes, wave-power, etc.) can cause problems to the network operator, ranging from:

- System stability problems when a significant proportion of system demand is supplied by randomly intermittent generators, especially at light load. Small generators with low inertia do not provide the same buffering capacity as larger plant under the power swing conditions associated with system disturbances. If a generating plant fails, it is normally disconnected from the network to maintain system stability despite increased demand from the remaining generating sources. Only once the disconnected plant is running in a synchronised manner can it be reconnected to the grid.
- Voltage control and quality problems when generators embedded within the distribution network start/stop generating. This can cause other network users to suffer voltage fluctuation, dips and steps outside of the statutory limits and inject unwanted harmonics into the voltage waveform. The cure requires much more active operation of low-voltage tap-changers on transformers than these have been designed for leading to increased risk of failure, higher maintenance and replacement costs.
- Frequency control problems—many new forms of generation (CCGTs included) don't provide the expected response to low frequency, exposing users to more severe and more frequent excursions in system frequency.
- Large-scale renewable sources (tidal barrages, offshore wind and wave power, even new-generation nuclear) are likely to be situated remote from load centres. Exploitation of these sources requires major investment in reinforcing and expanding the transmission grid; however gaining rights of way to build new circuits can face

determined and prolonged opposition from environmental lobbyists.

- The traditional network infrastructure causes additional difficulties in the siting of new generators. Distribution networks are generally designed and operated in radial configurations and are not designed to accommodate active sources of energy. This practice is based on the well established aim of minimising infrastructure costs associated with the number of conductors, protection equipment and switchgear size, apart from obviating the need for power flow control. Embedded generation adds to local fault levels and hence, sooner or later leads to the need for larger switchgear as well as the redesign of the protective systems. In addition and, as a consequence of this design practice, the distribution networks are often tapered in power flow capacity from the bulk supply point down to the customer in much the same way as a road or water network. Much renewable generation, e.g. wind, is sited away from the bulk supply points and nearer to the ends of the network, hence the difficulties in finding suitable connection points on the joint grounds of limited power flow and switchgear capacity.

With suitable engineering redesign and investment these problems can be overcome in time to a certain degree, but the costs of reinforcing the existing distribution network, upgrading control and protection systems, switchgear, transformers and reactive plant to cater for substantial embedded generation have to be considered. It is not clear how these costs will be apportioned in the privatised electricity supply industries now in existence. Furthermore it is not clear either how much randomly intermittent power from wind, wave or solar sources an electricity supply system can tolerate. According to the International Energy Agency as the contributions of these sources approaches 12% of power supplied and electricity not being capable of storage, policy makers need to start thinking about creating an energy buffer. At a 20% level it is contended that a buffer is absolutely necessary. There is, therefore, a technical limit to the development of renewable energy supplies if their output is geared solely to direct connection to the electricity supply system. Such a buffer can be supplied by pumped storage schemes in principle if enough storage capacity is installed, but the big development foreseen is the eventual move to a hydrogen economy with hydrogen from electrolysis providing the buffer and energy storage needed. In this context the development of fuel cells is a complementary activity to the development of renewable energy sources.

### 27.1.2 Energy costs

Two major methods for evaluating the unit costs of generation are:

- as annual costs per unit of kWh output relating to the costs appropriate to any particular year including a share of capital expenditure, and
- as a levelised cost per unit of kWh output which allocates lifetime production costs over the lifetime of the investment.

The latter method takes into account the time value of money and is the average present value cost in constant money terms per unit of energy produced at which the revenue from total lifetime output equals the total lifetime costs including capital, O and M and any other plant costs. This levelised cost method is recommended for use by the IEA<sup>1</sup> for comparison of generating plant costs under equivalent conditions because it covers the whole investment life of the system under consideration.

Ideally the costs should be evaluated at the user end point of consumption which would then include not only generation but transmission, distribution, system security, environmental, administration and other overhead costs; however beyond the generation plant boundaries the allocation of these extra costs is complex and maybe arbitrary. In electricity analysis, therefore, the bus-bar cost at the point of production is the only cost considered.

To relate capital cost to energy supplied the levelised cost per unit of kWh is found using a sinking fund method for uniform capital recovery whereby a constant capital charge rate  $A$ , or annual payment, is made into the fund, which then accumulates interest and totals to the desired sum at the end of the period of, say,  $N$  years. Since no capital is redeemed interest is payable on the full capital amount  $P$  and the capital charge rate is

$$A = P \frac{i(1+i)^N}{i(1+i)^N - 1}$$

where  $i$  is the interest rate. Here the period  $N$  relates to the period for capital recovery rather than to the longer period of plant technical lifetime. The capital amount  $P$  is not usually the total capital cost of the project, because projects financed with private equity as well as loan, say in a 20%:80% ratio, would be able to sustain lower energy production costs to cover the loan with returns to investors from whatever revenues from prices surplus to costs are possible.

Defining the factor  $R$  as  $R = i(1+i)^N / (i(1+i)^N - 1)$  then values of  $R$  are given in Table 27.1 for periods of 3 to 25 years and for interest rates of 8 to 14%.

Given the rated plant full-load power generating capacity in kW, the load or capacity factor which is the equivalent proportion of the year that the plant would have to be generating at rated output to produce the actual energy output achieved and the total number of hours in a year (8760), then the energy  $E$  produced per annum in kWh is

$$E = (\text{rated power full-load capacity}) \times (\text{capacity factor}) \times (8760)$$

The cost of generation  $C_{cr}$  attributable to capital recovery is then  $C_{cr} = A/E$

To this cost must be added the annual operating costs including maintenance and, in the case of conventional plant, the annual fuel costs.

Comparisons of costs of energy produced from different renewable sources and from conventional generation plant involve a number of factors, which are inevitably site specific; therefore calculated costs should be considered only as indicative. The costs of any energy system could fall within a wide range depending on the specific conditions found at each site, the maturity of the technology, the economies of scale, the financing arrangements and the market conditions in which the electrical energy produced is traded.

**Table 27.1** Values of factor  $R$  for capital recovery

Periods $N$ years	Interest rate 8%	Interest rate 11%	Interest rate 14%
3	0.388	0.409	0.431
5	0.251	0.271	0.291
10	0.149	0.170	0.192
15	0.117	0.139	0.163
20	0.102	0.126	0.151
25	0.094	0.119	0.146

## 27.2 Solar<sup>2-9</sup>

### 27.2.1 Photovoltaic systems

The present day market in the application of photovoltaic (PV) cells is defined by three sectors

- the *professional sector* which includes the powering of orbiting satellites or telecommunication repeaters in remote locations where the requirement for reliable, maintenance-free, independent power is essential,
- the *off-grid sector* which includes applications in developing countries, rural health, water pumping, irrigation and rural lighting and education, and
- the *grid-connected sector* where the PV electricity flows into a national grid. This sector is sub-divided again into two, that which forms part of centralised generation, e.g. for powering pumped storage schemes, and that which forms the larger sub-section of building integrated photovoltaic systems (BIPV).

#### 27.2.1.1 Principles

When light strikes certain semiconducting materials such as silicon, gallium arsenide or cadmium sulphide, fabricated in the form of a p-n junction, an electric current can flow through an externally connected circuit. About 80% of PV cells manufactured are based on crystalline silicon. The silicon semiconductor band-gap energy of 1.1 eV, equivalent to a photon wavelength of 1100 nm, is the minimum threshold photon energy required to excite an electron-hole pair. Light of wavelength greater than 1100 nm, about one third of the spectral content of sunlight, does not have sufficient energy to create an electron-hole pair, whereas light of wavelength less than 1100 nm has sufficient energy to create an electron-hole pair, but only the band-gap energy can contribute to the cell voltage. The excess energy is lost in phonon transitions which heat up the cell. The theoretical efficiency of the silicon cell is thus around 30%. At present because of material imperfections the best laboratory cells are 24% efficient.

In bright sunlight, an irradiance of  $1 \text{ kW/m}^2$ , a  $10 \text{ cm}$  square cell will give an output of about  $0.5 \text{ V}$  and  $3 \text{ A}$ , i.e. about  $1.5 \text{ W}$  of power, or  $150 \text{ W/m}^2$ . Manufacturers quote the output of their cells for a sunlight intensity of  $1.5 \text{ kW/m}^2$  (similar to that of the Sahara Desert at noon). This standard output is labelled 'peak watts' or ' $W_p$ ', and is measured at a standard temperature of  $25^\circ\text{C}$ . The power output of a solar cell varies with the intensity of light falling on it, which includes the angle of the sun to the plane of the module. The current output is halved if the light intensity is halved, but the voltage will drop by only a few per cent. The voltage output also depends on the temperature of the cell and decreases by about  $0.5\%$  for every degree Celsius rise in temperature above  $25^\circ\text{C}$ . Such cells need to be connected in series/parallel to provide a current-voltage relationship suitable for the load.

#### 27.2.1.2 Technology

Three feasible broad groups of cell modules comprise crystalline flat plate, thin film flat plate and concentrator designs. Currently available commercial flat plate modules are based on either crystalline silicon or thin film amorphous silicon cells. There are also a number of concentrator installations in different countries based on single crystal silicon cells. Crystalline silicon flat plate modules dominate the power market, defined as arrays larger than  $50 W_p$ . Cells are made from single crystal or polycrystalline material with individual cells series-strung and then encapsulated behind

low iron-content tempered glass. The best commercially available product at present is 16–17% efficient. Thin film cells based on materials having better photon absorption properties such as amorphous silicon, cadmium telluride and copper indium have had considerable development for the consumer market and also several large demonstration plants are in operation around the world. Low cost manufacturing of thin film solar cells has yet to be realised and, although having lower efficiencies than silicon cells, they hold the promise of being eventually cheaper to manufacture in high volume. The use of more expensive cells is possible by using optical concentration and high efficiency cells based both on gallium arsenide and silicon.

### 27.2.1.3 Photovoltaic systems

Typical modules produce about 14 V d.c. and about 3 A under an irradiance of  $1 \text{ kW/m}^2$ . Higher power levels are obtained by series and/or parallel connections. Various module sizes rated from 30 W to 120 W are presently available. The module must also be mechanically supported to withstand wind loads and be correctly orientated to obtain maximum irradiance. The power output must be delivered in an acceptable form such as a constant d.c. voltage or 240 V, 50 Hz a.c. and this usually needs power-conditioning equipment. Presently available solar modules are manufactured to withstand extremes of climate and carry a twenty-year warranty to back up claims of trouble-free reliability.

The cost of a PV system comprises the manufacturing costs of silicon wafer production and assembly of modules plus the costs of installing the system. The silicon wafer cost is approximately 25% of the system cost at present of which 5% is the silicon feed-stock material cost, the wafer-to-module conversion cost represents a further 25% with the installation of the system comprising the mechanical support structure, cabling and inverters making up the remaining 50% of the total installed cost.

The PV industry is growing rapidly at about 30% per annum with significant urban markets developing in Germany, Holland, Japan and the USA stimulated by attractive subsidies. In the USA, for example, in 1998, there were 8500 solar buildings, up from only 2000 the previous year. The projected numbers of solar buildings for 2000, 2005, and 2010 are 51 000, 376 000 and 1 014 000 respectively. By way of illustration the Long Island Power Authority is providing a \$4.5 million grant to help underwrite the capital cost of a photovoltaic system requiring 7 800 PV panels of varying sizes on the roofs of three buildings, having a capital cost of \$9.3 million (2001). The system will generate 1.5 MW of power during peak periods.

Guidelines and standards applicable to PV systems in various countries cover the requirements for safe installation of PV building-integrated systems applicable to PV modules and arrays, e.g. critical temperatures, voltage ratings, cable and insulation types, sizing for safe design, over-current protection, manual disconnects, grounding, anti-islanding protection, and in-surge and transient protection.

The major barriers to PV becoming a large-scale energy source are generated electricity costs and availability of raw materials. Today's PV systems sell for about \$6–\$10/ $\text{W}_p$ , with an implied electricity price of about \$0.4 to \$0.7/kWh in California and \$1.00/kWh in the UK. This compares with a domestic electricity price of around \$0.10/kWh in the UK and average generation costs of \$0.04 to \$0.05/kWh. Projections of future costs based on progress in PV technologies are consistent with module costs below \$0.5/ $\text{W}_p$  (compared to \$3/ $\text{W}_p$  today) with further reduction in installation costs. In the longer-term material availability may

have to be addressed because several thin film PV technologies that are expected to have excellent cost potential use a rare raw material: germanium in amorphous silicon; tellurium in cadmium telluride; and indium and gallium in copper indium diselenide.

In the UK PV technology is likely to be grid-connected avoiding the cost of battery storage with integration into building facades or rooftops. Of all the renewable energy technologies contributing to the generation of electricity, photovoltaics is perhaps the one most easily integrated into the existing electricity supply structure, also with minimal environmental impact.

## 27.2.2 Solar thermal applications

Solar energy can be converted easily into useful heat and provide a significant proportion of space heating and hot water demand for low temperature-rise applications, e.g. domestic hot water.

### 27.2.2.1 Active solar systems

The most widely used active method for converting solar energy into heat is by the use of flat plate collectors comprising an absorber plate (transparent cover), tubes or channels integral with the collector absorber plate carrying water or other fluid, an absorber plate which is normally metal and with a black surface, insulation to minimise heat losses and a casing for protection against the weather, combined with pumps or fans for the circulation of the heat. Collectors come in a variety of forms, with combinations of flat, grooved and corrugated shapes for transferring the absorbed solar radiation from the surface. Solar ponds about 1 m deep with a blackened bottom can also be used as a collector offering the possibilities of achieving water temperatures up to  $100^\circ\text{C}$  with a collection efficiency of 15–20% using salt concentration to ensure that the density of water increases towards the bottom, thus preventing circulation by convection. Heat can be removed by circulating the lower levels of water through a heat exchanger without disturbing the upper layer. Advanced collectors are necessary for temperatures greater than  $100^\circ\text{C}$  because of the relatively large heat losses of simple flat plate collectors. Although there is a considerable technical potential market for active solar systems in North European countries such as the UK, for example, and, despite the publication of several Codes or Guides to good practice, the high costs of installations have reduced the development of the market in favour of alternative conventional sources of energy supply.

### 27.2.2.2 Passive solar systems

In passive systems use is made of the building materials and design for both space heating and cooling. By combining energy efficiency measures with passive solar design techniques for energy collection, storage and distribution energy costs in buildings can be greatly reduced from present day standards.<sup>4,5</sup> Several categories of passive systems exist including

- the 'direct gain' approach using windows as solar collectors,
- the Trombe or thermal storage wall in which the heat is stored in the wall which also absorbs the solar energy passing through the glazing,
- the solar greenhouse combining these two approaches whereby glazing, i.e. a greenhouse, is added to the outside

- of a thermal storage wall facing south (in the northern hemisphere),
- the roof pond system in which a shallow pond or tank with moveable insulation is located on and covers the roof affording both heating and cooling options depending on the time of day covered and season and
- the natural convective loop using air.

Factors to be considered in passive solar design schemes include the influence of the local climate on the optimum design, the perceived merits or otherwise measured against energy use and cost, comfort and amenity value, public acceptance and the integration of energy use into the overall design process.

#### 27.2.2.3 Photochemical conversion

In the photochemical conversion process, irradiation of an electrode/electrolyte system results in a current flow in an external circuit. The current may be generated by a photochemical reaction in the electrolyte, or by a photosensitive electrode. Devices based on this effect, the absorption of solar photons in a molecule producing an excited state or alternatively in a semiconductor raising electrons from the valence band to the conduction band, may be used either to produce electric power directly or to produce a chemical product (photo electrolysis). The latter process stores the energy and regenerates the reactants on subsequent conversion to electricity. It is this capacity for energy storage that makes the devices based on the electrochemical effect particularly attractive for solar energy conversion. So far, however, only low efficiencies have been obtained and the process is at present almost entirely experimental. The majority of photochemical reactions are exothermic and not suitable for converting solar radiation into stored chemical energy. The known endothermic (energy storing) reactions that occur with visible light are, in theory, capable of producing valuable chemical fuels. A major problem, however, has been that most of these endothermic reactions reverse too quickly to store the energy of absorbed light.

#### 27.2.2.4 Chromogenic materials

Most of the literature on this subject concerns small-scale electronic information display, but chromogenic materials offer also the possibility of developing advanced glazing which combines variable control of solar gain with efficient thermal insulation. Electrochromic windows are essentially electric cells comprising an electrochromic layer and a counter-electrode, or ion storage layer separated by an ion conductor and sandwiched between two transparent electronic conductors that are deposited onto transparent substrates, e.g. glass or polymeric materials. In operation a d.c. electric field is applied across the transparent conductors and ions are driven either into or out of the electrochromic layer. In addition the electrochromic layer may be caused to bleach or to colour in a reversible way under the influence of the field causing reflectance or absorbance modulation of visible and near infrared electromagnetic radiation and hence changes in the optical properties of the window.

#### 27.2.2.5 Transparent insulation materials

Transparent (or translucent) insulation materials (TIMs) are a relatively new class of materials that combine the uses of glazing and insulation. With these materials high transmission of light and heat from the sun (solar gain),

good insulation (U-value), i.e. low conduction of thermal wavelengths, and strong convection suppressant characteristics are possible.

## 27.3 Marine energy<sup>10-16</sup>

The main potential sources of marine energy are tides, marine currents caused by tidal movement but including other effects as well, waves and ocean thermal energy.

### 27.3.1 Tidal energy

There are two types of technology involved in extracting energy from the tides, the first capturing and subsequently using the potential energy within a storage basin, the second converting the kinetic energy of tidal streams. The concept of installing turbines in a barrage that encloses inlets or estuaries is well established, whereas the use of tidal streams, although considered for some time, has recently seen a marked increase in interest through comprehensive studies and progress towards demonstration projects.<sup>10</sup>

The sea level varies approximately sinusoidally with a 12.4-hour period, the diurnal ebb and flow cycle, superimposed on a longer sinusoid with a period of 353 h, the spring-neap cycle. When the sun and the moon are almost in line with the earth the tides have their maximum amplitude and are known as the spring tides; when the moon-earth-sun angle is a right angle the tides are at minimum amplitude and are known as the neap tides. The ratio between the amplitudes of the maximum spring tide and the minimum neap tide can be up to as much as 3 to 1. Smaller seasonal variations also occur. The peak-to-peak amplitude of the tidal variation is known as the tidal range. In mid-ocean this range is about 1 m, but it is often amplified in coastal areas by a complex interaction with coastal features. The greatest amplitude occurs in estuaries where the tide is in resonance condition with the advancing tidal wave interacting with the reflected waves from the side of the estuary.

#### 27.3.1.1 Tidal barrages

The simplest method of extracting energy from the tide is to build a dam (barrage) across an estuary or inlet, the dam containing turbines to generate electricity. In its most basic form the rising 'flood' tide enters the basin through gated openings or sluices and through the turbines idling in reverse. At high tide all openings are closed until the tide has ebbed sufficiently to develop a useful head across the barrage. The turbines are then opened and generate electricity for several hours until the difference in water level between the emptying basin and the next flood tide has dropped to the minimum at which the turbines can operate. Shortly afterwards the levels will be equal, the sluices are opened and the cycle repeats. There are alternative methods of operation, the main options being generating at ebb tide only with or without using the turbines also as pumps at high tide to raise the level of water in the basin and generating during both flood and ebb tides. Studies have shown that the method of operation that results in the lowest unit cost of energy is either simple ebb generation or ebb generation with pumping at high tide. With ebb generation electricity is produced for 5-6 h during spring tides and about 3 h during neap tides out of a tidal cycle lasting approximately 12.4 h; thus a tidal barrage produces two blocks of energy each day, the size and timing of which follows the lunar cycle. As the generation period is about 1 h later each day, the generation (and pumping if used) needs

**Table 27.2** Mean tidal range in selected locations<sup>11</sup>

Location	Range (m)
Bay of Fundy Canada	10.8
Severn Estuary, UK	8.8
Rance Estuary, France	8.45
Passamaquoddy bay, USA	5.46
Solway Firth, UK	5.1

to be planned in advance to integrate with the demand and supply of the grid.

Assessments of technical and economic feasibility of tidal barrages are site specific. Some locations are particularly favourable for large tidal schemes because of the focusing and concentrating effect obtained by the bays or estuaries. Typical ranges are shown in *Table 27.2* which includes the world's largest tidal range in the Bay of Fundy and Europe's largest, the Severn Estuary.

Other sites representing important energy resources include Alaska (Cook Inlet), Argentine (San Jose), Australia (north west coast), Brazil (north coast), China (Yellow Sea), France (Iles de Chausee), India (Gulf of Cambay, Gulf of Katchch), South Korea (west coast), Russia (Okhotsk Sea, Jugursk Bay).<sup>12</sup>

The largest scheme in operation is the 240 MW barrage at St Malo in the Rance Estuary France. Work on the Rance site commenced in June 1960, the final closure against the sea in July 1963 and the last of the 24 × 40 MW turbines being commissioned in November 1967. The overall length of the barrage is 700 m. Tides follow a two-week cycle throughout the year. During the first week the tidal range is between 9 m and 12 m and in the second week between 5 m and 9 m. For the lower ranges electricity is generated on the ebb tide with the basin level increased by pumping while for the higher ranges the electricity is generated during both ebb and flood tides, sometimes augmented by pumping. The output is computer controlled and optimised to match the needs of the French national grid. The nominal average output of between 50 and 65 MW is thus not the maximum that could be obtained, but contributes maximum savings to the grid.

While La Rance electricity is the cheapest electricity on the French national grid Electricité de France say that it would be too expensive to build any further power stations. The same conclusion applies to the proposed Severn Barrage scheme in the UK. This larger project would involve a single basin ebb generation scheme with a 13 km barrage. The estimated total installed capacity would be 8640 MW obtained from 216 turbine generators, each 9 m in diameter and rated at 40 MW with an annual output of about 17 TWh. The nominal lifetime is taken to be 120 years, but in practice with maintenance and turbine replacement as necessary is indefinite. Elsewhere in the UK the second largest project would be the Mersey Barrage. Here the installed capacity would be only 600 MW, but there would be substantial benefits to the local economy. Overall in the UK the theoretical tidal barrage capacity is considered to be approximately 25 GW.

Tidal barrage schemes have a large impact on an estuary. With a reduced tidal range above the barrage there are potential changes to land drainage, fish migration, navigation of ships, wading bird activities plus the possible increased sedimentation due to altered channel turbulence and flow in the estuary. Several advantages follow from building a barrage, however, through the provision of a

route for road traffic across an estuary and with the reduced tidal range come increased opportunities for recreational sailing and water sports.

### 27.3.1.2 Marine currents<sup>10</sup>

Relatively rapid marine currents exist at locations where natural marine flows occur through constraining channels such as straits between islands, shallows between open seas and around the ends of headlands. Marine currents are driven primarily by the tides, but also to a lesser extent by coriolis forces due to the earth's rotation, salinity and temperature differences between sea areas.

Studies of the European resources showed 106 locations suitable for exploitation with a total capacity of some 12 GW yielding about 48 TWh per annum. Other large resources exist in SE Asia, Canada, the SE coast of South Africa and elsewhere. Typical velocities at peak spring tides are in the region of 2 to 3 m/s or more. The main requirements are fast flowing water, a relatively uniform seabed to minimise turbulence, sufficient depth of water to allow large enough turbines to be installed, such conditions to extend over as wide an area as possible to allow the installation of enough turbines to make the project cost effective, free from shipping constraints and near enough to a shore-based electricity supply network capable of taking the power delivered.

The extraction of energy from marine currents by means of propeller turbine rotors is governed by the same equations as for wind turbines, thus the power theoretically available from a stream of water through a turbine is

$$P = \frac{1}{2} \rho_w A V^3$$

where  $P$  is the power,  $\rho_w$  the density of water,  $A$  the area swept by the rotor blades and  $V$  the stream velocity. The power density of water compared to that of wind may be seen from the *Table 27.3* for different velocities assuming a density for salt water of 1030 kg/m<sup>3</sup> and an air density of 1.2473 kg/m<sup>3</sup> corresponding to air at 10°C.

The maximum amount of energy that can be extracted is 16/27 or 0.59259 of the theoretically available energy (the Betz limit) and, as for wind turbines, this efficiency can only be approached by careful blade design.

In contrast to wind turbines of similar output the high power densities achieved with streams of flowing water at the velocities encountered mean that large thrust forces are applied to marine turbines. *Figure 27.1* illustrates the power output and speed of a marine turbine for different rotor sizes assuming a stream velocity of 2 m/s and a conversion efficiency of 30%<sup>10</sup> with the possible overload torque and thrust loads encountered at the higher velocity of 4 m/s.

**Table 27.3** Relative power densities of marine currents and air at different velocities

Velocity m/s	Power density marine kW/m <sup>2</sup>	Power density wind kW/m <sup>2</sup>
1	0.52	—
2	4.12	—
3	13.91	0.2
10	—	0.62
15	—	2.10
20	—	4.99

Figure 27.1 Typical performance characteristics of marine turbines in 2 m/s tidal stream and 30% efficiency

The high axial thrust requires the turbine to be attached to a structure which is either anchored firmly to the seabed via gravity based or piled platform structures or floated beneath a vessel held by high tension moorings. Various designs are possible for the power train linking the horizontally mounted turbine to the generator from which output is delivered via a marine cable laid across the seabed to the shore at voltages of 11 or 33 kV.

### 27.3.2 Wave energy

#### 27.3.2.1 Resources

The oceans act as an integrator of wind energy. Waves arriving at any point can have originated from storms many hundreds of kilometres distant, the 'swell' sea, or

from local wind conditions, the 'wind' sea. The distance from the origin of the swell waves is known as the fetch. As a general rule coastlines with an ocean fetch of greater than 400 km are suitable sites for recovering wave energy with the greatest resources being available between latitudes 30° and 60° in the Northern and Southern hemispheres.

In the UK alone it has been estimated that the recoverable wave energy resource exceeds total UK electricity demand. Estimates of the total power available for wave energy systems in the UK in the mid-1970s were based on data gathered from the weather ship *India* (50°N, 19°W). Translating this data into wave power likely to be obtained from shoreline devices gave the analysis summarised in Table 27.4.

Measurements reported by the then CEB in 1983 at inshore sites in the UK showed power levels between 40 and 50 kW m<sup>-1</sup> of wave front in water about 50 m deep

Table 27.4 Achievable wave power resource in the UK<sup>13</sup>

TOTAL RESOURCE Estimated in 1974 by assuming weather ship data of 80 kW/m mean annual output applied to 1500 km of UK coastline	120 GW
GEOGRAPHICAL LIMITATIONS Land masses prevent formation of energetic waves from easterly direction and Eire screening part of UK coastline	-72 GW
DEVICE CONFIGURATION LIMITATIONS Waves from different directions are not absorbed with equal efficiency by a line of devices. Directionality factor = 0.76	-12 GW
STATION DESIGN LIMITATIONS Some sites are not suitable: devices must be spaced apart and permit navigation. Device/space ration = 0.75	-9 GW
DEVICE CAPTURE LIMITATIONS Efficiency of power absorption varies with wavelength. Some power is rejected. Overall efficiency = 40%	-16 GW
POWER TRAIN LIMITATIONS Losses due to efficiencies of turbine, generator, transmission system. Overall efficiency = 50%	-5 GW
AVAILABLE RESOURCE May be subject to further limitations both environmental and economic	6 GW

near South Uist and  $25 \text{ kW m}^{-1}$  off the north-east coasts of England or south-west Wales.

Further assessments made in 1988<sup>14</sup> gave a larger technical potential of 30 GW capable of providing some  $50 \text{ TWh yr}^{-1}$ , mainly off the Western Isles of Scotland and the coast of Cornwall. Such estimates have to be moderated by the lack of electrical transmission network infrastructure in NW Scotland and between Scotland and England that need to be installed if wave power is to contribute significantly to the UK demand for electrical energy.

### 27.3.2.2 Device design

Over three hundred ideas have been considered in the UK Department of Energy programme.<sup>15</sup> In general three main approaches to capturing wave energy are as follows:

- (i) *Floating or pitching devices* These devices generate electricity from the bobbing or pitching action of a floating object. Examples include tethered buoy structures where the rise and fall is restrained by the mooring with energy extracted from a pump in the mooring. Alternatively the device can be mounted to a floating raft or fixed to the sea floor where energy is extracted from the relative motion between inner and outer parts of converters mounted on a common frame or spine across the wave front or to hinged wave-contour structures perpendicular to the wave front where the energy is extracted from the relative motion of adjacent sections.
- (ii) *Oscillating water columns (OWC)* These devices generate electricity from airflow caused by the wave-driven rise and fall of water in wave energy collectors which are in the form of a partially submerged shell into which seawater is free to enter and leave. As the water enters or leaves a column of air, contained above the water level, is alternately compressed and decompressed to generate an alternating stream of high velocity air in an exit blowhole. If this air stream is allowed to flow to and from the atmosphere via a pneumatic turbine, energy can be extracted from the system and used to generate electricity. Designs exist for 2 MW near shore gravity anchored wave stations designed for regional power generation and coastal protection and for larger 3.5 MW near shore combined wave and wind stations which can be constructed also in multiple units when large quantities of electricity are required.<sup>16</sup>
- (iii) *Wave surge or focusing devices* These devices rely either on naturally occurring 'tapered channel' gullies in shorelines or on a shore-mounted structure to channel and concentrate the waves. 'Overtopping' schemes as in the 'Tapchan' system in Norway, use the enhanced height of the wave action to cause water to flow over a dam where it is stored and allowed to run out through a turbine when needed. An alternative approach is to combine the tapered channel approach with the oscillating water column. Such a scheme is the first commercial wave power station on the Scottish island of Islay based on the LIMPET 500, a 0.5 MW shoreline wave power station.

### 27.3.2.3 Mooring and anchoring

The provision of storm resistant mooring and anchoring for floating wave energy devices especially in deep water presents difficult technical problems which have not been readily solved. In general the cost of mooring and anchoring, or the provision of seabed attachment, together with the

cost of the initial device installation would be a significant proportion of the overall capital costs. It could range from 10 to 15% for floating devices and possibly up to 30% for devices fixed to the seabed. The latter systems would be virtually maintenance free whereas moorings require periodic inspection and replacement, thereby incurring an extra operational cost.

### 27.3.2.4 Power conversion and transmission

Various hydraulic and mechanical systems have been proposed, but the largest numbers of designs use air as a working fluid. Either the flow of air is rectified by valves, or it flows backwards and forwards through a turbine such as the Wells turbine. Wells turbines have the property of turning in the same direction regardless of which way the air is flowing across the turbine blades. No large wave power scheme comprising many devices exists at present, but in principle the generation of electricity by means of a number of small alternators can be aggregated by a d.c. system for transmission to shore and thence inverted by power electronics to the electricity supply network requirements.<sup>12,13</sup>

### 27.3.2.5 Environmental acceptability

Wave power development has not yet progressed sufficiently to encounter institutionalised environmental opposition. The establishment of large schemes offshore, however, would raise questions for the shipping and fishing industries. In addition changes to shoreline wave environments and noise, particularly from the oscillating water column devices, would have to be considered unless the installations were suitable distances from habitation.

### 27.3.2.6 Economics

To date the costs of prospective wave power schemes has led to unfavourable comparisons with alternative ways of harnessing renewable energy such as wind. Wave power generators are as yet only likely to be useful at suitable coastal sites, especially on remote islands where the costs of conventional diesel generated power is high. In addition for coastal sites in areas of outstanding natural beauty they will have less environmental impact than large wind turbines and thus may be more readily acceptable.

## 27.4 Hydro

The technology for the use of hydropower for the direct generation of electricity has developed from wooden water wheels (overshot, undershot and crossflow) through to the Francis, Kaplan, Pelton, Crossflow and Turgo turbines of the 20th century. In developed countries the larger hydro resources were among the first to be exploited. Attention has focused more recently on smaller resources which are generally classified as shown in Table 27.5<sup>3</sup> (other size classifications are also found in the literature).

**Table 27.5** Definition of hydro scheme size

Large	50 MW and above
Small	5 MW to 50 MW
Mini	500 kW to 5 MW
Micro	500 kW and below

By the 1980s the country with the greatest experience in small-scale hydropower development was the People's Republic of China where nearly 100 000 plants had been constructed in the previous twenty years.

With a mature technology the investigation, design and construction of conventional large-scale hydroelectric schemes is well defined and understood and can be costed with reasonable certainty. For small schemes at the mini and micro scale, however, economic constraints demand an innovative approach. Novel low head designs for prime-movers together with a trend towards the use of off-the-shelf components and plastics for small impeller-type turbines, the use of micro and power electronics in generation and again the use of plastics for pipelines in the civil engineering works all contribute to extending the boundaries of economic viability.

The distinctive features of small hydropower plants include being usually run-of-river type, construction in a relatively short period of time, using well developed technology with an overall efficiency of over 80% and having automatic operating systems with low operation and maintenance costs.

As for all renewable resources the size of an exploitable resource depends on both technical and economic factors. For hydro the broad categories are

- the gross river potential which is approximately the summation of (annual run-off  $\times$  potential head),
- the exploitable technical potential which is the gross river potential less the potential which is technically impossible to develop,
- the economic potential which is the technical potential less the potential which is uneconomic to develop, and more recently in the history of this technology,
- the environmentally acceptable potential which is the economic potential less the potential which is considered environmentally unacceptable to develop.

Without significant storage capacity large variations in available water flow may be experienced. In the UK the capacity factor for hydro, i.e. the ratio of actual annual energy generated to energy produced at rated output over twelve months, is approximately 30% which is nearly the same as for wind energy. Small-scale hydro-schemes with turbines having sufficient rotational velocity can employ either induction or synchronous generators. Low-head run-of-river turbines run more slowly and so need either a gearbox or a large multiple pole generator for energy conversion.

A more detailed discussion of hydroelectric plant is given in Section 26.4.

## 27.5 Wind<sup>17-25</sup>

### 27.5.1 Wind energy

The annual energy available from a wind turbine in any particular location depends on the wind speed at hub height, which in turn depends on the shape of the local landscape, the height of the turbine above the ground and the annual climatic cycle. An empirical relationship between mean wind velocity  $V$  and turbine height  $H$  is  $V = H^a$  where  $a$  has a value of 0.13 in the UK for open, level ground, rising to 0.25 for an urban site and to 0.33 for a city site.<sup>8</sup> An ideal site is a long, gently sloping hill.

Offshore wind speeds are generally higher than on land, e.g. ten kilometres from the shore speeds are typically 1 m/s higher than on land. Although wind/wave interactions exist,

turbulence is lower which reduces the fatigue loading on the turbine blades. It is offshore where the very large wind-farms of several tens or even hundreds of MW in size are anticipated in the future.

### 27.5.2 Wind turbines

The theoretical power in an air stream is  $0.5 d_a A V^3$  where  $d_a$  is the density of air,  $A$  the cross-sectional area and  $V$  the velocity. The actual power  $P$  extracted by a wind turbine, however, is of the same form as for water turbines

$$P = C(0.5 d_a A V^3) \leftarrow$$

where  $C$  is a coefficient of performance or power coefficient. The German Engineer Betz showed in 1927 that the maximum power extracted from a moving air stream to be 16/27 or 0.59259 of the theoretically available power. This efficiency can only be approached by careful blade design with blade tip speeds a factor of six times wind velocity and is known as the Betz limit. Modern designs of wind turbines for electricity generation operate with a power coefficient ( $C$ ) of about 0.4, with the major losses caused by drag on the blades and the swirl imparted to the air flow by the preceding rotating blades. Any wind turbine will operate only between a minimum starting wind velocity value,  $V_s$ , and its rated value  $V_R$ . Typically the ratio  $V_R/V_s$  is between 2 and 3, although if the pitch of the blades can be altered at velocities greater than  $V_R$  then the turbine should continue to operate at its rated output, the upper limit being set by design limitations. Depending on the location the wind speed may be less than  $V_s$  for 25% of the year when the turbine is shut down and the annual load factor, the ratio of energy produced to the energy that would be produced if run at maximum rated output over the whole year, is typically between 25% and 35%. A typical operating power characteristic is shown in Figure 27.2.

In general machines are designed to operate with a peak output in the range 250–500 W/m<sup>2</sup>; thus 20 m machines have ratings of around 200 kW, 30 m machines around 300 kW and 50 m machines around 1 MW. Power limitation is accomplished either by using feathered blades in larger machines, with feathering along the whole blade length, or in smaller machines by taking advantage of the natural tendency of blades to stall as the angle of attack increases in high winds. Current commercial wind turbines tend to operate at a fixed speed with tip speeds of around 50–80 m/s for power generation and slower speeds for high torque applications such as pumping.

The technical options available to designers of wind turbines and the interaction of option choices in the determination of machine weight and cost are discussed.<sup>17</sup> This work examines the extensive debate surrounding the optimal size of machines and the engineering implications of a move from heavy, stiff designs to more lightweight, compliant designs. Typical turbine characteristics are summarised in Table 27.6.<sup>21</sup>

### 27.5.3 Wind generators

With wind speed fluctuations being inevitable it is important to damp out the consequent driving torque oscillations in the generator. For network-connected fixed speed turbines synchronous generators do not provide adequate damping which must be supplied elsewhere in the transmission otherwise power fluctuations and blade loads may be unacceptable; hence most use 4- or 6-pole induction generators. Induction generators provide inherent damping where

**Figure 27.2** Typical wind turbine power/wind-speed operating characteristic

**Table 27.6** Typical wind turbine characteristics

Ratings	1 to 2 MW now available and increasing
Availability	98–99%, a mature reliable technology
Rotor diameter	Up to 80 m, larger diameters to follow
Number of blades	Majority now three, reducing percentage of two or even one
Blade material	Glass-reinforced plastic or wood-epoxy
Rotor orientation	Mostly upwind of tower, some downwind
Rotational speed	Usually constant, c. 25 rpm at 52 m diameter, some two speed and variable speed
Power control	Stall control in high winds with fixed blades, pitch control where all or part of blades rotate to limit power
Power train	Step-up gear boxes most common, direct drive without gearbox now also used
Yaw control	Wind direction sensors linked to powered rotor alignment, some passive yaw control
Towers	Cylindrical steel construction, concrete towers used for some large machines

the damping is provided by the slip speed difference between the rotor and stator rotating mmf, but suffer from the disadvantage of drawing reactive power from the system and also from drawing high starting currents which may cause local flicker. Typically the induction generator is wound for 690 V, 1500 or 1000 rpm operation and generally of squirrel-cage construction. Connection to the network is via power-factor correction capacitors and power electronic converters to accommodate starting conditions or, in the case of variable speed operation, to decouple the speed of the rotor from the frequency of the network.

#### 27.5.4 Economics

Onshore wind farms are relatively competitive. Costs have fallen from 8.6 pence per kWh in 1992 to an average of 2.88 pence per kWh for the new farms coming on line now. They are among the most competitive renewable energy plants and are less expensive than some new coal plants. Electricity from offshore wind farms remains uncompetitive, however, at present in comparison with electrical energy provided by conventional power sources.

The estimate of capital costs of wind farms in the USA is \$983/kW (1999 prices).<sup>22</sup> The same source gives a typical capacity factor at 32% although the average for UK wind farms is approximately 24%<sup>23</sup> as shown in *Figure 27.3* which illustrates typical monthly variation in capacity.

European installed costs are quoted at

- Euros 875/kW<sup>24</sup> onshore and Euros 1600/kW offshore,<sup>25</sup>
- 15 year depreciation, 7% discount rate
- O and M costs: Euros 20/kW/yr + Euros 0.004/kWh.

Using these figures *Table 27.7* illustrates the calculation of the generation costs for a 50 MW wind farm assuming a capacity factor of 28% giving a total cost of Euros 0.051/kWh or 3.07 p/kWh.

*Figure 27.4* shows the effect of different capital recovery periods where for short pay-back times the costs are prohibitive and the value of longer term guaranteed support over fifteen years can be seen. With significant differences in generation costs being measured in tenths of p/kWh the importance of capacity factors, i.e. choice of site, turbine hub height, etc., can also be appreciated.

**Figure 27.3** Wind farm typical monthly capacity factors (Annual average 24%)

**Table 27.7** Generation cost estimates

Capital cost	Euros/kW	875
Total capital cost, $P$	Euros	$875 \times 50\,000$
Annual energy generated, $E$ at 28% capacity factor	kWh/yr	122 640 000
Discount rate	%	7
Capital recovery period	years	15
	$R$ (see section 27.3)	0.110
Capital cost $A/E = P \times R/E$ for 24% capacity factor	Euros/kWh	0.039
O & M costs		
maintenance	Euros/kWh	0.008
operation	Euros/kWh	0.004
TOTAL generating cost	Euros/kWh	0.051

### 27.5.5 Environmental issues

Wind energy is a non-polluting form of energy fulfilling the aims of present governments to replace polluting and non-renewable hydrocarbon-generated electrical power with power generated from cleaner forms of energy. In the

course of the development of the industry, however, other forms of pollution have been noted and been the object of much debate and hostility. The principle environmental issues to be considered in deploying wind farms are:

- Visual and landscape impact;
- Noise;
- Electromagnetic interference;
- Effect on birds and wildlife; and
- Land use.

The same considerations apply, however, to all other forms of renewable energy exploitation. Wind energy has been in the forefront of development, deployment and commercialisation so has been the first renewable industry to meet the environmental objections and constraints.

Chief among these effects are visual pollution and noise. Visual pollution, although subjective, is easy to comprehend arising simply from the juxtaposition of industrial plant in areas of outstanding natural beauty, i.e. unspoiled countryside. Other wind-turbine sites in 'brown field' sites in or near urban areas where industry has been before have not created the same opposition and indeed have been taken as symbols of regeneration.

Noise is more of a problem inasmuch as there appears to be some evidence of low frequency (infrasound) noise effects near some sites, but the data is sparse. Early problems of noisy gears have largely abated with better design and manufacture. The level of noise of the aerodynamically generated swishing noise of the turbine blades, however, varies from site to site and can be negligible. Particularly strange effects have been reported from Montgomeryshire in Wales where the existence of steep nearby valleys seems to act in some cases as a means of focusing noise at different places away from the wind farm sites.<sup>18,19</sup>

Offshore wind farms will have less of these problems, but for on-shore sites local objections have meant that the majority of planning applications in the UK have been refused so it is vitally important that projects are properly and sensitively integrated into the landscape and developed in consultation with local communities.<sup>20</sup>

### 27.6 Geothermal energy

The Earth is an almost infinite source of heat with a continuous heat flow of some  $10^{13}$  J/s. Unlike the other renewable

**Figure 27.4** The influence of capital recovery periods and capacity factors on wind generation costs

resources, which are intermittent, geothermal energy can deliver a constant source of power until the reservoir is exhausted. There are two possible techniques for exploiting geothermal energy:

- (1) use of existing hydrothermal sources;
- (2) to attempt to extract heat from hot dry impermeable rocks deep below the surface.

The first technique is now commercially established, whilst the second is still at the research and development stage.

### 27.6.1 Hydrothermal sources

Although steam and hot water come naturally to the surface of the earth in some locations, for large-scale use boreholes are normally sunk with depths of up to 3 km, releasing steam and water at temperatures of 200–300°C and pressures of up to 3000 kN/m<sup>2</sup>.

Flowing well-head steam pressures vary between 200 and 1500 kN/m<sup>2</sup>. From the well heads the steam is often transmitted by pipelines of up to 1 m diameter over distances up to about 3 km to the central power station. Water separators are usually required, as superheating the steam to minimise wetness requires fossil fuel, the use of which is usually uneconomical. Care must be taken in the choice of materials for the plant, as the steam may contain solid and gaseous impurities. Steam may come from several bore holes at different pressures, so that the steam layout of the generating station may involve two or three different pressures in cascade. If water quality is satisfactory, direct use of the steam in turbines is possible. In most cases jet condensers are used, with the condensate being discharged to waste along with the cooling water. The only major electrical plant required in the generating station is a cooling-water pump. The thermodynamic efficiency of the power station at these low temperatures and pressures is about 10–15%. Thus large quantities of exhaust heat are available for local use or, alternatively, must be discharged as waste heat.

Heat from aquifers at lower temperatures is unsuitable for electricity generation but may be used for district heating or agricultural purposes. Several such aquifers with temperatures in the range 60–80°C exist.

Recent examples of district heating schemes exist in Southampton where the City Council is exploiting the heat from the Wessex Basin for space heating of Council office buildings. Several schemes are now operating in the Paris and Aquitaine Basins.

Power generation from geothermal aquifers began in 1904 in Lardarello, Italy, where installed capacity now exceeds 400 MW. Similar power-generation developments have taken place in China, El Salvador, Greece, Hawaii, Iceland, Indonesia, Japan, Kenya, Mexico, New Zealand, Nicaragua, the Philippines, Turkey, the CIS and the USA. Overall, it is estimated that some 8 GW of power is now being produced world-wide from geothermal aquifers.

At first sight geothermal energy would appear environmentally benign. However, no system of power generation is without some adverse environmental effect. Conventional geothermal power stations involve surface pipelines bringing steam from widely distributed bore holes to central power stations, and these can be unsightly and lead to visual intrusion. Geothermal aquifers incorporate gaseous components such as carbon dioxide, hydrogen sulphide, methane and radon. Such discharges need to be considered at the planning stage for new geothermal plant, otherwise environmental legislation may inhibit further expansion of the geothermal resource. Power generation from geothermal

aquifers in volcanic areas can provide cheap electric power. Indeed, the generation costs are often quoted as being comparable with those of hydroelectric stations.

### 27.6.2 Hot dry rocks

The average thermal gradient near the surface of the earth is about 25°C/km. This temperature gradient is exceeded in some granites because of the local heat generated by the decay of radioactive elements. For example, in New Mexico granites have been identified with a thermal gradient of 50–60°C/km and in Cornwall gradients of 30–40°C/km have been measured in the Carmenellis granites.

In order to exploit these elevated subsurface temperatures for power generation, a temperature of greater than about 200°C is required. Thus wells of depths between 4 and 7 km are required. Current drilling technology sets a practical limit of about 6 km.

Two sets of field trials have been carried out in an attempt to exploit this enhanced heat source in granites. The first was conducted by the University of California at the Los Alamos Laboratories in New Mexico; the second was done by the Cambourne School of Mines at Rosemanowes quarry in Cornwall. The trials involve drilling a bore hole deep into the granite, fracturing the rock at the base of the bore hole using hydrostatic pressure and explosives, and then drilling a second bore hole to intercept the fractured zone. Water can then be circulated down one bore hole, permeate through the fractured zone, and hot water can rise to the surface through the second bore hole.

There are a number of practical difficulties associated with this scheme. The drilling of a second bore hole that is located sufficiently accurately to intercept the fractured zone is a problem in itself. Having created a circuit for water circulation, it has proved difficult to manage the flow of water such that a large surface area of hot rock is contacted by the circulating fluid. In practice, circulation through larger channels has tended to dominate and, therefore, depress the temperature rise of the circulating fluid. A further problem is the loss of circulating fluid due to subterranean leakage and the requirement for large volumes of cooling water for a process the overall thermodynamic efficiency of which is about 5%. Environmental problems from hot dry rocks include the release of radon gas, visual intrusion from cooling towers, and the stimulation of minor seismic events associated with the creation of the reservoir.

## 27.7 Biofuels

### 27.7.1 Introduction

Biomass and biofuels have no strict definition, but include agricultural residues, energy crops, municipal solid waste (MSW) and landfill gas.<sup>26</sup> It is convenient to differentiate between biofuels arising from agricultural sources and those which arise from human, urban and industrial processes. *Table 27.8* compares solid and gaseous fuels used for power generation according to this distinction<sup>27</sup> and *Table 27.9* lists relative energy content of the different materials used as fuel.

### 27.7.2 Biomass technologies

#### 27.7.2.1 Overview

Energy can be recovered from biomass in a variety of ways including aerobic and anaerobic digestion, combustion with heat recovery and gasification/pyrolysis processes.

**Table 27.8** Renewable and waste fuel resources

<i>Agricultural resources</i>	<i>Waste resources</i>
Sugar cane waste (bagasse)	Sewage Digester Gas (SDG)
Timber mill waste or sawdust	Landfill Gas (LFG)
Forestry residues	Mines gas
Short-rotation coppicing (SRC)	Coke-oven gas (COG)
Straw	Refinery and process plant flare/off gas
Rice husks and coffee husks	Stripped crude gas
Peanut and other nut shells	Municipal solid waste (MSW)
Palm oil and coconut residues	Hazardous and chemical waste
Meat and bone meal (MBM)	Hospital and clinical waste
Poultry litter	Sewage sludge
Livestock slurry	Vehicle tyres

**Table 27.9** Calorific values for different materials used as fuels

<i>Material used as fuel</i>	<i>Calorific value (MJ/kg)</i>
Coal	23–32
Fuel oil	40–45
Natural gas	50–55
Plastic	27–34
Municipal solid waste	8.5–11
Hospital and clinical waste	17.5–22.5
Chemical waste	18.5–23
Sewage sludge	7–13
	(depending on dryness)
Vehicle tyres	32–40
Sugar cane bagasse	8–12.5
	(depending on dryness)
Wood	17–20
Rice husks, Rice straw	12–18
Straw	14–15.5
Meat and bone meal	20–28
	(depending on fat content)
Poultry litter	13–14

**Table 27.10** Bio-conversion processes and products

<i>Process type</i>	<i>Process</i>	<i>Initial product</i>	<i>Final product</i>
Aqueous	Anaerobic digestion	Biogas (2 parts CH <sub>4</sub> to one part CO <sub>2</sub> , 22–28 MJ/m <sup>3</sup> )	Methane (38 MJ/m <sup>3</sup> )
	Alcohol fermentation		Ethanol (19 MJ/litre)
	Chemical reduction		Oils (35–40 MJ/kg)
Dry thermo-chemical	Pyrolysis	Low/Medium energy gas (7–15 MJ/m <sup>3</sup> )	Pyrolytic oils (23–30 MJ/kg)
			Gas (8–15 MJ/m <sup>3</sup> )
			Char (19–31.5 MJ/kg)
	Gasification		Methane (38 MJ/m <sup>3</sup> )
			Methanol (16.9 MJ/litre)
Direct combustion		High pressure steam	Ammonia
			Electricity (3.6 MJ/kWh)
			Methane (38 MJ/m <sup>3</sup> )
			Ethane (70.5 MJ/m <sup>3</sup> )
			Char (19–31.5 MJ/kg)
	of various fuels, e.g. wood chips (17–20 MJ/kg dry weight)		High pressure steam
			Electricity (3.6 MJ/kWh)

The main bio-energy conversion routes are represented in Table 27.10 along with the principal products formed.

With the exception of sewage sludge and animal slurries most biomass materials are not in a form well suited to digestion processes. Commercially available digester plants have a relatively limited capacity, typically up to about 1 MW of biogas; hence for larger commercial applications the thermal treatment technologies for solid biomass are presently of more significance. Much work is underway at present, however, in the development of enzyme treatments to enable fermentation of cheap agricultural feedstock such as corn leaves and wheat straw into ethanol. A demonstration plant consuming 40 t of straw per day is reported as producing up to 4 m litres of ethanol/year. A car fuelled by a mixture containing 85% ethanol produces 91% less greenhouse gas emissions compared with petrol and so, given the present focus on reducing such emissions worldwide, this particular biomass transformation should feature more prominently in the future.

### 27.7.2.2 Pyrolysis and gasification

Pyrolysis is the thermal degradation of biomass in the absence of oxygen, but this may include partial gasification. Three products result: a solid char residue, gas and a complex, oxygenated hydrocarbon liquid containing water with the relative yields optimised according to the requirements and process control. The pyrolysis liquids can be burned in boilers, dual fuel diesel engine and turbines. Typically the pyrolysis gas is vented because of its low concentration of combustible gases, but high temperature pyrolysis produces a fuel gas that could be used in an engine or turbine.

Thermo-chemical gasification is the conversion by partial oxidation at elevated temperature of a carbonaceous feedstock such as biomass into a gas containing CO, CO<sub>2</sub>, H<sub>2</sub>, CH<sub>4</sub>, trace amounts of higher hydrocarbons such as C<sub>2</sub>H<sub>2</sub> and C<sub>2</sub>H<sub>6</sub>, water, nitrogen (if air is used as the oxidising agent) and various ash, oil and tar contaminants. The partial oxidation can be carried using air, oxygen, steam or a mixture of these. Air gasification produces a low heating value gas (up to 4–7 MJ/Nm<sup>3</sup>) suitable for boiler, engine and turbine operation but not for pipeline transportation because of its low energy density; oxygen gasification produces a medium heating value gas (up to 10–18 MJ/Nm<sup>3</sup>)

suitable for limited pipeline distribution and as synthesis gas for conversion to methanol and gasoline.<sup>34</sup>

### 27.7.2.3 Direct combustion

The direct combustion of organic matter to produce steam or electricity is the most advanced of these conversion processes and, when carried out under controlled conditions is probably the most efficient. Waterwall incineration whereby water pipes within the walls of the incinerator are heated produces steam at high efficiencies for both electricity generation and CHP purposes. The moving grate combustion technology is well proven for coal firing and can accept many forms of biomass including relatively coarse solid materials, but has limited ability to handle wet sludges. Fluidised bed (FB) technology is also well established and proven for biomass combustion. It features intimate mixing of gases and high-temperature solids and allows very close control of temperature and reaction stoichiometry. The major advantages of fluidised beds are:

- Greater fuel flexibility—the ability to combust a variety of fuels with a wide ranging characteristics such as very-high ash fuels, high moisture fuels such as bark and sludges and high grade coal fuels.
- Lower temperature combustion without decrease in combustion efficiency thus inhibiting the formation of NO<sub>x</sub> emissions.
- The ability to fire fuels with low melting point ash.

There are two types of fluidised bed technology in common use in Europe, the bubbling fluidised bed (BFB) and the circulating fluidised bed (CFB). BFB units are available up to 100 MWe and have been proven on biomass and waste materials with homogeneous characteristics, especially lower capacity units starting from 5 MWth using well pre-prepared fuel. CFB units are available up to 400–600 MWe and have been demonstrated on up to seventy different fuel types both as single fuels and co-combusted providing increasingly cost-effective plant for combusting low-grade fuels and different wastes with low environmental impact.

## 27.7.3 Major biomass sources

### 27.7.3.1 Short rotation coppicing and forestry residues

Short rotation coppicing (SRC) consists of shrub willow planted at high density. At the end of the first year after planting the shoots are cut back to ground level to encourage a multi-stemmed form and the crop is then harvested on a three-year rotation in the winter. Fuel consumed in the harvesting represents a significant proportion of final electricity costs and care is needed to optimise fuel supply chains both from SRC and forestry residues. Studies<sup>28,29</sup> showed that for a base case transport distance of 56 km the energy ratio of energy content of delivered wood to energy expended in production was 26:1, with even a transport distance of 320 km showing a positive ratio of 8:1.

### 27.7.3.2 Municipal solid waste

Household waste (municipal solid waste) is processed by either recycling and/or composting or disposed of in landfill sites. For the UK the amount generated at present totals about 27 mt/y and increasing at 3% per year with some 85% of this total being sent for landfill (more than most other EC countries). The EC landfill directive will enforce major changes in landfill practices, however, requiring reductions in the biodegradable domestic waste sent to

**Table 27.11** EC emission control requirements for energy from waste plant

Component	Emission to air in ng/Nm <sup>3</sup> —dioxins in ng/Nm <sup>3</sup> —dry gas 11% O <sub>2</sub>
Particulates	10
HCl	10
HF	1
SO <sub>2</sub>	50
NO <sub>x</sub> as NO <sub>2</sub>	200 (plant >3 tph)
CO	50
VOC	10
Hg	0.05
Cd	0.05 (Cd and TI)
7 HM (heavy metal summation)	0.5
Dioxin	0.1
I-TEQ ng/Nm <sup>3</sup>	

landfill by 2016 to be no more than 35% of its level in 1995. The development of more energy from waste schemes (EfW) is a virtual certainty.<sup>35</sup>

With the limitations imposed on the landfill option the major route for EfW is by mass burn incinerators. Gasification and pyrolysis of municipal solid waste has reached the large-scale pilot plant stage but their implementation is expected to be gradual and not to supersede conventional combustion processes.<sup>35</sup> Although the prime purpose of EfW plants is to dispose of waste, the typical plant size of 30–50 MWe output allows close integration into CHP schemes as is common in Austria, Denmark, France, Germany, Sweden, etc.

A further EC requirement is expressed in emission standards as shown in Table 27.11. All UK plants are being retrofitted and new ones designed to meet these requirements.

### 27.7.3.3 Landfill gas

Landfill gas is the general name given to the gaseous products of bacterial decomposition of organic material within landfill sites. Such sites are constructed according to strict controls to limit their environmental impact with impermeable capping and internal lining, drainage control, in situ refuse compaction and ventilation. Organic matter decomposes aerobically in the presence of oxygen to produce carbon dioxide, but exclusion of air by means of the impermeable cap ensures anaerobic decomposition to produce water, and a flammable mixture of carbon dioxide and methane. The composition of landfill gas is variable depending on many factors, the rate of production depending on the rate of refuse decomposition with a half-life for the refuse-to-gas decomposition typically in the range of 3 to 10 years depending on the physical and chemical conditions within the waste, especially moisture levels.

It should be noted that not all landfill gas can be collected, but 25–50% is currently typical of a well-engineered site. A landfill site taking around 300 tonnes of degradable waste per day for ten years could theoretically generate as much as 4.5 billion cubic metres of gas over a period of forty years.

Spark ignited gas engines have provided the most popular means for the generation of electricity from landfill gas with the turbo-charged engine offering the best compromise in terms of capital cost, efficiency, performance and

maintenance. Modern gas engines have a thermal efficiency of up to 39% and, with low compressor energy consumption, about 77% more electricity can be generated from the same volume of gas than by using gas turbines, which are also not very suitable for several reasons. Capital costs of a 1 MW installation (excluding gas collection and grid connection) would be about £400 K (£400/kW) with engine maintenance about 0.75 p/kWh. The most cost-effective packages comprise 1–1.3 MW units and installing multiple units provides the flexibility to cope with the gas supply variations associated with landfill site operation.

## 27.8 Direct conversion

Some methods of extracting electrical energy from renewable sources do not rely on a heat stage, and the limitations of Carnot efficiency are avoided. Some other methods, still largely small scale and experimental, also eliminate machinery, relying instead on direct conversion processes. Like solar cells, the direct conversion processes described below produce electricity at low direct voltage; many units need to be interconnected and coupled to inverter systems to give a.c. output. Direct conversion processes generally need to be operated at high temperatures, and difficulties are encountered in finding suitable materials to withstand such temperatures over a long lifetime.

### 27.8.1 Thermoelectric generators

#### 27.8.1.1 Principles

If two dissimilar materials are joined in a loop with the two junctions maintained at different temperatures, an e.m.f.  $E = \alpha \theta$  is set up around the loop, where  $\theta$  is the temperature difference and  $\alpha$  is the Seebeck coefficient (itself depending to some extent on temperature). The phenomenon, long used in thermocouples, enables generators with semiconductor junctions to supply up to 5 kW for radionavigation beacons and satellites. A useful figure of merit is  $Z = \alpha^2 \sigma / K$ , where  $\sigma$  is the electrical conductivity (which should be high, to reduce  $I^2 R$  loss) and  $K$  is the thermal conductivity (which should be low, to limit heat transfer between junctions).

If the thermoelectric generator works between absolute temperatures  $T_1$  and  $T_2$ , the efficiency as a fraction of the Carnot efficiency is

$$\eta = [(1 + ZT)^{1/2} - 1] / [(1 + ZT)^{1/2} + T_2/T_1]$$

where  $T = (T_1 + T_2)/2$ . Thus the efficiency depends on the product  $ZT$ , which is a convenient assessment for possible thermoelectric materials. In practice, no single combination maintains a high  $ZT$  over a wide temperature range: most practical designs use a series of stages with n- and p-type semiconductor junctions that have a high  $ZT$  over their relevant temperature differences.

Taking into account mechanical characteristics, stability under operating conditions and ease of fabrication, bismuth telluride appears to be one of the most suitable materials; it can be alloyed with such materials as bismuth selenide, antimony telluride, lead selenide and tin telluride to give improved properties, is suitable for temperatures up to about 180°C, and can give efficiencies up to about 5%. A silicon-germanium alloy with phosphorus and boron impurities can be used up to 1000°C and might give efficiencies up to 10%.

#### 27.8.1.2 Practical developments

A typical thermoelectric couple could be designed to give about 0.1 V and 2 A (i.e. about 0.2 W), so that a 10 W device suitable for a navigational beacon or unattended weather station would require about 50 couples in series. Various methods have been used to provide a source of heat for the hot junction. These include small oil or gas burners, isotopic heating and solar radiation. Although some progress has been made in developing suitable materials, theoretical studies seem to show that the scope for improvement in  $ZT$  values is rather limited. For this reason, interest in thermoelectric devices has declined over the last decade.

### 27.8.2 Thermionic generators

In its simplest form the thermionic converter comprises a heated cathode (electron emitter) and an anode (electron collector) separated in a vacuum, the electrical output circuit being connected between the two. Heat supplied to the cathode raises the energy of its electrons to a level enabling them to escape from the surface and flow to the anode: at the anode their energy appears partially as heat (removed by cooling) and partially as electrical energy delivered to the circuit. Although the distance between anode and cathode is only about 1 mm, the negative space charge with such an arrangement hinders the passage of the electrons and must be reduced—e.g. by introducing positive ions into the inter-electrode space, caesium vapour being a valuable source of such ions. Anode materials should have a low work function (e.g. barium oxide and strontium oxide), while that of the cathode should be considerably higher, tungsten impregnated with a barium compound being a suitable material. With these materials temperatures up to 2000°C will be needed to secure, for the generator itself, efficiencies of 30–35%, although higher overall efficiency can be obtained by using the heat from the coolant. Electrical outputs of about 6 W/cm<sup>2</sup> of anode surface have been suggested.

Developments of thermionic generators using radioactive isotopes as the heat source have taken place for space applications. Thermionic devices, in general, do not appear to offer significant potential as power sources.

### 27.8.3 Magnetohydrodynamic generators

In the magnetohydrodynamic generator a partially conducting gas is heated by a fuel fired or nuclear reactor, allowed to expand through a nozzle to convert the heat energy to kinetic energy, and then passed between the poles of an electromagnet, the field of which converts some of the kinetic energy to electrical energy which can be collected from electrodes situated in the gas channel. The generator is thus not quite a direct heat-to-electricity device, as are the thermoelectric and thermionic devices, for there is an intermediate kinetic energy stage; also, largely owing to the power required for the electromagnets and other losses, it is unlikely to give a useful output unless built in sizes of 50 MW or more.

Provided that the gas is conducting and moving at right angles to the magnetic field, an e.m.f. will be set up at right angles to the direction of motion and of the magnetic field, being proportional to the velocity of the gas and to the magnetic flux density. This e.m.f. can be collected from suitable electrodes located in the gas stream and can supply power to an external circuit. The power output is proportional to the square of the velocity, to the square of the flux density and to the conductivity of the gas between the electrodes.

The field density should therefore be as high as possible, making superconducting magnets to give fields of 4–5 T, a great advantage over conventional magnets. Gas velocities up to 1000 m/s are practicable. The electrical conductivity of gases even at temperatures of 2000–3000°C is too low to give practicable powers. Ionisation must therefore be artificially increased by *seeding* the gas with an easily ionisable element such as caesium or potassium. Either must be recycled for economical operation, but caesium is so expensive and corrosive that a closed-cycle system is essential.

The possibility of using a liquid metal, sodium or potassium, is being investigated; such a fluid would have a much higher electrical conductivity but a lower velocity, the major problem being that of producing a high velocity with sufficient liquid density to give an adequate conductivity.

With gaseous conductors a complication is introduced by the Hall effect—i.e. by the fact that the current flow between the electrodes is not in the same direction as the field: the Hall angle may reach 80°, increasing with low pressures, high magnetic fields and high electron mobilities. The resulting axial component of current flow leads to inefficiency. To counter the Hall effect the number and configuration of the electrodes is more complex. In the Faraday generator a single pair of electrodes, or several pairs connected to separate load circuits, are used, but these arrangements are not appropriate for Hall angles of more than 45°. In the Hall generator use is made of the axial component by a more complex electrode arrangement in which current is collected from axially spaced electrodes; Hall angles up to 80° are appropriate with this type.

Extensive programmes of work are in progress in the USA and the CIS to develop the open-cycle fossil fired system. In this the fuel-combustion products at temperatures over 2000°C, achieved by preheating the combustion air, are seeded with potassium carbonate and passed through a magnetohydrodynamic duct. The waste gases are then used to heat a conventional steam cycle. The magnetohydrodynamic process is therefore a topping unit increasing the overall efficiency of power generation to about 45% and potentially over 50%. The potassium carbonate also combines with the sulphur in the coal to form potassium sulphate which is removed from the boiler with the ash, the sulphur being removed and the potassium recycled. The system therefore has an added advantage where sulphur emissions must be controlled, as is required in the USA. The main problems are the development and cost of a suitable gas duct and electrode system to withstand the high temperature and corrosive effect of the gas for long periods, and the effective recovery and recycling of the seed material. In addition, large air heaters and superconducting magnets are needed. The CIS has a 20 MW prototype station which has operated continuously for up to 250 h at 10 MW on natural gas. A larger unit is proposed in which the duct-life problem is avoided by having two ducts which are used alternately and regularly refurbished. The US programme is also being directed towards the evaluation of large-scale components for open-cycle magnetohydrodynamic generation, but using coal as the fuel.

## 27.9 Fuel cells<sup>36–40</sup>

### 27.9.1 Introduction

Fuel cells are energy conversion devices, which by combining hydrogen and oxygen into water convert chemical energy into electricity and heat. A fuel cell works much like a battery. In both batteries and fuel cells two electrodes,

an anode and a cathode, are separated by an electrolyte. Whereas a storage battery contains all the substances in the electrochemical oxidation-reduction reactions involved and has, therefore, a limited capacity, a fuel cell is supplied with its reactants externally and operates continuously as long as it is supplied with fuel.<sup>36,37</sup>

### 27.9.2 Fuel cell types

There are five basic types of fuel cell being commercially developed, a classification being based on the electrolytes used. Low temperature types include the alkaline fuel cell (AFC) and the solid polymer fuel cell (SPFC), to which belong the proton exchange membrane fuel cell (PEMFC) and the direct methanol fuel cell (DMFC), the medium temperature type is the phosphoric acid fuel cell (PAFC) and the two high temperature types are the molten carbonate fuel cell (MCFC) and the solid oxide fuel cell (SOFC). An idealised schematic diagram illustrating the structure, electron and ion flow for the various types of fuel cell is shown in *Figure 27.5*.

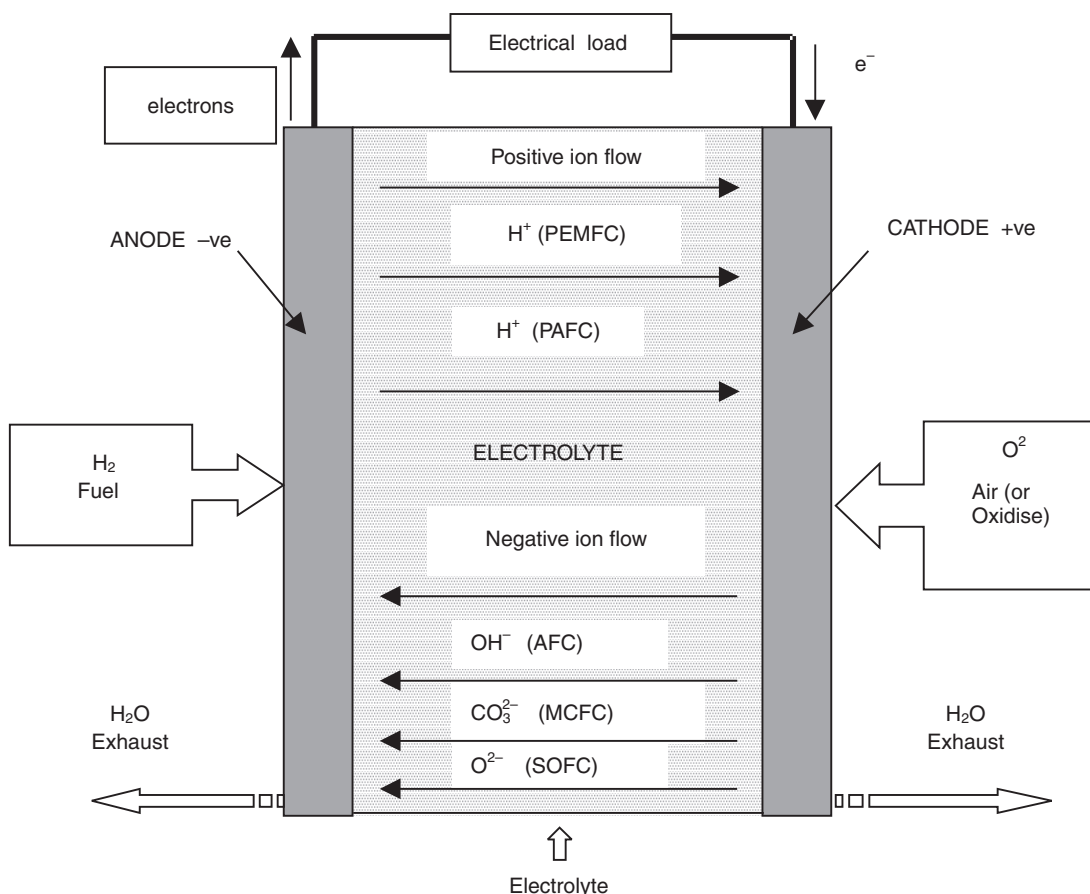

Phosphoric acid (PAFC) and proton exchange (PEMFC) fuel cells both use acid electrolytes, alkaline (AFC) and molten carbonate (MCFC) fuel cells use liquid alkaline-based electrolytes while solid oxide (SOFC) fuel cells use a zirconia-based ceramic. The direction of the ion flow depends on whether the ion is positively or negatively charged and also determines the site of water formation and subsequent removal. *Table 27.12* summarises the different characteristics of these fuel cells.

*Alkaline fuel cells (AFC)* The application of AFCs in space has been especially noteworthy. They are ideally suited to closed environments containing their own supplies of hydrogen and oxygen and have also been demonstrated in a variety of automotive applications. AFC performance is particularly sensitive to contaminants in the gas supplies, notably carbon dioxide, which reacts with the electrolyte to form a carbonate and reduces the conductivity. With the chemical reaction occurring at the cathode and the low operating temperature the start-up time of the AFC is very fast and the cell yields high power generation efficiencies as seen in *Table 27.12*.

*Proton exchange membrane fuel cells (PEMFC)* The low operating temperatures and the solid electrolyte—an acid-based ion conducting plastic membrane—also make PEMFCs suited to a wide array of uses from low and medium to high power applications. Such a list would include power tools, compressors, recreational applications in camping and boats, heat and electricity to dwellings and electricity to commercial buildings, schools and hospitals. They are most widely known at present for their potential in automotive applications where much evaluation is underway. The low temperature electrolyte requires platinum as the catalyst applied to either side of the membrane to accelerate the dissociation of hydrogen and oxygen. The hydrogen fuel stream should contain less than 10 ppm of carbon monoxide, preferably none, because carbon monoxide will bond to the platinum and poison its catalytic property leading to significantly degradation in the cell performance.

*Direct methanol fuel cell (DMFC)* This cell is similar to the PEMFC except that hydrogen is extracted from a methanol/water solution. This gives it an advantage inasmuch as the hydrogen is extracted by the catalyst and not by the addition of complex reforming plant. In addition

**Figure 27.5** Principle of fuel cell operation

the use of methanol would not require such major forecourt engineering for automotive purposes, as would the input of pure of hydrogen. The initial markets for DMFCs are considered to be in the small and medium power applications such as occupied by batteries in consumer and military electronic products. The power to weight ratio is theoretically of the order of 10:1 compared with batteries. The main outstanding problem is the 'cross-over' of methanol from the anode to the cathode through the membrane drastically reducing the cell performance. In addition significantly more platinum is required at the anode than in the PEMFC to catalyse the water/methanol mix.

**Phosphoric acid fuel cell (PAFC)** These fuel cells have given much durable service over many years with a very stable electrolyte in medium to high power stationary applications. Typically 200 kW units are found in hospitals, schools, hotels and various military installations. With its higher temperature carbon monoxide poisoning is not such a severe problem as in the PEMFCs, but with poor ionic conduction this comparatively large and weighty cell technology appears to be relatively expensive.

**Molten carbonate fuel cell (MCFC)** Multi-megawatt plants have been demonstrated with obvious applications in commercial buildings, especially those requiring high

quality heat such as in commercial buildings, hospitals and hotels. Developments include cells for use in natural gas and coal-based power plants in heavy industries. The high operating temperatures allow the use of fuels such as natural gas and coal gas without the need of noble metal catalysts and allow the fuel to be internally reformed without the need of complex reforming equipment. The quality of the heat allows for the possibility of higher efficiencies when coupled to CHP or combined cycle plant.

**Solid oxide fuel cell (SOFC)** Here the biggest problem in the development of these cells is coping with the high operating temperatures above  $850^\circ\text{C}$  where significant material problems occur. Below this temperature ionic conduction is a problem and the cell's performance deteriorates rapidly. Designs and demonstrations are being carried out to supply a wide variety of stationary needs from a few kilowatts to multi-megawatt industrial and power system plants as well as automotive power units. The high temperatures confer the same advantages onto this cell as for the MCFC design with the high temperatures adding further to CHP and combined cycle plants. As a completely solid state device, however, the management problems inherent in liquid electrolyte designs are avoided and, in principle, there are no constraints on cell configuration allowing flexibility in design.

**Table 27.12** Fuel cell types and characteristics

Type	AFC	PEMFC	DMFC	PAFC	MCFC	SOFC
Electrolyte	Aqueous potassium hydroxide (30–40%)	Sulphonated organic polymer (hydrated during operation)	Sulphonated organic polymer (hydrated during operation)	Phosphoric acid	Molten Lithium/ Sodium/ Potassium carbonate	Yttria-stabilised Zirconia
Operating Temp. °C	60–90°C	70–100°C	90°C	150–220°C	600–700°C	650–1000°C

### 27.9.3 Fuel cell structure

The theoretical limit on voltage developed by a single cell is about 1.23 V with typical operation being at about 0.7 V. Current (d.c.) delivered is approximately 0.5 amps/cm<sup>2</sup> of cell surface area giving an output power of about 0.35 watts/cm<sup>2</sup>. To generate more power the cells are connected together in stacks. *Figure 27.6* shows the structure of a phosphoric acid fuel cell stack together with the flow of gas. These fuel cells can be divided into two groups according to their structure: ribbed separators or ribbed electrodes. A thin layer, or matrix electrode, containing phosphoric acid is sandwiched between the electrodes. The electrodes, or the layers in contact with them, are ribbed to provide a manifold, which ensures that each cell is fed uniformly with air and fuel. The cells can be stacked horizontally or vertically and held together by endplates. The structure is much the same for all types of fuel cell.

### 27.9.4 Fuel cell plant

A complete fuel cell plant comprises a fuel delivery system, a stack, various controls over the plant operation and output power conditioning equipment. The fuel delivery system can range from a simple flow control unit to a fuel pre-processing unit. In practice hydrogen always occurs in combination with other elements. It is necessary, therefore, to produce it either by electrolysis in the case of water or by separation in a

reformer if a hydrocarbon fuel is used as a primary source. A fuel cell system, which includes a fuel reformer, can utilise, in principle, the hydrogen from any hydrocarbon fuel from natural gas to methanol. The two primary types of reformers being developed for transportation are steam reformers and partial oxidation reformers. Steam reformers have higher efficiency but partial oxidation reformers are simpler.

Plant control includes water management control and appropriate temperature control. As exhaust product water is seen as providing a potentially important added benefit in fuel cell operation in future, given concerns about the adequate local supplies of pure water for human consumption and industrial purposes. With regard to temperature control, a preheating stage particularly for high temperature fuel cells may be required for start-up. Heat exchangers are required to ensure the reactants enter the cells at appropriate temperatures for operation, again a particularly important requirement for high temperature cells. The flow rate of the oxidant generally controls the stack temperature.

Finally the power conditioning equipment converts the electricity generated, which is in the form of direct current, into the form required for use, usually alternating current at specified voltage and frequency.

*Figure 27.7* illustrates the structure of a fuel cell plant with heat reformer to convert fossil fuel such as natural gas or methanol into hydrogen, or a hydrogen rich gas for supply to the cells and *Table 27.13* provides an outline specification of a 2.8 kW alkaline fuel cell.

Figure 27.6 Stack cell structure for a phosphoric acid fuel cell

### 27.9.5 Regenerative fuel cells<sup>38-40</sup>

Fuel cell systems incorporating the collection of the water exhaust, its dissociation by electrolysis using an external source of electricity with storage and subsequent use of the hydrogen and oxygen produced, form a regenerative system. Such systems, for example belonging to the PEM group, could be independent of established fuel/energy infrastructures. The pure forms of the gases would be a further benefit in cells susceptible to carbon monoxide or carbon dioxide. Applications are seen initially in uninterrupted power supplies and in remote power requirements.

A different type of regenerative fuel cell has been developed known as the Regenisys<sup>®</sup> system which could also be considered as a flow cell type of battery using fuel cell technology. Its chemistry is not based on combining hydrogen and oxygen into water and converting chemical energy into

electricity and heat, but instead stores or releases energy by means of a reversible electrochemical reaction between two electrolyte solutions. The electrolytes are the respective salts sodium bromide and a sodium polysulphide and are physically separated by a permeable ion-exchange membrane.

The simplified overall reaction for the cell is given by

The electrolytes are pumped through two separate electrolyte circuits and transformed electrochemically inside the cell. The charge capacity is limited by the quantities of electrolytes stored in external tanks from which they flow into and out of the cell through separate manifolds via a controlled pumping supply plant. The input of electrical energy from an external source charges the cell with a cation selective membrane preventing the sulphur anions reacting

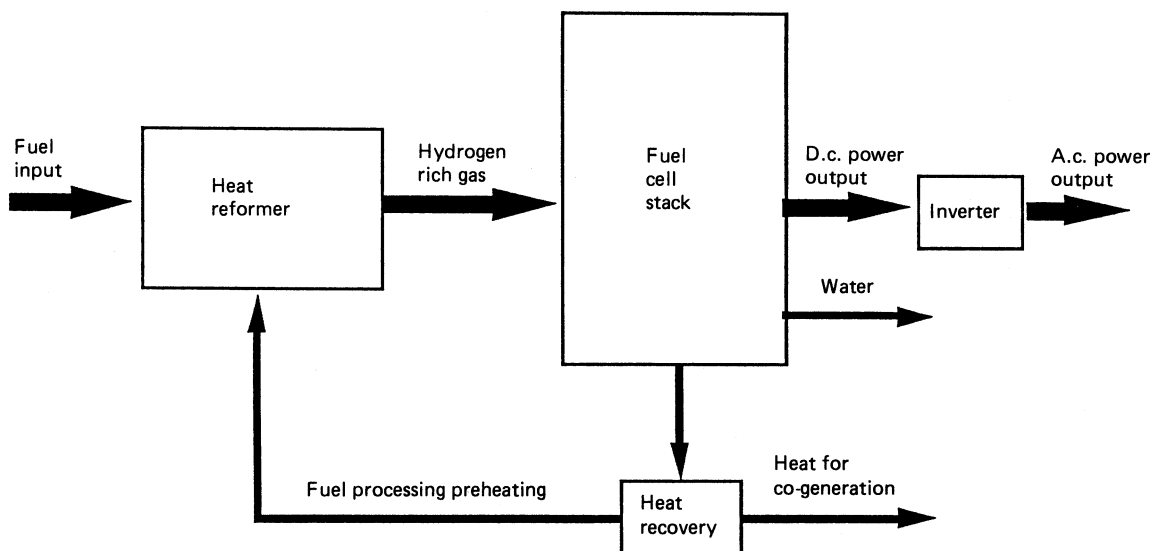

Figure 27.7 Fuel cell power-generation system

**Table 27.13** Specification of a low power alkaline fuel cell

<i>Stack configuration</i>		<i>Nominal operating conditions</i>	
8 modules connected in series		Reaction temperature	70°C
<i>Nominal dimensions</i>		Reaction pressure	Atmospheric
Length	895 mm	Hydrogen quality	Industrial grade (99.95%)
Width	250 mm	Air quality	Max. 50 ppm CO <sub>2</sub>
Height	310 mm	Nitrogen quality	Industrial grade (99.998%)
Weight (excluding electrolyte)	38 kg	Electrolyte	Potassium hydroxide
Weight (including electrolyte)	48 kg	Electrolyte concentration	6.6 mol/l (30% by weight)
Volume	69 litres	Hydrogen supply pressure	Ambient + 40 mbar
<i>Environmental operating conditions</i>		Air supply pressure	Ambient + 40 mbar
Temperature range		Electrolyte supply pressure	Ambient + 60 mbar
		Stack lifetime (10% degradation in output power)	5000 h
Humidity range	50% to 90%	<i>Fluid flows at full power</i>	
Pressure range	Ambient ±10%	Hydrogen consumption	2.15 Nm <sup>3</sup> /h
<i>Electrical output at nominal operating conditions</i>		Air consumption	22.5 Nm <sup>3</sup> /h
Open circuit voltage	Min. 44 Vdc +10%	Nitrogen consumption	0.16 Nm <sup>3</sup> per on/off cycle
Nominal voltage	32 Vdc ±5%	Electrolyte flow rate	400 l/h at ΔT of 2.5°C
Nominal current	90 A ±5%	Max. water production rate	1.93 l/h
Nominal power	2800 W ±5%	<i>Electrical efficiency</i>	
Maximum allowable current	100 A	45%–55% (subject to load, excluding heat recovery)	

directly with the bromine separating the solutions. Electrical balance is achieved by the transport of the sodium ions across the membrane.

The overall electrical efficiency of such a system comprising cell, control system and power conversion unit is about 65%, being restricted by membrane performance in transferring the sodium ion Na<sup>+</sup>, but with a target efficiency of 80%. Such a fuel cell operates at ambient temperatures and pressures and is, therefore, not suitable for CHP schemes. One design comprising one hundred 100 kW stacks or modules provides 120 MWh of energy storage capable of being released at a rate of 12 MW for 10 h with a peak output of 14.75 MW. In common with all electrochemical systems, maximum efficiency is achieved below the maximum power rating. Power response is fast with zero to full discharge being achieved in 10–15 ms, being limited by the performance of the power conversion unit.

## 27.10 Heat pumps

### 27.10.1 Introduction

Heat pumping is the use of a thermodynamic cycle to extract heat from a lower temperature source and supply it to a higher temperature sink where it is useful. In doing so, the purchased energy needed to drive the cycle is less than that usefully supplied. The ratio between useful heat delivered and the energy purchased is the coefficient of performance (COP). It should always be greater than unity.

Thermodynamic cycles have been well developed over the last century for refrigeration, but it is only in recent years that the heating application has developed. They were first applied in the USA where the coastal regions required air conditioned cooling in summer and space heating in winter.<sup>41–47</sup>

The energy crisis in 1974 produced a resurgence in interest in heat pumps, particularly in Japan, France, Germany and Scandinavia. The high capital cost of the units and the stabilisation of fuel prices led to a reduction in sales until the environmental problems of CO<sub>2</sub> were recognised in the 1980s. This provoked a renewed interest and led to newer more reliable, quieter compressors and more efficient cycles. The Japanese are leading this quiet revolution. The applications have widened from simple heat pumping in winter to industrial heat recovery and dehumidification.

### 27.10.2 Thermodynamics

The ideal thermodynamic cycle for heat pumps, developed by Carnot, assumes a perfect working fluid operating in perfect conditions:

$$\text{Ideal COP} = \frac{T_{\text{hot}}}{T_{\text{hot}} - T_{\text{cold}}}$$

where the heat is extracted from a cold source and supplied to a hot sink. The temperatures are absolute temperature (i.e. degrees Celsius + 273).

This ideal cycle shows that the usefulness of a heat pump cycle depends mainly on the temperature difference between the heat source and the heat sink. The heat pump performance improves as this temperature difference narrows. The heat pump also improves slightly with increasing temperature.

$$\text{COP} = \frac{\text{Heat out}}{\text{Compressor} + \text{Fan energy in}}$$

In practice, with real fluids and real equipment the best performance is obtained from the vapour compression cycle, which achieves about one-third of the ideal Carnot efficiency (see Figure 27.8).

Figure 27.8 Coefficients of performance in theory and practice

### 27.10.3 Practical cycles

The four basic cycles are described below.

#### 27.10.3.1 Air cycle

When air is compressed, it becomes warmer. Heat can be extracted and the cooled pressurised air expanded down to its original pressure. The expander can be a turbine which drives the compressor. This open cycle can be used for heating buildings. Unfortunately, the equipment is very bulky and its efficiency is very sensitive to the inefficiencies of both the compressor and the expander.<sup>48,49</sup> It is not commercially attractive except for special applications where compressed air is readily available, such as aircraft air conditioning.

#### 27.10.3.2 Vapour compression cycle

The vapour compression cycle relies on the condensation temperature increasing with increase in pressure. A vapour from the evaporator when compressed will condense at a higher temperature, corresponding to the new higher pressure. Successful working fluids must have a high latent heat of condensation so that the bulk of the heat can be extracted at the highest possible temperature. This principle applies to all conventional heat pumps (Figure 27.9).

The change in pressure between the evaporator and the condenser can be created by any mechanically driven compressor. Almost all the equipment in use is mechanically driven and electric motors are the driving units. They are

favoured because of their cost, simplicity, silence, efficiency, long life and reliability. However, there is an increasing use of fossil-fuel-driven engines because the waste heat from such an engine can often be incorporated into the heating scheme<sup>50</sup> (Figure 27.10).

The selection of heat pump working fluids is complex, but a critical factor is the range of permissible condensing temperatures. The upper-temperature limits depend on the compressor. Piston compressors, where the lubricating oil is in

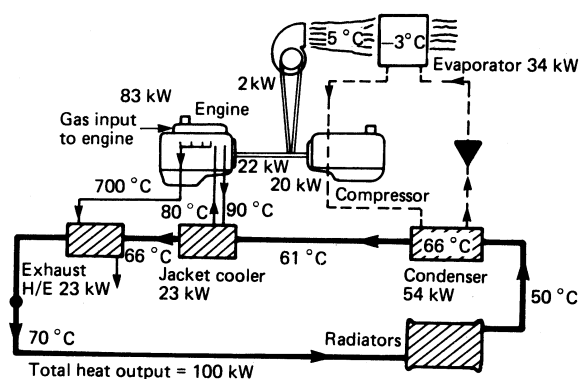

Figure 27.9 The vapour compression cycle (R22). From 1 to 2 the refrigerant vapour absorbs heat. From 2 to 3 the compressor compresses the gas. From 3 to 4 the gas is condensed and its latent heat released. From 4 to 1 the liquid expands to a vapour at the lower pressure

**Figure 27.10** A gas engine driven air-to-water heat pump with heat recovery from the engine (coefficient of performance 2.7)

intimate contact with the working fluid, are constrained by oil degradation. Dry compressors, where the bearings are sealed from the working fluid, can operate at higher temperatures. However, the chemical and physical stability of the working fluid itself then provides the working-temperature limits.<sup>51,52</sup>

In 1985 environmentalists discovered that certain refrigerants are attacking the protective stratospheric ozone layer around the earth and destroying it. These refrigerants are the chlorofluorocarbons (CFCs). Government action in Montreal in 1985 produced the first international agreement on restrictions necessary to protect the environment.<sup>53</sup> The two popular fluids R11 and R12 were amongst the most damaging chemicals and are progressively being phased out. Consumption in 1998 was down to 50% of the production in 1986. New ozone friendly refrigerants, in particular R134a, as a substitute for R12, are being developed.<sup>54,55</sup> A range of operating temperatures for different working fluids is illustrated in Figure 27.11.

Present-day refrigerants are normally pure single halo-carbon compounds. They have simple properties and boil

**Figure 27.11** The operating-temperature range for different working fluids

and condense at constant temperatures. They are azeotropic. Non-azeotropic mixtures have advantages in heat transfer and can be used to optimise cycle efficiencies. An illustrative enthalpy diagram is shown in Figure 27.12.<sup>56</sup>

This concept is now being used to control externally the refrigerant in the heat pump circuit by storing the refrigerant in a heated rectifier.<sup>57-59</sup> The composition of the refrigerant in the circuit is then controlled by the rectifier temperature (Figure 27.13).

### 27.10.3.3 Absorption heat pump

The absorption cycle works on the same principle as the vapour compression cycle, except that the change in pressure is brought about by adding heat to a solution and releasing the absorbed refrigerant at a higher temperature and pressure.<sup>45,60</sup> The circuit is illustrated in Figure 27.14.

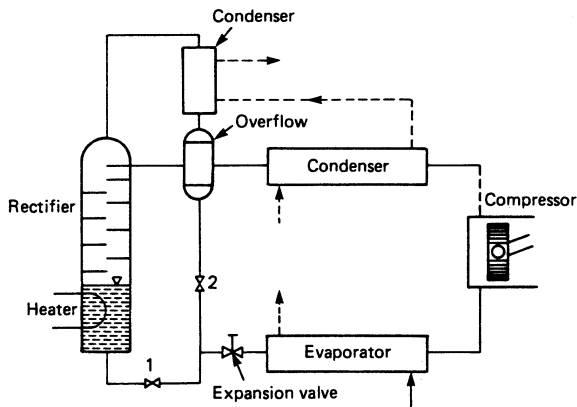

The refrigerant leaving the evaporator is physically absorbed in the absorbent, releasing heat. In this mixture the evaporator pressure becomes the partial pressure of the refrigerant in solution. This mixture is then brought up to the pressure of the generator by a liquid solution pump. Heat is applied to the generator and part of the refrigerant boils off and passes to the condenser when heat is released. The refrigerant then passes through an expansion valve to the evaporator. Meanwhile, within the generator, the solution, now depleted of much of the refrigerant, is brought down to the absorber pressure to restart the cycle.

The working fluids are usually ammonia and water or lithium bromide and water. Coefficients of performance are typically 1.2–1.4 on full load.<sup>59</sup> While this is modest, such units are usually gas fired with efficiencies of around 60–70%. The absorption cycle is, therefore, able to double the effectiveness of such energy use.

Part-load performance falls rapidly below 40% heating duty (Figure 27.15) and, therefore, the heat pump units are

**Figure 27.12** Non-azeotropic mixtures do not boil and condense at constant temperature. The enthalpy diagram illustrates the saturated liquid line (bubble point) and the saturated vapour line (dew-point) of a 70%/30% mixture of R13B1/R152A

**Figure 27.13** The refrigerant composition can be varied at will with a heated rectifier in the non-azeotropic refrigerant circuit

normally underrated for the design condition so that they spend most of their time at full load. The performance characteristics are much less sensitive to source temperature than vapour compression cycles<sup>61</sup> (Figure 27.16).

#### 27.10.3.4 Thermoelectric heat pump: Peltier device

When a direct electric current passes round a circuit incorporating two different metals, one junction of the two metals is heated and the other cooled.<sup>62,63</sup> To be effective, these Peltier couples must have a high thermoelectric coefficient  $\alpha$ , a low thermal conductivity  $\kappa$ , and low electrical resistivity  $\rho$ . The high thermal conductivity of metals normally makes the units very inefficient (coefficient of performance 1.01). However, recent progress in semiconductors

has improved  $\alpha$ , enabling much more effective units to be made.

The Peltier effectiveness ( $z$ ) is given by

$$z = \frac{\alpha^2}{\kappa \rho \zeta}$$

Present-day materials have  $z = 0.003/\kappa$ .

The overall performance of such devices is still short of that achieved by vapour compression cycles but the small size, reliability and ease of making low-capacity modules gives them a special market. A typical module layout is illustrated in Figure 27.17.

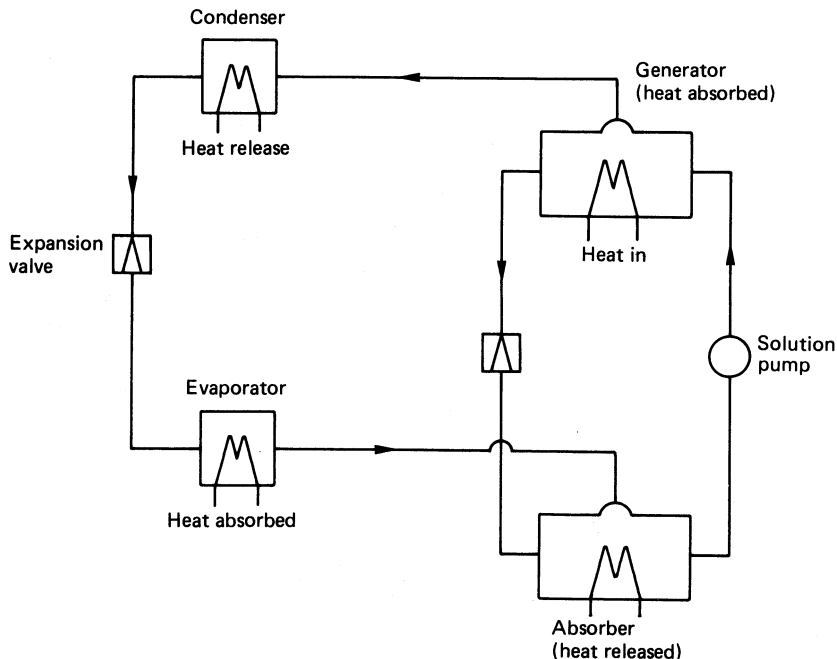

#### 27.10.4 Scale

The size and complexity of heat pump application is very wide, with appropriate specialist techniques for each application. For convenience, we examine applications by size.

##### 27.10.4.1 1–10 MW (thermal) schemes

Large-scale heat pump investments are attractive when the running time is long each year. Two types of application meet this requirement. These are base load space and water heating for district heating schemes<sup>64,65</sup> and heat-recovery techniques in large continuous industrial processes.<sup>66,67</sup> The compressors are usually of the high-speed centrifugal type or screw compressors.

Groundwater, sea-water, lakes or sewage treatment can provide the heat source for district heating schemes. Results from the Swedish Sala Municipal district heating network show that a screw compressor can provide 3.2 MW thermal energy at an annual COP of 2.7 (Figure 27.18). Availability in its first year was 80%. This heat pump operates throughout the year, providing the base load in winter and the hot water heating in summer.

**Figure 27.14** Schematic diagram of an absorption heat pump

**Figure 27.15** The effectiveness of the part-load condition for an absorption heat pump (ammonia/water pair, 12 kW input). (Courtesy of McLinden<sup>61</sup>)

**Figure 27.16** The performance characteristics of an absorption heat pump (ammonia/water pair, 12 kW input, 70°C water supply temperature returning at 50°C)

**Figure 27.17** The Peltier thermoelectric module (d.d. electric)

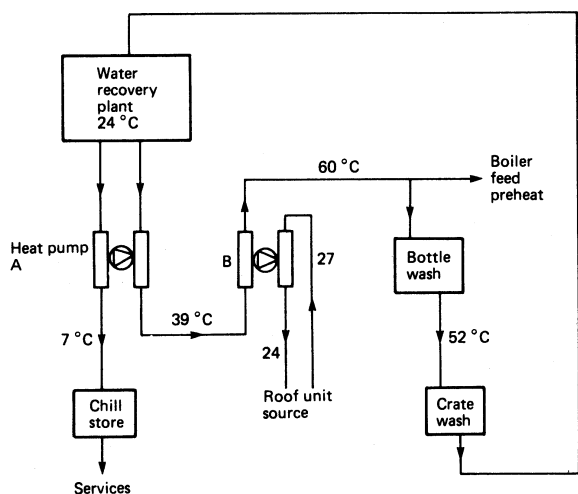

**Figure 27.18** Town sewage provides the heat for Sala, central Sweden, with an annual coefficient of performance of 2.7

Supplementary heating which is needed in the depth of winter is provided by a conventional oil-burning boiler.

Process heat treatment is illustrated by the 1 MW Milk Marketing Board dairy plant at Bamber Bridge, England. This dairy is a bottling and cartoning depot serving retail outlets. Two McQuay Templier centrifugal compressors are employed in series (*Figure 27.19*). Recycled effluent from the bottle washers is stored and then pumped through both the evaporator and the condenser sections of the first heat pump. The outlet water from the evaporator at 7°C is directed into the dairy supply tank as chilled water for dairy services. The water leaving the condenser passes into the condenser of the second heat pump, where it is heated to 60°C and provides a boiler feed preheat and a crate washing unit. The overall coefficient of performance is 5.5.

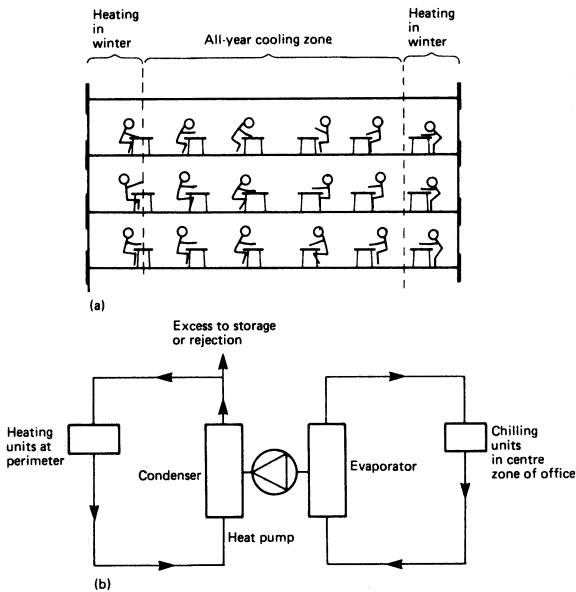

#### 27.10.4.2 100 kW to 1 MW (thermal) schemes

The three main applications are commercial buildings, small industrial batch drying plant and swimming pools.<sup>68,69</sup> The compressors are of the multicylinder piston or rotating vane types.

**Figure 27.19** Two McQuay centrifugal compressors operate up to 70°C to provide 1 MW of heat recovery in the British Milk Marketing Board's dairy at Bamber Bridge. The coefficient of performance under these conditions is 5.5

**Figure 27.20** Heat pump recovery in deep-plan offices: (a) section of a deep-plan office; (b) the cooling circuit provides the perimeter heating in winter

Deep open-plan offices require winter heating at the perimeter to combat the outdoor climate, but require permanent cooling of the central core. The heat pump enables the energy to be redistributed within the building (Figure 27.20). Such installations halved the energy cost of air-conditioned buildings in Britain, and formed the new concept of integrated environmental design. Coefficients of performances are 3–4.

The second batch of machines is usually a factory packages system for batch industrial drying.<sup>70–72</sup> Compact dehumidifiers which operate up to 80°C are now available for the controlled drying required for hardwood to avoid timber splitting (Figure 27.21).

Swimming pools are particularly energy intensive. Internal design conditions must not exceed 70% relative humidity of the pool hall air if condensation and mould

**Figure 27.22** Heat pump dehumidifiers can recover much of the sensible and latent heat from the warm moist air and return it to the pool water. Not only does this recover energy, but it also enables the conventional ventilation rate to be reduced<sup>68</sup>

growth are to be avoided. The conventional technique is to ventilate at a high rate and lower the moisture content of the air by dilution with air from outside. Heat pump dehumidification enables the moisture in the pool air to be controlled without losing great amounts of heat with high ventilation rates. The latent heat recovered from the moisture is used to heat up the pool water (Figure 27.22). The warm, moist air conditions mean that the heat pump can operate at a coefficient of performance of 5–6.

#### 27.10.4.3 10–100 kW (thermal) packaged units

Two types of machine of this size are factory packages. The most common is the reversible air-to-air space conditioner. It is reversible because, by an arrangement of valves, the unit can interchange evaporator and condenser by cooling in summer or heating in winter. The equipment is usually installed 'through the wall' in offices and shops, with each unit controlling a small zone within the buildings (Figure 27.23). It is also commonly sited on the flat roof of shops.

A modification of this principle is applied to large buildings, particularly older office blocks where the glazing area is large. In such buildings the individual heat pumps are attached to a ring main of recirculating tepid water. For those parts of the building needing cooling, the local heat pumps reject the heat to the ring main (Figure 27.24). Those parts of the building needing heating use the heat from the ring main as their heat source. Any net heating or cooling is provided from the central boiler or the central chiller.

The second and less common type is the air/water space heating heat pump.<sup>73–75</sup> They usually use outside air as the heat source and supply the heat to the house through conventional water radiators (Figure 27.25). They are often used in conjunction with supplementary heating because both the effectiveness and the output of such machines fall when the outdoor temperature falls and heating need is greatest (Figure 27.26). They also have a maximum water temperature of 55°C, which is lower than the figure for the conventional boiler of 80°C. Care must be taken, therefore,

**Figure 27.21** A single-stage heat pump dryer with subcooler has a coefficient of performance of 4.4<sup>71</sup>

**Figure 27.23** Reversible air-to-air room units can either heat or cool: (a) reversible air-to-air room unit; (b) self-contained ducted roof mounted heat pump

to ensure that the area of radiator is sufficient when operating at  $55^{\circ}\text{C}$ . There are two other cautionary points—noise and starting current surges. Air source heat pumps can be noisy and must, therefore, be selected and sited so that noise levels immediately outside the bedroom window are below 45 dB(A). Compressors with single-phase electrical drives greater than 1 kW rating must be checked with the local electricity company to see whether the electrical network would be unduly disturbed by the connection of such a pump. Soft-start units are now available on single-phase

**Figure 27.24** Linked room units can provide heating in some areas cooling in others

**Figure 27.25** An air-to-water domestic heat pump. The heat pump is shown inside the roof space but it can be sited in the garden

domestic units. Such devices are particularly helpful if the heat pump is switching on and off frequently.

While ambient air is the usual energy source, ground-water can be used. Even the earth around the building can supply the energy, provided that a sufficient area of brine filled pipes is buried in it (Figure 27.27).

**Figure 27.26** The output of an air source heat pump declines with colder conditions. The small step decline around  $5^{\circ}\text{C}$  is due to de-icing the evaporator

**Figure 27.27** Advanced house design uses the heat pump in conjunction with heat recovery. The 'chimney' is now a ventilator, the roof a solar collector and the floor a low-temperature heat emitter. The ground provides the extra energy<sup>65</sup>

#### 27.10.4.4 1–10 kW (thermal) packaged units

Most recent technical advances have occurred in these packaged units. New types of compressor, notably the scroll orbiting (not rotating) compressor, reduce noise levels, are small in size and low in cost and are combined with improved ribbed heat-transfer surfaces and more efficient electric motors. The operating cycle of the scroll compressor is shown in *Figure 27.28* and shown in section in *Figure 27.29*.<sup>76</sup>

New variable-speed drive motors are available to minimise frequent on/off cycles with their consequent wear and intermittent performance. This means that proportional control becomes readily available. The compressor speed range can vary from 1800 rev/min (40% load) to 7200 rev/min (12% design load).<sup>77</sup>

There are three types of application. The first domestic use is a hot water heater. This is usually combined with a hot water cylinder (*Figure 27.30*). The heat source comes from inside the building. Such application is very attractive if interior cooling is needed simultaneously, e.g. cooling a beer cellar and using the reclaimed heat to provide hot water for washing the glasses. Conventional equipment has a maximum temperature of 55°C and, therefore, the volume of stored hot water has to be slightly larger than normal.<sup>78</sup>

The second domestic application is in a mechanical ventilation heat-recovery system. The cycle is illustrated in *Figure 27.31*.<sup>79</sup> In a well-insulated house such units can provide 90% of the heating requirements. The heat pump can approach a coefficient of performance of 3.<sup>79</sup>

**Figure 27.28** The operating cycle of the scroll compressor

**Figure 27.29** Section of an orbiting scroll compressor

The industrial application is dehumidification. Portable units are available to dry out damp or newly built buildings. Fixed units are now being used to maintain low humidities in warehouses, particularly as warehouses are becoming automated and no longer require heating for the occupants.

#### 27.10.4.5 100 W to 1 kW (thermal) units

Damp, cold conditions characterise the winter climate in the UK. Small heat pump dehumidifiers extract moisture and translate the latent heat into sensible heat. Cool, damp air enters the evaporator and is chilled, depositing much of its moisture. The same air is then reheated over the condenser and returned to the room. Present equipment has a coefficient of performance which varies from 1.1 to 2.0, the higher value being associated with warmer and damper conditions<sup>80</sup> (*Figure 27.32*).

**Figure 27.30** A heat pump domestic water heater. Local water regulations may prohibit the direct immersion of a refrigerant heat exchanger into the water cylinder.<sup>78</sup> 1, Fan; 2, compressor; 3, evaporator; 4, expansion valve; 5, condenser; 6, storage; 7, hot water; 8, cold water

#### 27.10.4.6 10–100 W (thermal) modules

Peltier modules are effective ways of providing very small heat flows which can heat or cool. Their main application is to provide stable reference temperatures in scientific equipment.

### 27.10.5 Conclusions

Heat pump applications are very diverse. The expertise required varies widely with the different types of application. The very large plants (ca. 1 MW) are tailor-made for specific tasks which need much design analysis for successful

**Figure 27.32** A domestic dehumidifier removes water vapour and provides heat

integration. As the plant size decreases, the heat pump technology is built into packaged units and the application skills needed become those of a building service engineer. Illustrations of the performance and size of different applications are summarised in *Figure 27.33*.

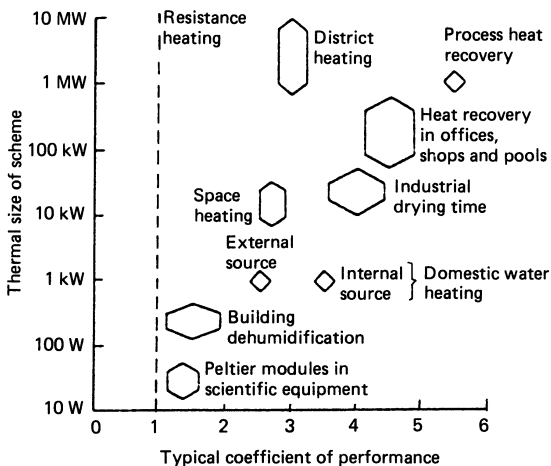

In general, the heat pump is an advanced piece of engineering which saves energy by extracting it from a low temperature source and making it available at a higher and more useful temperature. The three key factors for its successful use are:

- (1) where both heating and cooling are required, preferably simultaneously;
- (2) where moisture must be removed, and preferably where some heating is needed simultaneously; and
- (3) where the hours of use are long each year, so that the revenue savings can justify the increased initial cost which the heat pump incurs.

It also provides a dramatic reduction in carbon dioxide release and its associated greenhouse effect.

## 28.1 Introduction

For the generation, transmission, distribution and use of electrical power the three-phase system has large economic and practical advantages over single-phase or two-phase systems. Hence the great majority of alternating-current (a.c.) generators are three-phase machines, operating at one of the standard frequencies, 50 or 60 Hz. Some generators operate at other frequencies; examples are: (a) generators up to several megawatts in output operating at  $16\frac{2}{3}$  Hz have been used for years to supply rail traction systems, mostly in Europe, (b) high frequency generators, at 500–10 000 Hz, were used extensively for induction heating in industrial processes, (c) small shaft mounted generators with more than three phases are used as exciters for synchronous generators and some hydrogenerators, (d) aircraft ground power supplies operating at 400 Hz, and (e) a growing trend for machines to operate at other variable frequencies with power electronics being used to convert their output to 50 or 60 Hz. However, due to the cost of the electronic conditioning equipment, these are largely limited to less than 150 kW in output and under 1000 V.

The form of construction of the generator depends on its output power and its speed: these are determined by the prime mover that drives it. To generate at a frequency of  $f$  hertz when driven at  $n$  rev/min the generator must have  $2p$  poles, where

$$2p = \frac{120f}{n}$$

$n$  is the synchronous speed, being the same as the speed of rotation of the magnetic field produced by currents in a three-phase winding when connected to a supply of frequency  $f$  Hz. The maximum permissible diameter of the rotor will be determined by the rotational stresses acting on it and thus the speed of rotation determines the shape of the generator. For a given output power, a high-speed machine will have a smaller diameter, and longer length than a low-speed machine.

Generators may be classified as follows.

**Synchronous generator** This type of generator requires a winding carrying direct current (or in small sizes a series of permanent magnets) to establish the magnetic flux. In nearly all machines this excitation winding (known as the field winding) is carried on the rotor, which for a 50 or 60 Hz output must rotate at the synchronous speed.

There are two sorts of synchronous generator which are differentiated by the type of rotor used; rotors are either cylindrical or of the salient pole type.

The first type of synchronous generators are known as *turbogenerators*. This family of machines use a cylindrical rotor in which the field winding is housed in axial slots. They are invariably driven by a steam turbine or a gas turbine. At ratings below 60 MW a gear box may be used to provide a rotational speed of 3600 (2 pole) or 1800 rev/min (4 pole) to provide power at 60 Hz, or 3000 rev/min (2 pole) or 1500 rev/min (4 pole) to provide power at 50 Hz. Alternatively, and especially at higher power ratings the generator is directly driven by the steam or gas turbine. The rotors will thus have either two or four poles. Smaller machines may use a laminated construction for the rotor while larger machines will use a forged rotor. A feature of these machines is that their length is several times their diameter. Power outputs range from a few megawatts up to about 1500 MW. The machine is cooled by circulating air or hydrogen over the active parts or water through the

windings. Hydrogen was commonly used for outputs greater than about 50 MW; water was, and still is, used for the stator winding with outputs exceeding about 200 MW. Air-cooled machines are now available up to almost 200 MW.

The second type of synchronous generators use a salient pole rotor. Types of salient pole machines are:

**Hydrogenerators** This is a family of salient pole machines driven by water turbines at a speed in the range 50–1000 rev/min. The speed depends on the type of turbine, which in turn depends on the head and the flow rate of the water available. At low speeds, the permissible rotor diameter will be several times its active length. Generally, the largest allowable diameter of rotor is used to maximise the machine's inertia which is an important part of governing the water turbine. Outputs up to 800 MW have been achieved. A small high-speed unit will have a horizontal shaft, but for reasons of mechanical construction and stability larger machines have vertical shafts.

**Reciprocating gas, diesel or petrol engine-driven generators** For this application, the generator may be coupled directly to the internal combustion engine and the generator will invariably be of the salient pole construction. Many combinations of output power and speed are available, from a few kilovoltamperes, usually at four-pole speed, up to 45 MW or more at 100 rev/min, using a 2 stroke diesel engine of the type used for ship propulsion.

**Steam turbine or gas turbine driven generators** Salient pole generators connected to these prime movers are driven through a gearbox, usually at 4-pole speed. Ratings are limited to below 60 MW both by the gearbox capacity and by the difficulty of holding large salient pole rotors together.

**Synchronous compensators (also known as synchronous capacitors)** These machines draw current from the system at zero power factor, lagging or leading as required to control the voltage of the system. They also draw a small amount of real power to maintain the synchronous rotation. They will usually have six or eight salient poles, and a rating in the range from a few megavolt-amperes up to say 350 MVAR. For machines larger than say 50 MVAR, hydrogen cooling is used to reduce the windage loss. The synchronous compensator has been rendered obsolete by the development of static volt-ampere (VAR) control equipment.

**Asynchronous (induction) generators** In construction these machines resemble induction motors, and similarly draw their magnetising current from the power system, to which they deliver power when driven at very slightly above synchronous speed. Ratings are usually less than 3 MW, at speeds up to 1000 rev/min. Much smaller units, operating with capacitor excitation circuits, can provide isolated power supplies.

For generators of all types the practicable and economic voltage increases with the increase of rated output in order to limit the amount of current to be handled to a manageable level. Some standards specify preferred voltages, and some are normally mandatory. Typical ranges of output and voltage are:

MVA	1–6	4–16	4–100	100–400	400–800	800–1500
kV	1–4	5–7	10–13	14–16	18–23	26–30

However, a number of manufacturers have found significant markets by going away from these norms. Low voltage, high current machines together with an appropriate transformer have found favour where regulations restrict the installation of higher voltage generators. Conversely, high voltage generators, even at very modest outputs have proved attractive as the cost of a step-up transformer can be avoided.

*Operating generators singly or in a group* When a generating set runs alone to supply power to a load, the prime mover supplies the active power demanded. As the demand changes, small changes of speed cause the governor to adjust the mechanical input power to maintain as nearly as possible the correct speed and frequency. The generator supplies the active power and the reactive power required by the load, and this determines the power factor. Changing the generator's field current changes the terminal voltage, and the consequent changes in active and reactive power depend on the nature of the load, e.g. the proportion of motor load to static load. Usually, as the load changes, the voltage is held almost constant by adjustments to the excitation made by the automatic voltage regulator.

Most generators, however, are synchronous machines connected to an extensive supply network, and changing the excitation of one machine does not affect the system voltage, the speed or the power output of the generator. It changes only the reactive power, and a compensating change in reactive power is shared by other generators on the same or neighbouring bus-bars. Thus adjusting the generator field current when it is connected to a system results only in a change in the power factor at which the generator operates.

System engineers find it convenient to regard active power in watts ( $P$ ) and reactive power in vars ( $Q$ ) (the two components of the apparent power in volt-amperes (VA)) as separate but related entities to be generated, transmitted and absorbed.

Induction motors, chokes, transformers and underexcited synchronous machines all draw magnetising current, lagging the supply voltage by  $90^\circ$ . By convention, this is regarded as a demand for positive vars from the system. Capacitors and overexcited synchronous machines draw leading current, and so supply positive vars to the system. A synchronous machine is overexcited if its field current is more than is needed to make it operate at unity power factor.

## 28.2 Airgap flux and open-circuit e.m.f.<sup>1,6,7,8,11,17,19,23</sup>

### 28.2.1 Airgap flux waveforms<sup>7,16,23,44–47</sup>

Figure 28.1 shows the flux pattern of a turbogenerator (t.g.) on open circuit, and flux waveforms for it and for an 18-pole salient-pole (s.p.) generator. The t.g. flux waveform is inherently trapezoidal because of the distributed field winding and uniform length of airgap. Prominent ripples caused by the stator slots and teeth have been omitted (see Section 28.2.4).

The salient pole generator flux waveform is inherently rectangular, with short sections of low density between the poles. In this example, however, the shape is closer to sinusoidal, as the fundamental component shows, because the machine was designed with shaped pole shoes. These ensure that the length of the airgap at the extremities of the pole

shoe is greater than on the pole centre line. The slot ripples which arise as a result of the stator slot opening have been retained: they are not quite symmetrical because the stator did not have a whole number of slots per pole (actually  $10\frac{1}{2}$ ). Where integral slots per pole are used, great care is needed in the design and spacing of the pole face damper bars in order to avoid further additional ripples appearing in the voltage waveform.

These waveforms were produced using finite element analysis: the harmonic contents of the flux waves are shown in Table 28.1. The reference value of 100% is the peak of the fundamental component of the open-circuit wave of each machine.

Even harmonics do not normally occur on open circuit, because the waveshape is the same under all the poles, and is symmetrical about each pole centre line. All the harmonic flux density curves go through zero at the interpolar axes. The total flux per pole is, therefore, the fundamental component plus or minus the flux of one pole-pitch of each harmonic: 'plus' if the harmonic has a negative peak at the positive peak of the fundamental, and vice versa.

Wieseman<sup>44</sup> gave curves for a salient pole machine relating the peak flux densities of the fundamental and of the third harmonic to the peak of the actual flux wave. The multipliers

$$\frac{\text{Peak of fundamental}}{\text{Peak of actual flux wave}} = \epsilon 1, \text{ say}$$

and

$$\frac{\text{Peak of third harmonic}}{\text{Peak of fundamental}} = \epsilon 3, \text{ say}$$

were deduced as functions of the pole arc to pole pitch ratio, the minimum airgap to pole pitch ratio and maximum edge airgap to minimum airgap.

Ginsberg *et al.*<sup>45</sup> gave curves from which the flux wave fundamental and harmonics up to the 11th can be estimated, again in terms of the airgap lengths and pole profile.

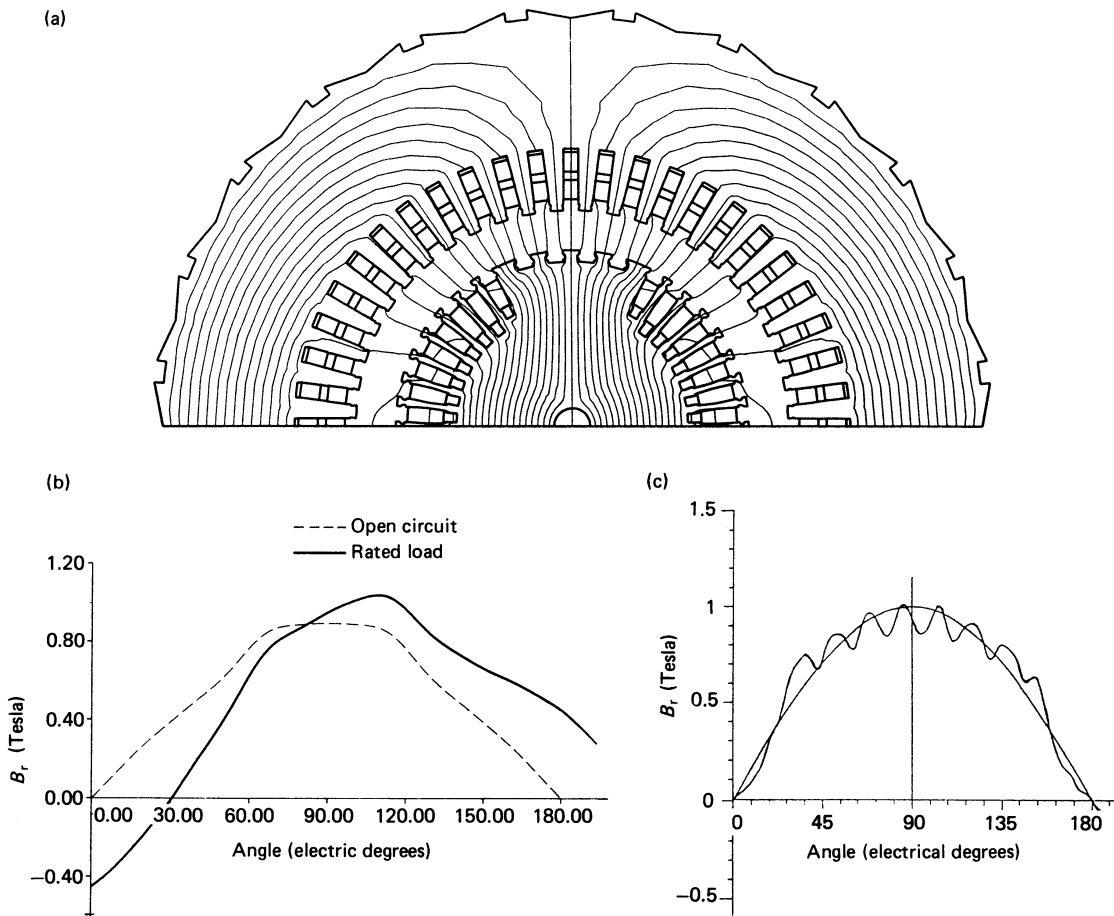

With usual pole shoe profiles, CI is between 1.0 and 1.1, i.e. the actual flux wave is a bit flatter than a sine wave, and the total flux per pole is rather more than the fundamental flux  $\Phi$ , alone. Wieseman's factor  $k\Phi$  is the total flux divided by the fundamental component. Narrow poles with an edge airgap of about twice the minimum tend to give a peaky waveform with CI just less than 1.0 and  $k\Phi$  down to about 0.93. Wider poles and a uniform airgap give  $k\Phi$  up to 1.06. The third harmonic flux can be made small by using a pole arc: pole pitch ratio close to  $2/3$ ; this together with a ratio maximum: minimum airgap ratio of 1.5 gives a  $k\Phi$  value close to unity. If  $\Phi$  is calculated from the e.m.f. equation, total flux and harmonic fluxes can be calculated.

Ginsberg *et al.*<sup>46,47</sup> provide curves from which the harmonic e.m.f.s on load could be calculated, as a per unit value of the fundamental. For detailed analysis, harmonic fluxes now are calculated by computer, e.g. by finite-element solution of the magnetic-field equations.

### 28.2.2 Open-circuit e.m.f.: integral slots per pole

#### 28.2.2.1 Fundamental frequency e.m.f.

The e.m.f. induced in a single conductor lying parallel to the shaft axis has the same waveform as the flux wave. It contains all the space harmonics in the same proportions as in the flux density. It may also contain ripples caused by local

**Figure 28.1** (a) Flux distribution of a turbogenerator on open circuit; (b) Flux waveforms of a turbogenerator; (c) Flux waveform of a salient pole generator on open circuit

variations in density caused by the winding slots (see Section 28.2.4). The root-mean-square (r.m.s.) value of the fundamental frequency component of the e.m.f. in a coil of one turn, spanning exactly one fundamental pole pitch, is

$$e_1 = 4.44f\Phi_1 \text{ (volts)}$$

(28.1)⇐

where  $\Phi_1$  is the fundamental flux per pole (in webers) and  $f$  is the frequency (in hertz).

28.2.2.2 Pitch factor,  $k_{p1}$

If there are  $N_p$  slots per pole, and the coil spans  $S$  teeth, it is short-pitched by an electrical angle

$$\beta_s = \left(1 - \frac{S}{N_p}\right) 90^\circ$$

and the e.m.f.s generated in each of the two coil sides will be out of phase with respect to each other by  $\beta_s$  degrees.

**Table 28.1** % harmonic contents of flux waves

		Harmonic order							
		Fundamental	3	5	7	9	11	13	15
<i>Turbogenerator</i>									
Open circuit	100	5.5	0.65	2.3	1.4	0.07	0.37	0.4	
Rated load	112	13.0	2.34	2.4	1.5	0.2	0.42	0.46	
<i>Salient pole generator</i>									
Open circuit	100	6.5	2.4	4.7	3.9	1.2	0.5	1.2	
Rated load	108	18.5	3.2	4.8	4.3	2.0	0.4	1.2	

The total e.m.f. is, therefore that of a full-pitch coil reduced by the factor

$$k_{p1} = \cos \frac{1}{2} \beta \zeta \quad (28.2a) \Leftarrow$$

or, in another form,

$$k_{p1} = \sin \frac{S}{N_p} 90^\circ \quad (28.2b) \Leftarrow$$

### 28.2.2.3 Distribution factor $k_{d1}$

If there are  $q$  slots per pole per phase ( $q = \frac{N_p}{3}$  for a three-phase machine), where  $q$  is an integer, the phase difference between successive slots causes the sum of their e.m.f.s to be less than  $q$  times the e.m.f. per slot by the distribution factor, or spread factor  $k_{d1}$ . This is because vectorally each successive coil voltage is at an angle to its predecessor. This angle is determined by the total number of stator slots distributed around the bore of the stator.

$$k_{d1} = \frac{\sin q(\alpha/2)}{q \sin(\alpha/2)} \quad (28.3) \Leftarrow$$

where  $\alpha$  is the electrical angle between adjacent slots.  $\alpha$  is numerically equal to  $180^\circ/N_p$  electrical degrees or  $60^\circ/q$  for three phases, with the usual  $60^\circ$  coil phase spread. Then, for a three-phase winding,

$$k_{d1} = \frac{\sin 30}{q \sin(30/q)} \quad (28.4) \Leftarrow$$

### 28.2.2.4 Skew factor, $k_{s1}$

If the winding slot, or the longitudinal axis of the pole, is skewed at an angle  $\delta$  to the shaft axis, there is a progressive change in phase of the e.m.f. along each conductor. The conductor e.m.f., and hence the phase e.m.f., is reduced by the skew factor

$$k_{s1} = \frac{2 \sin(\delta/2)}{\delta \zeta} \quad (28.5) \Leftarrow$$

Then, for a phase comprising of  $T_{ph}$  turns, divided into  $g$  parallel circuits, the fundamental frequency e.m.f. is

$$\begin{aligned} E_1 &= 4.44 f_1 \Phi_1 \frac{T_{ph}}{g} k_{d1} k_{p1} k_{s1} \text{ (volts)} \\ &= 4.44 f_1 \Phi_1 \frac{T_{ph}}{g} k_{w1} \text{ (volts)} \end{aligned} \quad (28.6) \Leftarrow$$

### 28.2.2.5 Harmonic e.m.f.s

For the following reasons a lot of attention is now being paid to the harmonic content of the generator's voltage waveform especially with the advent of increasing amounts of private power generation equipment connected to networks.

- (1) Limits of telephone interference factor (t.h.f.) are specified in many standards, and the weighting factors

emphasise harmonics that can be caused by slot ripples if the design does not suppress them.

- (2) Legislation is impending in the form of the Electromagnetic Compatibility Directive (EMC) 89/336/EEC. This will specify limits for the maximum levels of emitted electromagnetic radiation, and of the levels of voltage or current that can be impressed on the power system or on the load connected to the generator.
- (3) Generators are being more frequently required to provide a backup supply to uninterruptible power supplies if the mains supply fails. These schemes are used to feed loads that are sensitive to voltage distortion, such as computers, television monitors and control systems.
- (4) There is increased concern that harmonic currents may be large enough to cause unacceptable extra heating and losses, both in the generator and in equipment supplied by it.
- (5) Inadvertent malfunction of protection and switching equipment can occur particularly if the equipment is set to trigger at the zero crossing point of the voltage waveform.

It is difficult to estimate how large the harmonic currents arising from the harmonic voltages will be. Their values depend on the impedances of the system and of the generator at the harmonic frequency, and on the nature of the connection between their neutral points.<sup>42</sup>

The lower-frequency harmonics, up to say the 13th order, are produced by harmonics in the main flux wave. These result from the non-sinusoidal distribution of magnetomotive force (m.m.f.) and the non-uniform radial permeance around the circumference of the airgap. Hence they are often called *rotor permeance harmonic e.m.f.s*. The magnitude of each compared with the fundamental e.m.f. depends on the harmonic flux density relative to the fundamental density, and on the harmonic wavelength relative to the spacing and span of the stator coils, i.e. on the winding factors  $k_d$ ,  $k_p$  and  $k_s$  at the relevant frequency.

E.m.f.s at frequencies associated with the number of stator slots are caused by: (a) variations in gap permeance as the poles pass the stator slots and teeth; and (b) flux waves produced by currents induced at slot frequency in the damper winding, field winding and solid steel of the rotor. These e.m.f.s are generally called *slot ripple e.m.f.s* (see Section 28.2.4).

Considering only the field form harmonics, and taking  $q$  as an integer, the pole span of the  $n$ th harmonic flux is  $1/n$  of the fundamental span, and the harmonic flux per pole

$$\Phi_n = \frac{\Phi_1}{n} \frac{B_n}{B_1} \text{ (webers)}$$

where  $B_1$  and  $B_n$  are the peak or average flux densities.

The harmonic e.m.f. generated as a result of this flux is

$$E_n = 4.44 f_n \Phi_n \frac{T_{ph}}{g} k_{wn} \quad (28.7) \Leftarrow$$

where

$$k_{wn} = k_{dn} k_{pn} k_{sn}$$

or

$$\frac{E_n}{E_1} = \frac{B_n k_{wn}}{B_1 k_{w1}}$$

Because any angle  $\alpha$  on the fundamental scale embraces  $na$  of the  $n$ th harmonic, the winding factors become (where  $q$  is an integer)

$$k_{pn} = \cos \frac{1}{2} n\beta; \text{ or } \sin n \frac{S}{N_p} 90^\circ \quad (28.8) \Leftarrow$$

$$k_{dn} = \frac{\sin n 30}{q \sin (n \cdot 30/q)} \quad (28.9) \Leftarrow$$

$$k_{sn} = \frac{2 \sin [(n\delta)/2]}{n\delta\zeta} \quad (28.10) \Leftarrow$$

The r.m.s. value of the total e.m.f. per phase is then

$$E_{pn} = \sqrt{E_1^2 + E_3^2 + \dots + E_n^2} \quad (28.11)$$

The lower harmonic e.m.f.s are usually a few per cent of  $E_n$  and the higher orders smaller still. The total e.m.f.  $E_{ph}$  is rarely significantly greater than the fundamental,  $E_1$  although the harmonic e.m.f.s themselves may be troublesome.

For  $q = 1$ ,  $k_{dl}$  is 0.966, decreasing steadily to 0.955 for  $q = 9$  or more.  $k_{dn}$  decreases rapidly with increasing  $q$ , leading to a reduction in the e.m.f. harmonics caused by space flux density harmonics in the field form. Unfortunately,  $k_{dn}$  rises periodically to equal  $k_{dl}$  for  $n = m6q \pm 1$  (where  $m$  is any integer), i.e. for the slot frequency harmonics. If flux components exist at these frequencies they are usually small, but they appear in undiminished proportion as harmonics in the e.m.f. For example, for  $q = 3$

$n$	1	3	5	7	9	11	13	15	17	19	21
$k_{dn}$	0.966	0.667	0.217	0.177	0.333	0.177	0.217	0.667	0.960	0.960	0.667

$k_{pn}$  is less than  $k_{p1}$  for most slot numbers and coil pitches, but again  $k_{pn} = k_{p1}$  at the slot frequencies. For comprehensive tables of  $k_{dn}$  and  $k_{pn}$ , see references 1 and 22.

$k_{sn}$  can be made nearly zero for the slot frequencies by skewing slots or poles by one slot pitch in the length of the core. Then  $k_{s1}$  is still very nearly unity.

In principle, a particular harmonic e.m.f. can be eliminated by choosing a number of slots that allows the coil to be short-pitched by exactly half the harmonic wavelength, i.e. by  $1/n$  of the pole pitch, so making  $k_{pn}$  zero. In practice, it is very rarely necessary or acceptable to impose this constraint on other design considerations. Most windings have a coil pitch close to  $5/6$  of the pole pitch, as this usefully reduces both the fifth and seventh harmonic e.m.f.s. This pitch is easily obtainable with any even number of slots per phase per pole.

For certain slot numbers, and harmonic orders,  $k_{dn}$  becomes negative.  $k_{pn}$  becomes negative for certain pitches and harmonic orders. Thus the harmonic e.m.f. and the harmonic flux that produces it have opposite signs, each relative to its fundamental.

In a star-connected winding, third-order and other triplen e.m.f.s do not appear between the line terminals because they are in phase with each other in all three phases and cancel out. Triplen currents cannot flow unless they have a path via a connection made to the star point. Triplen e.m.f.s act in series round a closed delta winding, and would cause circulating currents, extra losses and, perhaps, overheating. For this reason, and because a star point is usually needed for earthing, generators rarely use delta windings.

Sometimes especially for generators operating at voltages below 1000 V,  $2/3$  pitch coils are used to suppress the triplens in the phase e.m.f. This allows the star point to be connected directly to earth without giving rise to circulating

third harmonic currents. This is especially desirable if multiple generators are to be run in parallel with the neutral point on each machine tied to earth. On higher voltage machines, large circulating triplen currents are avoided by using a high resistance or impedance in the connection of the star point to earth and the more economical and advantageous  $5/6$  pitch stator winding can be used.

### 28.2.3 Open-circuit e.m.f.: fractional slot windings

Equation (28.7) applies, but  $k_{wn}$  and the harmonic e.m.f.s are less than when  $q$  is an integer. In a winding with  $q = a + (b/c)$  slots/pole/phase (where  $a$ ,  $b$  and  $c$  are integers and  $b$  and  $c$  have no common factor) each phase has exactly  $(ac + b)$  slots arranged in  $c$  groups in  $c$  pole pitches. The position of each phase group of  $a$  or  $(a + 1)$  slots relative to its own pole is different for each of the  $c$  groups. Taking the  $c$  groups together, the  $(ac + b)$  slots are uniformly distributed within an angle of  $60^\circ$  electrical (the coil-to-coil connections allow for the  $180^\circ$  phase difference between adjacent poles). Therefore, the phase angle  $\alpha_c$  between the e.m.f.s that are electrically adjacent is  $60/(ac + b)$ , although the electrical angle between slots that are physically adjacent is

$$\alpha_s = \frac{60}{q} = \frac{60c}{ac + b}$$

i.e.  $\alpha_e = \alpha_s/c$  as if the winding had  $cq$  slots/pole/phase. The  $ac + b$  coils must be joined in series to form one repeatable section of the phase.

The winding factors that apply to the fundamental and harmonic m.m.f.s produced by a winding carrying balanced sinusoidal currents apply also to the e.m.f.s generated in it by the fundamental flux wave and any harmonic waves (including those produced by the damper winding, see Section 28.2.4). Walker and Kerruish<sup>38</sup> consider the e.m.f. and m.m.f. Liwschitz-Garik<sup>36,39</sup> considers the m.m.f. of fractional-slot windings. Their formulae for  $K_{dn}$  look different, but give the same values for a given winding. Equation (28.9), modified by putting  $cq$  in place of  $q$ , gives the same values too, except at the slot frequencies of a fractional-slot winding (see Section 28.2.4 and reference 43). In general,  $k_{dn}$  and  $k_{pn}$  are much smaller if  $q$  is not an integer than if it is. References 34, 35, 36 and 40 describe other methods of analysis and other types of winding.

### 28.2.4 Slot ripple e.m.f.s<sup>33,43</sup>

The causes of harmonics in the open-circuit e.m.f. wave at frequencies associated with the number of stator slots are:

- (1) The presence of harmonics at slot frequencies in the main flux wave produced by the rotor.
- (2) Cyclic variations in the flux distribution in the airgap, as the poles pass the stator teeth and slots. There is very little change in the total flux per pole, because change is resisted by currents induced in the damper cage and field winding.
- (3) Flux waves produced by currents induced in the rotor (damper cage, solid pole shoes, and field winding). These currents are caused by the ripple produced in the gap flux density by the stator slotting.

The stator e.m.f. ripples are greater if:

- (1) The machine has a whole number of stator slots per pole. Ripple e.m.f.s can be greatly reduced by choosing an appropriate fractional-slot winding.

- (2) The stator slot opening is large compared with the air-gap length. A slot opening to airgap length ratio greater than 2 emphasises the ripple (and the eddy current losses in the damper or pole surface).
- (3) The rotor has a low impedance damper cage rather than solid pole shoes, which have higher impedance.
- (4) The effective pole shoe arc covers other than a whole number of stator slot pitches. However, flux fringing makes this a rather imprecise relationship.

Walker<sup>43</sup> investigated mathematically the occurrence of slot ripple e.m.f.s, and illustrated his findings with oscillograms in which ripples, or their absence, were related to constructional features of the machine. He concluded that the main cause of such ripples is the presence of slot frequency currents in the damper cage of a salient pole machine, unless it is designed specifically to avoid them. They arise because the radial permeance of the airgap is less opposite each slot than it is opposite adjacent teeth. This imposes on the main flux waveform a ripple of wavelength equal to one stator slot pitch. The peak-to-peak depth of the ripple (its double amplitude) is approximately proportional to the *local* mean density of the flux wave (neglecting iron saturation). Hence the ripple is greatest over the pole shoe arc and dwindles to zero at the quadrature axis. At each slot or tooth position the mean flux density, and the ripple, rise and fall as the poles sweep past. This may make the ripple appear to rotate, but because it is caused by the stator slots, it is fixed in position relative to the stator. Therefore it does not induce e.m.f. directly into the stator winding.

It does, however, induce e.m.f.s at slot frequency into any available rotor circuits, most importantly into the rather low impedance damper cage. The frequency is  $2N_p f$  hertz, where  $2N_p$  is the number of slots per pole pair and  $f$  is the synchronous frequency ( $2N_p$  may or may not be a whole number). The number of damper bars is chosen primarily to provide effective damping, and the angular pitch of the bars is usually within 15% of the stator slot pitch. If the bars are symmetrically and similarly placed in all the poles, the ripple e.m.f.s in corresponding bars in successive poles circulate current from pole to pole. This produces a m.m.f. with a wavelength equal to two fundamental pole pitches, pulsating relative to the rotor at  $2N_p f$  hertz and rotating with it. This is equivalent to two waves of half amplitude rotating relative to the rotor at  $2N_p$  times synchronous speed, one forwards and one backwards. Relative to the stator the speeds are, therefore,  $(2N_p \pm 4)$  times synchronous speed, and harmonic e.m.f.s of these two orders are induced in the stator. These e.m.f.s are not reduced, relative to the fundamental, by their pitch and spread factors, if  $N_p$  is an integer.

As Walker points out, with a whole number of stator slots per pole pair, the pole-to-pole damper cage currents can be avoided, or at least greatly reduced, by offsetting the bars  $1/4$  of a stator slot pitch to the left in say the north poles, and  $1/4$  slot pitch to the right in the south poles. This can dramatically improve the e.m.f. waveform, and is standard practice when  $N_p$  is an integer.

A practical point of mechanical design arises. The bars usually occupy 75–80% of the circumferential width of the pole shoe. The slots for the outermost bars must be placed so that they do not cause the pole shoe to be overstressed by centrifugal force. Alternatively, the damper bar slots in this position may be closed or omitted.

Walker also shows that if  $N_p$  is odd, or fractional, the backward-rotating field does not occur, and the e.m.f. ripple frequency is  $(2N_p + 1/k)f$  hertz, where  $k$  is the

denominator of  $2N_p$  when it is expressed in its lowest terms, thus:

$$2N_p = \frac{N}{p} = \frac{A}{k}$$

where  $N$  is the total number of stator slots and  $p$  is the number of pole pairs. Second-order slot ripple at  $(4N_p \pm 4)f$  (for integral  $N_p$ ) or  $(4N_p \pm 4/k)f$  may sometimes contribute significantly to the telephone harmonic factor, because the weighting factor is near its maximum at the corresponding frequencies.

Tables showing combinations of  $k$  and  $2N_p$  that may, and those that will not, cause pole-to-pole currents and hence slot ripple e.m.f.s are given in reference 43. These are reproduced, for  $k$  up to 6, in Table 28.2. If  $b/c$  in  $q = a + b/c$ , is less than  $1/4$ , ripple e.m.f.s are usually tolerably small.

In a turbogenerator, the rotor tooth-tops, slot wedges and the damper winding will carry stator-slot-frequency currents. However, the gap-flux ripple at the rotor surface is not great, because the stator slot opening is less than the gap length, except in smaller machines (say below 30 MW). Although  $q$  is usually an integer, it usually is more than 6, so the ripple e.m.f. is rarely objectionable.

Walker has also shown that the uniformly spaced rotor bars, in conjunction with integral slots per pole per phase, may cause additional e.m.f. ripples at frequencies of  $[(N'/p) \pm 4]f$  Hz, where  $N'$  is a whole number given by the rotor circumference divided by the rotor slot pitch. Again this e.m.f. ripple is rarely troublesome.

In summary, design features used to reduce harmonics in the open-circuit e.m.f. are as follows.

- (1) Use a fractional slot winding, choosing the number of slots per pole pair from Table 2 of reference 43 (or Table 28.2).
- (2) Choose an optimum pole shoe arc, and increase the gap length towards the edges of the pole, to reduce the harmonics in the main flux wave. An arc of 65–70%

**Table 28.2** Slots per pole pair that do and do not produce slot ripple e.m.f.s\*

$k$	Fundamental harmonic	Second harmonic
<i>Slots per pole-pair that produce slot ripple e.m.f.s</i>		
1	$2K$	
2	$K \pm \frac{1}{2}$	$K$

4		$K, K \pm \frac{1}{4}$
5	$K \pm \frac{1}{4}$	$K \pm \frac{1}{8}, K \pm \frac{3}{8}$
6	$2K, 2K \pm \frac{2}{3}, 2K \pm \frac{4}{3}$ $K \pm \frac{1}{6}, K \pm \frac{5}{6}$	$K, K \pm \frac{1}{3}, K \pm \frac{2}{3}$ $K \pm \frac{1}{12}, K \pm \frac{5}{12}, K \pm \frac{7}{12}$
<i>Slots per pole-pair that do not produce slot ripple e.m.f.s</i>		
1	$2, K \pm 4$	$K \pm \frac{1}{2}$
2	$K$	$K \pm \frac{1}{2}, K$
3	$2K \pm 4, 2K \pm \frac{1}{3}$	$K \pm \frac{1}{3}, K \pm \frac{2}{3}$
4	$K, K \pm \frac{1}{2}$	$K \pm \frac{1}{4}, K \pm \frac{3}{4}, K$
5	$2K \pm 4, 2K \pm \frac{1}{5}, 2K \pm \frac{3}{5}$	$K \pm \frac{1}{5}, K \pm \frac{2}{5}, K \pm \frac{3}{5}, K \pm \frac{4}{5}$
6	$K, K \pm \frac{1}{2}$	$K \pm \frac{1}{2}, K \pm \frac{1}{6}, K \pm \frac{5}{6}, K$

\* $K$  is any integer;  $k$  is the denominator of the number of slots per pole pair.

of the pole pitch is usual, with a gap length at the pole shoes edges 1.3–1.7 times the minimum gap at the pole centre. With fractional slotting, or integral  $q$  of 5 or more, a parallel gap will often suffice. This is convenient for solid pole shoes, as it allows the shoes to be skimmed to give the correct rotor diameter after they have been bolted on. With a pole shoe arc of  $2/3$  of the pole pitch, the third harmonic flux is theoretically zero with a parallel gap, but a graded gap may be chosen to reduce the fifth and seventh harmonics.

- (3) Skew the stator slots, or the poles, by one stator slot pitch to reduce the fundamental slot ripple harmonic, or by half a slot pitch for the second order harmonic. Skewing is often used on small machines, but it becomes rather awkward and expensive on large ones.
- (4) For a salient pole machine with a whole number of slots per pole pair, offset the damper bars to the left and right alternately on successive poles. An offset of  $1/4$  of the stator slot pitch each way will largely eliminate the fundamental slot harmonic and will somewhat reduce the second-order harmonic. If necessary, the latter can be reduced further by skewing the stator slots or the damper bars by half a stator slot pitch.
- (5) With a whole number of stator slots per pole pair, it may sometimes be worthwhile to offset the poles in pairs to the left and right alternately, in order to avoid ripple caused by slot frequency currents in the field winding. Again, an offset of  $1/4$  stator slot pitch each way will reduce the fundamental slot ripple.
- (6) Make the ratio of the gap length to the width of slot opening as large as other requirements will permit. However, the gap length is governed chiefly by the shortcircuit ratio (approximately  $1/X_d$ ) that is specified, and to make it longer merely to reduce slot ripple would usually be unacceptably expensive.

The most effective and economically acceptable methods are to choose a suitable fractional slot winding and shape the pole shoes (for the lower harmonics): or, if an integral slot winding is selected, it is important to choose the most suitable damper bar pitch and to offset the bars as in (4) above.

Stromberg<sup>40</sup> explains how the fractional-slot winding reduces the harmonic e.m.f.s, gives reduction factors for various winding arrangements and indicates certain special constructions that can be used if a particularly good e.m.f. waveform is required.

### 28.3 Alternating current windings

In synchronous generators, the a.c. output winding is on the stator, except in some very small machines and some for particular purposes. For example, the a.c. winding and the diodes of a brushless exciter are necessarily on the rotor.

Low voltage machines with voltages up to 4160 V and with outputs of up to 2500 kVA, may have single- or two-layer windings with mush-type coils wound with round enamelled wire secured in semiclosed slots. Larger machines have two-layer windings using diamond-shaped short-pitched coils wound with insulated rectangular copper strip, secured in open slots. Each coil has one of its sides in the top layer and the other in the bottom. The coils and the connections between them are most often of the lap type but can be of the wave type. See Figure 28.2 for a diagrammatic explanation of these terms. Where such coils would be physically too difficult to manufacture, either because of their size or weight, single half coils, known as bars, are used. Bars may also be of either the lap or wave type. Almost always, in a three-phase winding, each phase-group of coils or bars occupies an arc of exactly or nearly  $60^\circ$  electrical

Figure 28.2 Stator coil arrangements: (a) coil groups,  $q$  an integer; (b) short-pitched lap connection; (c) short-pitched wave connection

under each pole. As explained previously, the number of slots per phase per pole for the stator winding may either be integral or non integral.

Most two-pole and four-pole turbogenerators use a bar type winding and a whole number of slots per pole per phase. Some large low-speed machines use wave-type windings; smaller machines quite often have skewed stator slots.

The two-layer short-pitched coil winding has the advantages that:

- (1) the coils all have the same shape, which reduces the tooling needed for forming and insulating;
- (2) a neat endwinding is obtained which is not difficult to support;
- (3) the coil span can be chosen to reduce harmonic e.m.f.s produced by flux wave harmonics, and to reduce harmonic m.m.f.s produced by the load current;
- (4) fractional slotting can be used, for the same purpose as in (3); and
- (5) in multipolar machines, several identical parallel circuits per phase can be formed, giving greater freedom to optimise the design.

Single-layer windings are now rarely used for generators, and are not considered here (see references 11 and 22).

### 28.3.1 Choice of slot number

Liwschitz-Garik<sup>22</sup> gives a very thorough treatment of this subject, to which acknowledgement is given. Considering only three-phase windings, let:

$N$  = total number of slots = total number of coils  
 $2p$  = number of poles

$N_p = \frac{N}{2p}$ , slots per pole

$N_{ph} = \frac{N}{3}$ , slots per phase

$q = \frac{N_p}{3} = \frac{N}{6p}$ , slots/pole/phase

$g$  = number of parallel circuits per phase  
 $y$  = full coil pitch  
 $y_f$  = front coil pitch  
 $y_b$  = back coil pitch

See Figure 28.2 for a diagrammatic explanation of these terms. Then:

- (1)  $N/3g$  must be an integer, to provide equal numbers of coils in each parallel circuit of each phase; and
- (2) the coils must be arranged symmetrically around the airgap, to the same pattern in all phases, to give equal phase e.m.f.s, spaced  $120^\circ$  electrical apart.

### 28.3.2 Integral-slot windings

The quantity  $q$  can have any practicable value, usually between 2 in multipole machines (though these are more likely to have fractional-slot windings) and 10 in large two-pole turbogenerators. The  $6q$  coils in  $6q$  slots per pole pair are almost always arranged in six groups, each of  $q$  coils, each group occupying exactly  $60^\circ$  electrical in each layer. Figure 28.2(a) shows the arrangement of full-pitch and short-pitch coils. The pitch is usually about  $5/6$  of the pole pitch which is chosen to minimise both the 5th and 7th harmonics.

If the left-hand top-layer conductor of each group is called the 'start' of the group, the e.m.f.s acting from start to finish of groups 1 and 4 are  $180^\circ$  out of phase; similarly, for groups 2 and 5, and 3 and 6. Phase A is formed by connecting F1 to F4 to put groups 1 and 4 in series. S1 is the start of phase A, and S4 the finish. Connecting S1 to F4 and F1 to S4 puts the two groups in parallel. Similarly, for phase B (groups 3 and 6) and phase C (groups 5 and 2).

If Phase A starts at slot 1, phase B can start at any slot numbered  $1 + 2q + 6nq$ , and phase C at  $1 + 4q + 6nq$  ( $2q = 420^\circ$  and  $6nq = 360^\circ$ ;  $n$  being any integer from 0 to  $p$ ).

In a short-pitched wave winding,  $y_b < g_f$ , but  $y_b + y_f$  is equivalent to two pole pitches. The step of  $2p \times \frac{y_f}{y_b}$  must be one slot more or less than  $y_f$  so that a connection can be made to the coil side next to the one at which that tour round the winding started.

### 28.3.3 Fractional-slot windings

These windings, in which  $q$  is not an integer, have the advantage that they can generate as good a waveform with few slots per pole per phase as an integral- $q$  winding with many more slots. Fractional slot windings are frequently used in multipolar machines where there is not room for  $q$  to exceed 3 or 4. For example with  $q = 3\frac{1}{2}$  the effect of harmonics in the gap flux is reduced as effectively as with an integral value of  $q$  of 27, an impracticable number. In this example, it would be necessary to have 14, or a multiple of 14 poles to allow the full pattern of groups of coils to be achieved that are required to give an arithmetic average figure of  $3\frac{1}{2}$  slots per pole per phase.

Fractional  $q$  also gives the designer a wider choice of slot numbers (for most numbers of poles), enabling flux densities to be adjusted more easily on a given frame size.

#### 28.3.3.1 Arrangement of the coil groups

- (1) Writing  $q = \frac{b}{c}$  where  $a$ ,  $b$  and  $c$  are integers and  $b$  and  $c$  have no common factor, then  $c$  is the least number of pole pitches that will contain a whole number of slots per phase, viz.  $(ac + b)$  slots. In the  $c$  pole pitches, there are  $3(ac + b)$  coils that form a complete three-phase unit of the winding.  $2p/c$  (= say) of these units make up the whole winding, which has  $N = \frac{2p}{c} 3(ac + b)$  slots and coils (of course  $N = 6pq$ ).

$F$  is the highest common factor of  $N$  and  $2p$ , because

$$\frac{N}{F} = \frac{N}{2p/c} = 3(ac + b)$$

- and is the number of slots in the unit that occupies  $c$  pole pitches, and  $c = \frac{2p}{F}$ . Of course  $N$  is a multiple of 3 and of  $F$ .
- (2) A balanced three-phase winding can only be obtained if  $c$  is neither 3, nor a multiple of 3. Then, in the  $c$  pole pitches in each layer of the winding, each phase occupies  $b$  groups of  $(a + 1)$  slots, and  $(c - b)$  groups of  $a$  slots.
  - (3) Starting from slot 1 of each unit of  $c$  pole pitches, the larger and smaller slot groups occur in different sequences in the three phases, but the phase e.m.f.s are balanced. The pattern of larger and smaller groups is the same in all  $F$  units.
  - (4) Taking all three phases together, the pattern of larger and smaller slot-groups is complete in  $c/3$  pole pitches. It occurs  $3F$  times in the whole winding, but does not itself form a balanced three-phase unit.

- (5) The sequence of  $a$ -slot and  $(a+1)$ -slot groups can be found as follows which is the same for lap as for wave windings.

$60^\circ$  electrical contains  $q$  slot pitches. Starting from  $0^\circ$  at slot number 1, the centre lines of the first and last slots of successive slot groups (often called phase belts) must lie within the electrical angles  $0-60^\circ$ ,  $60-120^\circ$ , ...,  $420-480^\circ$ ; etc., from slot 1. Therefore, the centre line of the last slot of the  $n$ th group lies just within  $nq$  slot pitches of slot 1, where  $n$  is an integer. In general,  $nq$  is an integer plus a fraction, say  $nq = (ac+b)/c = X + (Y/c)$ . Then, the slot number  $(1+X)$  is the last slot of the  $n$ th group. But when  $n = c/2$ , etc.,  $X = (ac+b)/2$ , etc., and  $Y = 0$ . Then slot number  $(1+X)$  lies exactly  $60n^\circ$  from slot 1, and so is the first slot of the  $(n+1)$ th group. Table 28.3 illustrates the method for a 12-pole machine with 135 slots,  $q = \frac{3}{4}$ ,  $c = 4$  and  $F = 3$ . The slot sequence 4, 4, 4, 3 can be determined by considering only  $c$  steps of  $q$  slots but the complete table allocates all slot numbers to phases.

The fraction  $b/c$  determines the numbers of larger and smaller coil groups and their sequence in the winding. References 8 and 22 contain tables of coil group sequences for a wide range of values of  $b/c$ .

- (6) Within the  $c$  pole pitches of the repeatable unit all the conductors of a phase have different positions relative to the poles. Thus their e.m.f.s are out of phase, and all the  $cq$  coils must be connected in series. But the e.m.f.s of the  $F$  units of a phase are in phase, and can be put in parallel if necessary (see Section 28.3.4).
- (7)  $2q$  slot pitches span  $120^\circ$ , but the smallest integral number of pitches covering  $120^\circ$  is  $2cq$ . Slots spaced at multiples of  $2cq$  pitches are the obvious starting slots for phases A, B and C. In the example, slot 31 is  $120^\circ$ , and slot 16 is  $240^\circ$  from slot 1. But as with  $q$  an integer, the starts can be at other phase groups that are 2 or  $(2+6n)$  phase groups apart; e.g. phase B could start at slot 9, although that is  $128^\circ$  away from slot 1. The sum of the coil e.m.f.s is independent of the order in which they are connected (so long as the polarities are kept correct). Starts and finishes can therefore be arranged in the most convenient positions. This can be used to advantage to ensure that the leads from each phase group are distributed around the machine, thus avoiding two adjacent leads having full line-to-line potential between them.
- (8) The bottom coil sides have the same pattern as the tops but their groups are displaced to the left or right by the amount of the coil pitch.
- (9) Sometimes multipolar windings are used that do not obey all these rules; for example, an existing core design may be usable with a few empty slots or unconnected coils.<sup>8,11,22</sup>

## 28.3.4 Parallel circuits

### 28.3.4.1 Integral slot windings

Each phase has two groups of coils per pole pair, i.e. there are  $2p$  groups in the machine. Whether the coils are lap or wave connected, the groups can all be put in series, all in parallel, or in series-parallel connection. For the latter, the number of parallel circuits in each phase must be a factor of  $2p$ , say  $t$ , so that there can be  $2p/t$  groups in series in each parallel path. For example, for  $2p = 40$ , only two or five parallel circuits are possible.

### 28.3.4.2 Fractional slot windings

In each repeatable section, occupying  $c$  pole pitches, the  $ac+b$  coils of each phase must be put in series. Hence the maximum number of parallels per phase is the number of sections  $F = (2p)/c$ . If less are needed, their number must be a factor of  $(2p)/c$ , so that there will be  $2p/ct$  repeatable sections in series in each parallel path. For example, for  $2p = 40$  and  $q = \frac{2}{5}$ , there are  $40/5 = 8$  repeatable sections and 2, 4 or 8 parallels are possible. With  $2p = 40$ , but  $q = \frac{1}{4}$ ,  $(2p)/c = 40$ , only two or five parallels are possible.

### 28.3.4.3 Concentrated or distributed parallel circuits

Whether  $q$  is integral or fractional, in each parallel circuit the coils that are in series may be arranged under adjacent poles, or may be distributed around the machine under alternate poles. Figure 28.3 shows two possible arrangements for two parallel circuits in one phase of an eight-pole winding. The concentrated arrangement shown in Figure 28.3(a) has the advantage that it reduces the unbalanced magnetic pull caused if the rotor is offset radially from the true centre of the stator bore. If, for example, in this 8 pole machine, the airgap becomes narrower opposite pole 2, the gap flux density tends to increase there, and to decrease opposite pole 6. The change in induced e.m.f.s circulates current round the parallel circuits, which tends to reduce the difference in flux densities and so reduce the unbalanced magnetic pull (u.m.p.).

## 28.4 Coils and insulation

### 28.4.1 Service conditions

The effects that may eventually cause a breakdown of the insulation of a winding are described below.

**Table 28.3** Slot, or coil, grouping for a fractional slot winding\*

Pole No.	1			2			3			4			5, etc.
Slot group No., $n$	1	2	3	4	5	6	7	8	9	10	11	12	13
$nq$	$3\frac{3}{4}$	$7\frac{1}{2}$	$11\frac{1}{4}$	15	$18\frac{3}{4}$	$22\frac{1}{2}$	$26\frac{1}{4}$	30	$33\frac{3}{4}$	$37\frac{1}{2}$	$41\frac{1}{4}$	45	$48\frac{1}{4}$
Slot Nos	1-4	5-8	9-12	13-15	16-19	20-23	24-27	28-30	31-34	35-38	39-42	43-45	46-49

No. of slots	4	4	4	3	4	4	4	3	4	4	4	3	4

\*12 poles. 135 slots,  $q = \frac{3}{4}$  slots/phase/pole,  $c = 4$  poles per section,  $F = 3$  sections.

Top coilsides 1-4, 13-15, 24-27, 35-38, with their associated bottoms, form one parallel circuit of phase A.

**Figure 28.3** Parallel connection of coils: (a) concentrated; (b) distributed

**Thermal ageing** This affects all windings, and is the main reason for setting limits for winding temperature (see Section 28.5). In smaller machines running at full class H temperatures it is the most usual cause of deterioration.

**Electrical stress** The trend in stress levels is continually upwards as manufacturers seek to minimise costs and reduce the effect of the thermal barrier of the insulation which is a factor in determining a machine's output. This requires considerable care in the design of the insulation system, in the manufacture of the coils and their insertion in the stator slots. Values of 3 kV/mm are now common with even higher figures being achieved by some manufacturers. The voltages encountered in field windings increase with machine size up to ceiling voltages (see Section 28.14) of around 1500 V on the largest generators. Thyristor excitation systems also superimpose spike voltages sometimes requiring extra insulation.

**Electromagnetic forces** Stator and field coils are both subjected to forces due to the magnetic fields operating in the machine. Any looseness of an a.c. winding in its slot will quickly lead to mechanical abrasion of the insulation on the coils. On higher voltage machines, equipped with a corona shield, this will lead to slot discharge with eventual failure of the main wall of the insulation causing an earth fault in the slot portion. Field coils able to move on their poles or in their slots will also lead to failure through abrasion.

**Mechanical forces** Rotor windings carry centrifugal forces that become very onerous in high speed and large machines. Interturn insulation and coil-to-earth insulation placed under the pole shoe and adjacent to supporting 'V' blocks used between poles must withstand the stress caused by centrifugal force and temperature. Non-supported parts of the winding, between 'V' blocks and in the endwinding overhangs are particularly vulnerable especially in the event of an overspeed. In long rotors, especially two-pole turbine-type rotors, expansion of the winding relative to the rotor body may damage the insulation. Stator windings of long machines may also suffer from differential expansion between the copper and the core. In large generators double

frequency vibration caused by electromagnetic forces may abrade insulation or even cause conductor strands to break due to fatigue.

**Vibration** External vibration, imparted by the prime mover can lead to premature failure of the stator or rotor. In the case of the stator this results from lateral vibrations setting up resonance or fatigue in mechanical components or in the endwinding bracing system. Rotor failures are associated with the effect of running at or near the critical speed of the shaft system leading to high levels of vibration or high torsional perturbations leading to fatigue failures of components.

**External electrical fault conditions** Mal-synchronising, line-to-line faults or short duration interruptions of the supply can all impart high mechanical and electrical forces on both the stator and rotor windings. Under these conditions, mechanical failure of the stator endwinding bracing, looseness of the winding in the slot or separation of the phase groups can all occur. Rotor field coils suffer from mechanical forces under these faults which can lead to coil connection failures, failure of the insulation or damage to components in the rectifier assembly if a brushless machine. Lightning strikes and switching transients arising from the operation of circuit breakers can also lead to failure of the inter-turn insulation in the end groups of the stator windings if the machine is not suitably protected by lightning arresters and/or surge diverters. Similarly, opening a field circuit breaker without suitable discharge resistors fitted can give rise to very high voltages of sufficient magnitude to break down the field coil insulation.

**Environmental** Contamination of the stator coil insulation by dirt, moisture or oil encourages surface tracking which may eventually become severe enough to penetrate the insulation.

#### 28.4.2 Stator coils<sup>5,11,22,53</sup>

The various types of stator coils most used for generators are described below. The type used depends primarily on the size, output and voltage of the generator, but the choice

is, of course, influenced by the maker's facilities and practice.

#### 28.4.2.1 Mush coils

These are used for smaller machines, up to 2500 kVA, at voltages up to 4160 V, in single layer or two-layer windings. Coils are wound with round wire insulated with enamel or enamel and glass tape. The number of turns per coil depends on the size, voltage and frequency of the machine, and the chosen number of slots. The turns are laid at random in slots that may be open, but are often semi-closed, especially if the airgap is short. The main insulation between the coil and the core is a slot liner of a tough but sufficiently flexible sheet, such as polyamide or aramid paper (Nomex). Two-layer windings may have a separate liner for the top and/or bottom coil side (a top or bottom 'box') or a separator between the coils.

#### 28.4.2.2 Diamond coils

These are arranged in two layers in open slots and used for a wide range of outputs and voltages. Coils are wound with rectangular copper strip that is small enough to have acceptably low eddy current losses in service. Sizes are usually within the range 5 mm × 2 mm to 10 mm × 4 mm. The strip is insulated with enamel or enamel plus a thin covering (say 0.2 mm) of lapped or braided glass or polyester-glass plus resin. The number of turns needed are wound into a flat loop on a looping machine and the straight sides are then pulled sideways to form a coil with the required axial length and transverse span. Depending on the equipment used, strip up to about 10 mm wide by 4 mm deep can be pulled. The width-to-thickness ratio should not much exceed 3, to avoid buckling at the bends. If necessary, several strips are wound in parallel to provide the conductor area needed to carry the current, or to make the coil flexible enough to be pulled without damaging the insulation.

Normally a coil has either one or two strips across the width of the slot. Additional inter-turn insulation, enclosing the number of strips that form a complete conductor may be applied after the coil is pulled. However, it is often practicable to apply this insulation as the copper strips are wound on the looping machine, provided that the insulation contains enough resin (see later).

Coils too large to be pulled are shaped on formers. Those for turbogenerators and large hydrogenerators are made as half coils (also known as 'bars') because full coils would be too difficult to handle. In addition, coils made for large 2-pole machines are exceedingly stiff and are difficult to insert through the bore of the machine. *Figure 28.4* shows typical coil cross-sections, all to the same scale. *Figure 28.4(a)* shows a typical pulled diamond coil for a diesel-engine-driven 14-pole generator of 9.5 MVA where the conductor strands are not transposed. The coils in (b) and (c) are formed as bars and incorporate a Roebel transposition which is used to reduce the eddy currents circulating within the full coil (see para 28.4.2.3. below). Coil (b) is for a hydrogenerator of 110 MVA at 600 rev/min and (c) is for a 590 MVA two-pole turbogenerator. In (c) all the strands are squarish tubes to allow for direct water cooling of the conductors: a mixture of tubes and solid strips is often used, especially for the bottom coil side, where eddy current losses are lower than in the top coil side. An appropriate choice of the number and dimensions of tubes and strips can lead to a reduction in the sum of d.c. and a.c. copper losses.

**Figure 28.4** Stator coil sections: (a) three turns of six strips; (b) single-bar, two-stack Roebel; (c) single-bar four-stack Roebel

#### 28.4.2.3 Transposition<sup>51,52</sup>

If each turn consists of more than six or eight strips it is desirable, and in larger conductors necessary, to reduce the eddy current losses set up by the leakage flux set up across the slots by the load current. In principle this requires the e.m.f.s induced by the leakage flux to be equal in all strips in the length between points where they are all joined together. In a multistrip coil side for a turbogenerator or hydrogenerator this is achieved within each slot length by using a 360° Roebel transposition. In this construction, each strip is given two edgewise bends separated by half the slot length and differently positioned in the various strips so that when assembled the strips mesh together. When the strips are assembled to form the coil side, each strip occupies each position in the height in turn and they all do so for equal distances. Hence the voltages induced by the cross-slot flux is equal in each and only a small current circulates between strips due to endwinding leakage fields.

In large generators (say 500 MVA or more) the endwinding leakage fields can cause significant circulating currents. The effect can be reduced by using a 540° Roebel transposition. This reverses the positions of the strips in one endwinding relative to the other and approximately cancels the e.m.f.s arising from the endwinding leakage fields.

In all Roebel coils, the radius of the edgewise bends must be sufficiently generous to avoid damage to the strip insulation. Usually a slip of, for example, Nomex is placed between strips at the cross-overs. The undulating top and bottom surfaces are made level by applying a suitable filler, such as a filled resin dough, which is cured when the conductor stacks are consolidated, before the main insulation wall is applied.

Large turbogenerator slots are often wide enough to require four, not two, stacks of tubes, or strips and tubes. The eddy current losses are rather less if stack 2 is transposed with stack 3, and stack 1 with stack 4, rather than 1 with 2 and 3 with 4. For smaller bars with relatively few strips, and for full coils, the Roebel transposition in the slot is not justified: simpler schemes are possible which are sufficiently effective in reducing circulating losses. For example, in a bar winding individual strips can be joined at the coil-to-coil connections in insulated, segregated groups,

not all together as is done with a Roebel bar winding. The strips are joined so that within a phase group of coils the groups of strips occupy a succession of positions in the slots that gives a sufficiently good balance of leakage flux e.m.f.s.

With full coils the natural roll-over of the conductors at the noses inverts the strips, i.e. a strip nearest the wedge in the top coil side is nearest the slot bottom in the bottom coil side. Summers<sup>52</sup> gives formulae for calculating the reduced circulating current loss that can be obtained by additionally inverting one or more turns in the overhang portion. He concludes that the most generally useful arrangement is to invert the strips of one turn only at the connection end before forming the last turn; or to invert them at the back end after making only the first half-turn. These sorts of transposition are only effective on 2 or 3 turn coils—above this number it is not necessary to incorporate a transposition in the coil overhangs to reduce the circulating losses to an acceptable value.

### 28.4.3 High voltage insulation systems<sup>53,58–61</sup>

Two systems<sup>60</sup> are in general use: resin rich (r.r.) and vacuum pressure impregnation (v.p.i.). Both use mica paper (mica flake, which was universally used until the early 1960s, is very rarely used today). The mica paper is bonded with a thermosetting resin to a thin backing material,<sup>54</sup> frequently woven glass or polyester fabric or polyester film. Polyester, epoxy and epoxy-novolac resins, or mixtures of them, are most widely used for r.r. and v.p.i. systems, with appropriate hardeners and catalysts to control the curing process. Resin rich tapes contain about 30% resin, dried to the B stage, at which it can be stored in cold conditions (5–10°C) long enough to be convenient in manufacture. It can be applied at room temperature by hand or by a taping machine; the machine gives better control of lapping and tension. Resin rich tape can be applied as additional turn insulation<sup>56</sup> to a group of strips that is then wound and pulled to form a coil of several turns. Tape for the v.p.i. process contains 4–10% of a different resin system to make it handable and is more fragile than the resin rich tape.

Normally, the strips in the straight sides of the coil, or in the bar, are consolidated in a heated press before any turn insulation or main wall insulation is applied. If the turn insulation (r.r.) has been applied as the pulled-coil loop was wound, this and the strips are cured and bonded at the same time. If turn taping is to be applied after this consolidation stage, a release film is put between turns to allow the additional taping to be applied. After any turn taping and the main wall insulation has been applied, the slot portion of the coil is again consolidated under heat and pressure to cure the resin contained in the mica tapes. For turbogenerators and large-hydrogenerators the endwinding portions are consolidated too, both before and after the insulation is applied to improve their thermal conductivity.

In the v.p.i.<sup>59</sup> process, the low-resin content mica paper is applied after the conductor strips have been consolidated. If individual coils or bars are being manufactured, these are placed in an autoclave. Air is drawn out of the tape under vacuum in the autoclave, which is then flooded with low-viscosity resin under pressure. After impregnation, excess resin is drained off, and the coil is pressed to size in a hot press.

Alternatively, for machines up to 5.3 m in diameter and 5 m in length (dependent on the manufacturer's facilities) the global v.p.i. impregnation process can be used.<sup>57</sup> Here, the coils are wound at the so-called 'white stage' into the stator core and the whole wound stator is then placed in a suitable pressure vessel. Absorbent packings and lashings

are used in the endwinding bracing structure (e.g. glass or polyester tapes and polyester fleece). Again, a vacuum is drawn to remove any air trapped in the insulation materials followed by a pressure cycle where resin is introduced. Following impregnation, the wound stator is immediately transferred to an oven where it is baked to cure the resin. If treated with an epoxy resin, the stator would be rotated during the baking cycle to ensure both an even distribution and retention of the resin. Stators impregnated with a polyester resin do not require rotation during the curing cycle as the resin gels before becoming sufficiently fluid to flow out of the stator. The resin fills the gap between the coils and the core, improving thermal conductivity and permitting some increase in current for a given temperature rise in service. Complete impregnation of the endwinding structure increases its strength and its resistance to moisture, dirt and contaminants.

The r.r. and v.p.i. processes can both produce good quality stator insulation systems. Essentials to achieve a high level of quality are:

- (1) uniform lapping and tension of all tapes;
- (2) correct choice of resin, tapes etc., to suit the process;
- (3) r.r. tapes must be allowed to warm up to room temperature before being applied;
- (4) v.p.i. resin must have a low enough viscosity at the impregnating temperature, and an economic life over many cycles of storage and impregnation;
- (5) careful control of each cycle of the processes to ensure sound consistent results. In the consolidation stages, the soaking temperature (about 150°C), the heating and cooling rates, and the application of pressure all need careful control. During the v.p.i. process, times, temperatures, the degree of vacuum and the amount of pressure are all critical to achieving a satisfactory result.

#### 28.4.3.1 Electric stress control

At line voltages up to about 5 kV the insulation material and thickness depend very much on mechanical and manufacturing factors. The nominal stress (phase voltage divided by insulation thickness) may be up to about 1.5 kV/mm. At higher voltages electrical stress determines the design, and nominal stress on resin-mica systems is usually 2.5 to 3.0 kV/mm.

At or above 6 kV, the outer surface of the slot part of the coil (whether r.r. or v.p.i.) must be adequately earthed to the stator core to avoid corona discharge in the gap between coil and core. This gap occurs because of the need to have a clearance to allow the coils (or bars) to be wound. The surface may be painted with a conducting paint, but preferably should be taped with a low resistance tape, e.g. a graphite loaded glass or polyester, before the final consolidating press. At the ends of the core the longitudinal stress gradient along the coil surface must be kept low enough to avoid breakdown of the air or surface tracking and eventual failure of the insulation. The surface may be painted with a higher resistance paint than is used on the slot part, but preferably is taped with, for example, a tape loaded with silicon carbide. The length of this stress grading treatment depends on the machine voltage, the insulation thickness and the voltage-current characteristic of the material used. (The resistance decreases with increasing stress.) The treatment must be effective for the short-time high-voltage tests on the coils (greater than twice line voltage to earth) as well as for the long-term operating voltage.

## 28.4.4 Insulation testing

### 28.4.4.1 Acceptance tests

Acceptance tests<sup>66</sup> are made on the finished generator to prove that it meets contractual requirements. Tests include:

- (1) d.c. insulation resistance (IR), recorded after applying the test voltage continuously for 1 and 10 min;
- (2) polarisation index (PI)

$$PI = \frac{\text{IR after 10 min}}{\text{IR after 1 min}}; \text{ and}$$

- (3) high-voltage test with, usually, power frequency voltage, applied after satisfactory IR and PI results have been obtained. The test voltage is maintained for 1 min between each phase and earth in turn, the other phases being earthed.

Procedures and test voltages are specified in BS EN 60034-1:1998 which is equivalent to IEC 60034-1:1994 and replaces BS 4999: Part 101:1987, in ANSI C50.10 1990, NEMA MG1: Part 32-1998, and other national specifications. (see Section 28.21.) The latest issue of the appropriate specification should be consulted for complete information; broadly, the test voltages are, except for low-voltage machines rated less than about 1 kW:

A.c. windings:  $2 \times \text{rated line voltage} + 1000 \text{ V}$ .

Field windings:

Rated voltage  $V_f \leq 500$ ;  $10 V_f$ , minimum 1500 V.

Rated voltage  $V_f > 500$ ;  $2 V_f + 4000 \text{ V}$ .

Document BS EN 50209:1999 specifies tests on conductor bars and coils for machines with rated voltage  $U_N$  from 5 to 24 kV. Tests include: (1) measurement of loss tangent ( $\tan \delta$ ) and loss tangent tip-up ( $\Delta \tan \delta$ ) on all or some coils of a machine set; and (2) voltage tests on the strand insulation, turn insulation and main insulation. The specification applies to generators of 5 MVA and above, and to 1–5 MVA ratings by agreement. It may or may not be specified as a contractual requirement. The  $\tan \delta$  limits are, for rated voltages  $U_N$  of 5–11 kV inclusive:

- (1) at  $0.2 U_N$ ,  $\tan \delta$  not greater than  $30 \times 40^{-3}$  for any sample coil or bar;
- (2)  $\tan \delta$  at  $0.6 U_N - \tan \delta$  at  $0.2 U_N$ ,  $\frac{1}{2} \nless 2.5 \times 40^{-3}$ ; and
- (3)  $\Delta \tan \delta$  over any step of  $0.2 U_N$ ,  $\nless 5 \times 40^{-3}$ .

Limits (2) and (3) apply to 95% of the test samples; 5% are acceptable at  $3 \times 40^{-3}$  for item (2) and  $6 \times 40^{-3}$  for item (3).

The measurements must be made at room temperature before the samples are heated to at least 90°C, and again after they have cooled to room temperature. Guard electrodes at the ends of the slot length of the bar exclude the loss in the stress grading from the measurement. R.r. and v.p.i. systems can comfortably meet these limits. Typical values are:

Voltage	$0.2 U_N$	$U_N$
$\tan \delta$	10–15	15–20 $\times 40^{-3}$

Most of the increase occurs between  $0.8 U_N$  and  $U_N$ . Of course  $\tan \delta$  of a globally impregnated winding can only be measured on complete phases, and the limits stated above cannot apply; comparison with individual coils is necessary.

### 28.4.4.2 Quality assurance tests

Quality assurance tests are made at the manufacturer's discretion at suitable stages of manufacture. They include:

- (1) Dimensional, mechanical and dielectric tests on incoming materials.
- (2) Voltage tests such as:
  - (a) between insulated strands in a conductor, at 110–250 V r.m.s.;
  - (b) between turns of multi-turn coils;
  - (c) on individual coils or bars;
  - (d) on groups of coils after they have been wedged in the slots, but not connected; and
  - (e) on each phase of the completed winding before the acceptance tests.

Supply frequency voltages in (c) and (d) and (e) must be rather higher than the final test voltage; (b) must be an impulse test unless the turns are cut through at the coil nose: it is obviously undesirable to cut a full-wound coil, so a Biddle or other surge tester is used.

BS EN 60034-15:1996 specifies rated phase-to-earth impulse withstand voltages for machines rated 3–15 kV inclusive, with form-wound coils. For the standard lightning impulse, a  $1.2/50 \mu\text{s}$  wave, the rated impulse voltage has a peak value  $U_p = 4U_N + 5 \text{ kV}$ , where  $U_N$  is the rated voltage. The standard recommends that impulse test voltages should not be applied to a complete machine. It describes test procedures on sample coils, and specifies test levels of  $(4U_N + 5)$  kilovolts between the conductor and a dummy slot, and half that value between turns, i.e. applied across the ends of the coil.

International discussions are being held to agree upon a withstand level for impulse voltages with steeper wavefronts probably down to rise time of  $0.2 \mu\text{s}$ . In service many generators are protected to some extent from impulse voltages by the impedances of transformers or cables. These reduce the peak voltage and steepness of the wavefront, so the generator does not suffer the full impulse generated by some forms of switchgear. Alternatively, lightning arresters and/or surge diverters may be fitted at the machine terminals to protect the stator windings from fast fronted surges.

- (3) IR and PI measurements before (2)(d) and (2)(e).
- (4) (a)  $\tan \delta$  test on all or some coils or bars.  
(b)  $\tan \delta$  test on each phase of the complete winding and between phases before impregnation.
- (5) Measurement of integrated discharge magnitude using a dielectric loss analyser,<sup>69</sup> on individual coils, phases and the complete winding.
- (6) Measurement of the partial discharge value on individual phases or the complete winding.
- (7) Measurement of the resistance per square of the corona shield on the slot part of the coil:  $2\text{--}30 \text{ k}\Omega/\text{square}$  is acceptable.

### 28.4.4.3 Diagnostic tests in service<sup>67–70,79–82</sup>

The electrical, mechanical and thermal stresses of normal service cause gradual degradation of the insulation. If this general deterioration can be adequately monitored, preventive maintenance of the winding can be co-ordinated with other planned maintenance in an attempt to avoid the cost of failures and unplanned outages. It is true that some generators work in less harsh environments than some motors do, or have closed air circuit cooling arrangements so suffer less contamination, but the cost of an unplanned outage or the damage caused through inadequate maintenance can be appreciably higher. Consequently, more and more attention is now being placed on the need for continuous on-line

monitoring and preventative maintenance based on regular inspections for generating plant.

No single test can indicate the extent of deterioration at a particular time. It is necessary to review the results of several non-destructive tests made at reasonably regular intervals, preferably starting with a 'foot-print' from when the machine was first manufactured.

Simons<sup>69</sup> recommends measurements of:

- (1) IR and PI with direct voltage at say 1, 2.5, 5.0 kV, appropriate to the machine's rated voltage  $U_N$  (r.m.s.);
- (2) IR, capacitance  $C$  to earth, and integrated discharge energy at rated frequency (50 or 60 Hz) with voltages up to  $U_N$  to earth; and
- (3)  $C$  and  $\tan \delta$  at steps of 0.2  $U_N$  up to about  $U_N$  to earth. Tests are made, as usual, on each phase to earth with the other phases earthed, and on the whole winding to earth.

A local defect, unless it is a severe one, will not greatly affect the results. It may, therefore, be desirable to apply a proof h.v. test at say 1.2–1.5  $U_N$  (r.m.s.) to earth at supply frequency, or a 0.1 Hz voltage with a peak of 1.7  $U_N$  (r.m.s.).

#### 28.4.5 Rotor coils

See Sections 28.15.3 and 28.17.2.3.

### 28.5 Temperature rise

Limits of temperature or of temperature rise are specified in national and international standards (see Section 28.21: BS EN 60034-1:1998, BS EN 60034-3:1996, ANSI C50: Parts 10–15 and NEMA MG1: Part 32).

The limiting values apply at rated load under specified ambient conditions, of which the most important figure is the temperature of the primary coolant (air, hydrogen or water) entering the machine or the winding. Temperatures of stator windings are measured either by resistance for machines rated below 5 MVA, or by embedded temperature detectors (e.t.d.), either of the thermocouple or resistance element type, above this rating or when supplied to NEMA MG1. Temperatures of rotating windings, usually field windings, are measured by resistance. In small machines without e.t.d.s fitted, winding resistance or surface temperatures would be measured on test, and monitoring in service may be of air temperature only. Temperature rises are calculated above the temperature of the primary coolant. Alternatively, but less often, it may be calculated above the temperature of the cooling water entering a heat exchanger.

Machines are designed to comply with the temperature rise limits specified as long as the primary coolant temperature does not exceed 40°C. If the ambient air temperature is high, or there is a water-cooled heat exchanger, the primary coolant temperature may exceed 40°C. Then the design rises are correspondingly reduced, so that the limiting total temperatures are not exceeded. This is especially likely to occur with turbogenerators using turbine condensate, which may enter the heat exchanger at a temperature of up to about 35°C. Conversely, if the temperature of the primary coolant entering the machine is less than 40°C, then the standards allow the temperature rises to be adjusted upwards to maintain the same total temperature. Below a primary coolant temperature of 30°C, any further adjustment is by agreement between the customer and the supplier.

The aim of all standards is to keep the temperature of the winding insulation down to a value at which the insulation, and therefore the generator, will have an acceptably long life. Standards do not specify or imply a lifetime. Accepted norms for life are 20 years for large capital equipment installed in prime power applications. A life expectancy of 10 years is more appropriate for industrial and smaller units. Some machines last much longer than these figures partly because they do not operate for long times near their temperature limits. Large machines or those subject to frequent load changes, or whose reliability is especially important, are commonly specified to meet class B temperature limits, although they have class F insulation in order to achieve a protracted life.

In all windings, the design must allow for the difference between the observable temperature and the hotspot temperature that ages the insulation most rapidly. In an indirectly cooled high voltage stator coil this difference may be 10–20 K, and the innermost insulation may run close to the classification temperature for the insulation system (130°C for class B and 155°C for class F). In an indirectly cooled turbogenerator rotor too, the temperature difference across the main slot insulation is a major component, but the temperature rise of the gas in the 'air' gap, and the surface-to-gas temperature difference, are important. In a salient-pole rotor, the end parts of bare strip-on-edge field coils are well cooled, but down the length of the coils turns can overheat, especially on four- to eight-pole rotors that have 'V' block coil supports between the poles.

Direct cooling avoids the temperature drops through the insulation, and permits higher current densities with acceptable temperature rises, e.g. up to about 10 A/mm<sup>2</sup> in a turbogenerator rotor hydrogen cooled at 5 bar absolute pressure, compared with about 3 A/mm<sup>2</sup> with indirect air cooling. Axially cooled rotors, with ends-to-middle gas flow, must have a modest temperature rise by resistance to avoid excessive temperatures at the midlength. Radial flow, or a combination of radial and axial, gives a mean temperature closer to the permissible hotspot temperature.

In a directly cooled stator coil the best indication of copper temperature is given by the temperature of the coolant, hydrogen or water, where it leaves the coil. The copper temperature is up to about 10 K higher than the hydrogen temperature, and only approximately 1 K above the water. The traditional e.t.d. between coil sides is still used as the routine temperature indicator in service, though some turbo generators are instrumented to measure the outlet temperature of the water from every coil. (For stator windings in new turbogenerators, water has superseded hydrogen, and it is the only choice for hydroelectric generators.) If the water flow fails the copper temperature rises very quickly, say 20 K/min, so the turbine output should be automatically reduced to avoid gross overheating and failure of insulation.

Gas turbine driven generators (see Section 28.21: BS 5000: Part 2 and ANSI C50: Part 14) are specified differently from others because the maximum output available from the turbine changes quite widely as the inlet air temperature changes. The generator must deliver the range of outputs that is the base capability of the turbine over the whole range of air temperature. If the generator is cooled by ambient air, and is allowed to operate up to limits of total temperature, the changing temperature rise allowed as the air temperature changes gives the generator a capability that matches that of the turbine more closely than if the rise were fixed at the rated-load value at all loads and ambient temperatures. Hence a smaller and cheaper generator can be used to cover the turbine rating across the operating temperature range.

The range of still higher outputs that is the peak capability of a gas turbine or internal combustion engine is handled by allowing higher total temperatures in the generator. At these, the insulation ages much more quickly than at standard temperatures. This is accepted because: (1) peak operation demands more frequent engine or turbine maintenance, so will not be used frequently or for long periods, and (2) many internal combustion engine or gas-turbine-driven sets are not expected to have a life of 10 years or more.

If a gas turbine driven generator has water-cooled heat exchangers, its range of permissible temperature rise will probably be less than the ambient air range due to the long thermal time constant of the source of the cooling water. The capability of the generator no longer matches the turbine output so closely and its frame size and design details are determined by the maximum turbine output but using the primary coolant temperature corresponding to the minimum cooling water temperature.

## 28.6 Output equation

The generator output in apparent power ( $S$  volt-amperes) is a function of the stator bore diameter  $D$ , the active axial length  $L$ , the speed  $n$ , the specific magnetic loading  $B$ , the specific electric loading  $A$ , and the stator winding factor  $K_w$ . The output is given by

$$S = \frac{1}{2} K_w B A D^2 L n \quad (\text{volt-amperes}) \quad (28.12) \Leftarrow$$

$$= G D^2 L n$$

where  $G$  is the output coefficient  $((V-A \text{ s})/m^3)$ ,  $B$  is the average fundamental frequency airgap flux density  $((2p\Phi)/(\pi DL)$  tesla),  $2p$  is the number of poles,  $A$  is the ampere-conductor density  $((I_c N)/(\pi D)$  ampere/metre), where  $N$  is the total number of stator conductors  $= 2T_{ph} \times \text{number of phases}$ , or number of slots  $\times$  conductors per slot,  $I_c$  is the

current in each conductor  $(= \text{phase current}/g \text{ amps})$ ,  $n$  is the speed in (rev/s),  $g$  is the number of parallel circuits per phase and 11 is a numerical multiplier when all dimensions are in metres.  $K_w$  is the product of the individual winding factors.  $(K_d K_p K_s)$  and  $\Phi$ , is the fundamental component of the flux per pole (in webers).

The stator winding is designed to develop the specified voltage with  $B$  and  $A$  close to chosen values. For different types and sizes of generator,  $B$  does not vary widely: it is limited primarily by the degree of saturation that is acceptable in the various parts of the magnetic circuit. Typical values of  $B$  are in the range 0.5–0.65 T on no load, corresponding to peak densities in the airgap of say 0.7 to 0.95 T. On load the increase of total flux and the distortion caused by armature reaction will cause the peak density to rise by about 15–20%.

The electrical loading  $A$  varies very widely with size and with the intensity of cooling, short-circuit ratio, reactances, etc.

$G$  is numerically more convenient if expressed as

$$\frac{\text{kV-A}}{D^2 L \text{ rev/min}}$$

i.e. in  $(\text{kV-A min})/m^3$ . Figure 28.5 gives typical mean values of  $G$  against rated MVA; the values range from 5 to 35, but variations can easily be  $\pm 15\%$  for a given output. With  $G$  in  $(\text{kV-A min})/m^3$ ,  $A$  is approximately  $(6G)/B$  kA/m. Assuming  $B = 0.6$  T,  $A$  ranges from 50 to 350 kA/m.<sup>27</sup>

The steady increase in  $G$  for salient pole generators is a result of the scale effect and progressive improvements in design, mainly in more effective cooling of the stator and field windings. For turbogenerators, a sharp increase in  $G$  occurred in the 1950s with the introduction of direct cooled rotor windings using hydrogen at 3 bar absolute pressure. Rapid increase in unit ratings and in  $G$  soon occurred, using hydrogen at pressures up to 5 bar absolute and improved methods of circulating it through the windings. It was necessary also to improve stator cooling in order to handle

**Figure 28.5** Output coefficients,  $G$ . Turbine generators: (a) directly hydrogen cooled + stator winding water; (b) directly air cooled; (c) indirectly hydrogen cooled; (d) salient-pole generator

the higher capability of the rotor. Water cooled stator windings have been universally adopted for machines of say 200 MW or more, although direct hydrogen cooling had been used for many stator windings up to 800 MVA output.

In recent years the demand for electric power has grown steadily at the rate of 5% per annum though there has been much public outcry against nuclear power and against acid rain from large fossil-fired stations. Hence there has been almost no call for turbogenerators larger than 500 MW recently, though the recent power shortages on the west coast of America and the insatiable demand for power both in the developing and the developed nations means that there is now renewed interest in nuclear power to meet those needs. In order to maximise efficiency and to satisfy the economics of building nuclear power stations, large generator units possibly up to 1500 MW may well be required in the near future. In recent years, there has been a large number of combined heat and power (CHP) systems have been installed. Here the waste heat from the prime mover, which may be a gas or diesel internal combustion engine or a gas turbine is used for a supplementary purpose such as district heating. This has the effect of increasing the efficiency of the power station. Another possibility to achieve enhanced efficiency has been the use of combined cycle systems where the exhaust gases from a gas turbine are used to raise the steam to be used in a steam turbine located alongside or on the same shaft as the gas turbine. These schemes require generators with ratings up to 150–200 MW at 3000 or 3600 rev/min. For low first cost, and for cheap installation and operation, air-cooled machines have been developed using directly cooled rotors, reaching output coefficients exceeding those of the early low hydrogen pressure machines.

## 28.6.1 Some design parameters

### 28.6.1.1 Specified requirements

Appendix B of BS EN 60034-1:1998 lists information that should be supplied to the manufacturer.

A generator is required to meet specified values of output (kilovolt-amperes, voltage, and power factor) at a specified speed under stated operating conditions, of which the cooling conditions are most important. Specified limits of temperature rise or of total temperature must not be exceeded. The machine must maintain the performance during a life that is specified (or understood by custom and practice), and should do so with reasonable maintenance but without needing major repair. Normally a maximum value of  $X_d$  (or a minimum short-circuit ratio) is specified. A minimum  $X_d^{\prime\prime}$  and or a maximum  $X_d^{\prime}$  may also be specified if currents under fault conditions are to be limited to a certain value or if voltage dips when starting specified loads are to be limited. National specifications recommend preferred voltages (e.g. ANSI C50: Parts 12, 13 and 14), but for large units connected by transformers to the system the generator voltage can be chosen to give the most suitable design.

### 28.6.1.2 Length to diameter ( $L/D$ ) ratio

For two- and four-pole cylindrical rotor machines the cheapest design is usually one using the smallest diameter that does not lead to excessive length. The ratio usually lies in the range 3.5–6, perhaps up to 7 for the largest outputs (over 1000 MW) where the strength of retaining ring material limits the diameter to a surface speed of about 220 m/s (1.35 m diameter at 3000 rev/min). With such ratios,

two-pole rotors for more than about 10 MW will have first and second critical speeds below the running speed. Higher ratios are avoided because they would lower the critical speed still more and make the rotor very sensitive to small (e.g. thermal) changes in balance.<sup>93</sup>

Cooling also becomes more difficult in very long machines. Salient pole machines with four poles and outputs of, say, 3–30 MVA may have a  $L/D$  close to unity but, because there are so many combinations of output, speed, overspeed, reactance, inertia, etc., no simple rule can cover the whole range of outputs. The ratio of  $L$  to pole pitch varies rather less than  $L/D$ , but still runs from 2.5 to 6 for outputs in the range 150–800 MVA, associated with speeds in the range 500 to 83 rev/min.

### 28.6.1.3 Stator winding

The most suitable type of winding is usually obvious from the specified current and voltage and the manufacturer's established practice (see Sections 28.3 and 28.4). The cost of making and installing the winding will be smaller the fewer the coils, but too few will cause difficulties. The current per slot, and the copper cross-sectional area, must be such that specified temperature rises are not exceeded. With too few slots, they are necessarily wide, and the total loss per slot may cause excessive temperature rise. With too many slots (and coils) they become narrow and deep, and much slot space is used for insulation; the coils are awkward to form and to support effectively in the endwinding. The ratio of slot depth to width should preferably not exceed 7 (4–6 is usual).

The ratio of slot width to airgap length should be about  $1\frac{1}{2}$  to 2 with solid pole shoes; with laminated shoes or poles  $2\frac{1}{2}$  to  $3\frac{1}{2}$  is permissible. Higher ratios increase the tooth ripple e.m.f., and the eddy current losses in the pole surface.<sup>32,33</sup> This is particularly important in salient pole machines with short airgaps especially machines with solid pole shoes. In turbogenerators the airgap is so long that this effect is rarely troublesome.

The tooth width must be enough to avoid excessive magnetic saturation on load, allowing for the radial vent ducts in the core. Roughly, the width of the tooth tip is about half the slot pitch.

### 28.6.1.4 Short-circuit ratio, synchronous reactance, and rotor temperature rise

The short-circuit ratio (SCR) and  $X_d$  are defined with reference to Figure 28.10.

$$\text{SCR} = \frac{0b}{0d} \quad \text{and} \quad X_d = \frac{0d}{0a} = \frac{\text{SF}}{\text{SCR}}$$

where SF is a saturation factor,  $\frac{0b}{0a}$

which usually has a value between 1.1 and 1.2.  $X_d$  is almost inversely proportional to the length of the airgap, and the SCR is approximately directly proportional to the length,  $l_g$ . Changing  $l_g$  adjusts SCR and  $X_d$ , but has only a small effect on other reactances.

For a given output and frame size, increased SCR requires increased excitation, especially if the length of the airgap is increased to raise the SCR, which may cause excessive field temperature rise. Then, unless the cooling can be improved, a lower electrical loading or a larger frame size becomes necessary.

Evidently, a lower SCR permits more output from a given frame size which will be determined by the thermal

limit set by the rotor: of course the stator must also be adequately cooled.

As turbogenerator ratings increased, lower values of SCR came to be accepted, partly as a matter of necessity to restrain the increase in physical size, but largely because faster control of excitation and of turbine valves, and shorter fault-clearing times, made it possible to operate safely closer to the stability limit. SCRs fell from the usual range of 0.8–0.6 to 0.6–0.45 for turbogenerators.

Hydrogenerators too have benefited from improved excitation control, power system stabilisers and faster clearing times, but are still required to supply a higher line-charging capability than most turbogenerators. Their SCRs are therefore usually in the range of 0.8–1.5. Other salient pole generators up to say 40 MW (see Section 28.18) have an SCR usually between 0.5 and 0.8, with some up to 1.0 for particular locations.

#### 28.6.1.5 Other reactances (see Section 28.8 for the identification of these reactances)

The stator leakage reactance is a large component of the subtransient and transient reactances. The slot leakage flux contributes most to the leakage reactance, as the endwinding leakage flux is comparatively small, especially in long machines.

Kilgore<sup>84</sup> expresses each reactance as the product of a reactance factor

$$X = \frac{AK_w}{\sqrt{2} \cdot \epsilon_1 B_g} \text{ (per unit, p.u.)}$$

and a permeance  $\lambda_c$  calculated from the geometry of the path of the flux associated with the reactance concerned. For the stator slot,  $\lambda_c$  is approximately proportional to the slot depth divided by the total width of the  $3q$  slots in each pole pitch. Hence for a given output and frame size, a winding with fewer, wider and, therefore, shallower slots has a smaller slot leakage reactance than one with more, narrower and deeper ones. It should cost less too, but the copper will be less well cooled, unless it is cooled directly.

$$X_d' = X_1 + X_F$$

and

$$X_d'' = X_1 + \left( \frac{X_F X_D}{X_F + X_D} \right)$$

where  $X_F$  and  $X_D$  depend on the dimensions of the pole and the damper cage, and these are chosen primarily to suit the electromagnetic and mechanical design requirements. For most salient-pole machines the ratio of  $X_d'/X_d''$  is 4–4 to 1.6; for most turbogenerators the ratio is 1.3–1.5.

The electrical design can be manipulated to change  $X_d''$  and  $X_d'$  by changing  $X_1$  and there is a little scope for changing  $X_D$  to alter the ratio  $X_d'/X_d''$ . Reducing the electrical loading  $A$  will reduce  $X_1'$  but will require a larger  $DL$  product to increase the main flux with unchanged  $B$ . Leaving empty slot above the stator winding increases  $X_1'$  but requires a corresponding increase in the outer diameter of the core to avoid increased back of core flux density. So specifying reactances different from those naturally occurring with the otherwise optimum design will raise the cost.

Some compromise between the values of  $X_d'$  and  $X_d''$  may have to be made. A high  $X_d'$  is desirable to limit the initial short-circuit current and hence reduce the duty of the

associated switchgear. A low  $X_d'$  may be preferred because it would reduce the voltage dip when load is suddenly applied. For example to start a large motor on a fairly small generator or generator group. Or it may help to retain stable operation after a disturbance on the power system. In a generator with laminated salient poles, the damper cage design can be adjusted to bring  $X_d'/X_d''$  down towards 1.4, but solid poles and shoes permit almost no adjustment from the usual 1.5–1.6. In turboalternators the rotor tooth tops and wedges, and any damper winding beneath them, are in parallel. Again, the dimensions and wedge materials must first satisfy mechanical and magnetic requirements, and only a very small adjustment of the  $X_d'/X_d''$  ratio is possible.

Kostenko<sup>11</sup> and Ames<sup>2</sup> use methods similar in principle to Kilgore's for calculating reactances. Kostenko gives formulae for  $\lambda_c$  for different slot shapes; Ames presents a detailed treatment of gap leakage reactance that is considered to give better results for short gap designs. Ames also has a useful section on the currents and torques resulting from three-phase and single-phase short circuits, and on voltage dip caused by a suddenly applied load.

Today, analysis using finite element techniques is used to derive reactance figures with increased accuracy.

#### 28.6.1.6 Inertia constant, $H$

A minimum inertia of the whole generator set may be needed: to help to maintain transient stability during a system fault; to limit the overspeed of a hydrogenerator set; or to limit the cyclic speed irregularity of a set driven by an internal combustion engine.

When  $H$  is defined as the stored energy at rated speed in watt-seconds, divided by the rated volt-amperes, then in SI units stored energy =  $\frac{1}{2} J \omega^2$  metre-newtons, i.e. watt-seconds, and

$$H = \frac{1}{2} \frac{J \omega^2}{VA} \text{ seconds} \quad (28.13)$$

where  $J$  is the polar moment of inertia of the rotor ( $= \frac{1}{2} m k^2$  kgm<sup>2</sup>, where  $k$  is the radius of gyration);  $\omega$  is the speed (in rad/s); and  $m$  is the mass (in kg). The term  $WR^2$  is also frequently used in this context where  $GD^2 = 4 \times WR^2$ . If this is the case, the term 1.37 in equation 28.14 is increased to 5.48 for an inertia figure quoted as the  $WR^2$ .

Alternatively, in usual engineering units,

$$H = \frac{1.37 GD^2 (\text{rev/min})^2}{\text{Rated kVA}} \text{ seconds} \quad (28.14)$$

where  $GD^2$  is the polar moment of inertia (in kg-m<sup>2</sup>)

$$GD^2 = \frac{1}{2} m (2k)^2 = 4J$$

Typical values of  $H$  for the generator alone are

<i>Salient pole</i>	
Medium speed:	1–2 s
Low speed (100–150 rev/min):	2–4 s
<i>Hydrogenerator</i>	
	Usually 3–5 s, can be up to 8 s
<i>Cylindrical rotor</i>	
2 and 4 pole	2–4 s

A directly coupled steam turbine may have 2–4 times as much inertia as its generator, but a hydraulic turbine adds

relatively little. A hydrogenerator may therefore have to be larger than the electrical performance would require, whereas the turbogenerator designer can usually accept the inertia of the design that meets the other criteria.

## 28.7 Armature reaction

Balanced three-phase sinusoidal currents in the stator winding produce an approximately sinusoidal m.m.f. wave rotating round the airgap at synchronous speed  $n_s = f/p$  rev/sec. The wave continuously changes shape between two extremes, which occur in turn every  $1/12$  of a cycle of the current. The wave can be represented as a fundamental plus harmonics thus:

$$\text{m.m.f.} = 1.35 \frac{IT_{ph}}{g} \left[ k_{w1} \sin(\omega t - \theta) + \frac{1}{5} k_{w5} \sin(\omega t + 5\theta) + \frac{1}{7} k_{w7} \sin(\omega t - 7\theta) + \dots + \frac{1}{n} k_{wn} \sin(\omega t \pm n\theta) \right] \quad (28.15)$$

where  $1.35((IT_{ph})/g)k_{w1}$  ampere-turns per pole is the amplitude of the fundamental wave and  $\theta$  is a space angle in electrical degrees (one fundamental pole pitch =  $180^\circ$ ). Harmonic orders  $n$  are  $n = 6m \pm 1$  where  $m$  is any integer. The sign of  $n$  is opposite to that of 1 in  $n = 6m \pm 1$ .

Each harmonic rotates at a speed inversely proportional to its order; the higher order of each pair, the  $(6m + 1)$ , goes forwards (i.e. the same direction as the fundamental) and the lower one  $(6m - 1)$  goes backwards.

The harmonic fluxes induce small e.m.f.s at supply frequency in the stator winding, not large enough to affect the r.m.s. value of the phase voltage. However, they induce currents at  $6m$  times supply frequency in the rotor damper winding, pole faces, etc. These can cause significant extra losses and local temperature rises.<sup>32,33</sup> The fifth and seventh harmonic m.m.f.s are the largest, but with a  $5/6$  pitch winding, for which  $K_{p5} = K_{p7} = 0.259$ , and spread factors of about 0.2, they are reduced to about 1% of the fundamental m.m.f. The m.m.f. winding factors are the same as those applied to the calculation of open-circuit e.m.f.

Figure 28.6 shows how the gap flux wave shown in Figure 28.1(c) is distorted by armature reaction, and shows a small increase in the (mainly slot) harmonics. Harmonic currents supplied by the generator are not often troublesome, unless the load has large capacitance, or resonates to give a low impedance at a particular frequency. The harmonic content in the terminal voltage will depend on the impedances of the load and the generator at the harmonic frequencies.

In fractional slot windings the currents produce also even harmonics and subharmonics: the latter have wavelengths that are multiples of the fundamental double pole pitch. In large multipolar machines such as large hydrogenerators, the subharmonic flux may cause unacceptable deflection and vibration of the stator core, especially if it is a bit shallow radially behind the slots, or has a natural frequency of vibration close to a subharmonic frequency. Some such stator frames have been damaged by this effect (see Liwischitz<sup>36,34</sup> and Walker<sup>38</sup>)

### 28.7.1 Cylindrical-rotor machine

The gap flux wave developed by the fundamental stator ('armature') m.m.f. acting alone is nearly sinusoidally

Figure 28.6 Salient-pole flux waveform on load

distributed because of the uniform airgap. The gap flux developed by the rotor ('field') m.m.f. acting alone has a trapezoidal distribution. On load the gap flux results from the stator and rotor m.m.f.s in combination. The fundamental components of the distributed m.m.f.s can be represented by phasors of peak values  $F_a$  and  $F_f$  ampere-turns per pole, respectively, each directed along the corresponding axis of maximum m.m.f. The fundamental component of gap flux on load is proportional to the phasor sum  $F$  of  $F_a$  and  $F_f$  (neglecting magnetic saturation).

$F_f$  is centred on the pole axis (the direct or d axis) to which the interpolar axis (the quadrature or q axis) is in electrical space quadrature. In general, the axis of  $F_a$  is displaced from the d axis by an angle  $\beta$  depending on the load and the power factor.  $F_a$  can be resolved into components  $F_{ad}$  and  $F_{aq}$ , respectively, on the d and q axes. Figure 28.7(a) shows, for a balanced three-phase cylindrical-rotor machine, the stator and rotor current-sheet patterns for an instant of zero current in stator phase C. (The black areas represent outward, and the cross-hatched areas inward, current direction.) The m.m.f. phasors  $F_a$  and  $F_f$  are displaced by angle  $\beta$ . The resultant m.m.f. acting on the airgap is the phasor sum  $F_f + F_a = F$ . Assuming each m.m.f. to develop an individual flux, the e.m.f.s  $E_f$ ,  $E_a$  and  $E_{ph}$  in Figure 28.7(b) are respectively induced by  $F_f$ ,  $F_a$  and  $F$ . Then  $E_{ph}$  is the terminal e.m.f. for a representative stator phase.

### 28.7.2 Salient-pole rotor machine

The gap reluctance is far from uniform, and a given stator m.m.f. acting on the q axis produces less flux than it would if acting on the lower reluctance of the d axis. This is indicated in Figure 28.7(c). The d axis flux is distributed almost sinusoidally, but the q axis flux contains significant space-harmonics, chiefly the third. To deduce the d and q axis fluxes, hence e.m.f.s and reactances, it is necessary to resolve  $F_a$  into the axis components  $F_{ad}$  and  $F_{aq}$ , then to evaluate separately the fluxes they produce. This is done in detail using, for example, finite element analysis of the field. Hand calculation can be done using coefficients presented

Figure 28.7 Airgap m.m.f. distribution

by Wieseman<sup>44</sup> and by Ginsberg *et al.*<sup>45</sup> in terms of the pole and airgap profile, and the minimum gap reluctance at the pole centre line.

### 28.7.3 Magnitudes and equivalence of stator and rotor m.m.f.

For a balanced three-phase winding with  $60^\circ$  phase spread, the peak of the fundamental component of the m.m.f. wave is

$$F_a = 4.35 K_w \frac{IT_{ph}}{gp} \text{ (A-t/pole)} \quad (28.16)$$

where  $I$  is the r.m.s. phase current,  $g$  is the number of parallel circuits per phase,  $T_{ph}$  is the total number of turns per phase, and  $2p$  is the number of poles. With a cylindrical rotor the proportions of the trapezoidal m.m.f. waveshape and the peak of its fundamental component depend on the field form factor  $C_f$  which is a function of the ratio

$$\lambda = \frac{\text{Total slotted arc}}{\text{Total circumference}}$$

i.e.

$$\lambda = \frac{\text{Number of slots}}{\text{Number in the circumference if all were cut}}$$

$$\text{e.g. } \lambda = \frac{28}{37} = 0.757$$

$$C_f = \frac{8\pi^2}{\lambda C} \sin(\lambda \cdot 90^\circ) \quad (28.17)$$

$\lambda$  is usually 0.65 to 0.75, and  $C_f$  therefore from 1.06 to 1.0. Then the peak fundamental m.m.f. of the rotor is given by  $C_f I_f N_f$  A-t/pole, where  $N_f$  turns per pole carry the field current  $I_f$ .

On load the rotor m.m.f.  $F_f$  must be such that when combined with the armature reaction m.m.f.  $F_a$  the net m.m.f.  $F$  must be sufficient to provide the flux needed to generate the e.m.f.  $E$ . Hence  $F_a$  must be put in terms of the rotor m.m.f. that would develop the same flux as  $F_a$ , i.e. equating the peak fundamental m.m.f.s of stator and rotor:

$$C_f I_f N_f = 4.35 k_w \frac{IT_{ph}}{gp} \text{ (A-t/pole)} \quad (28.18)$$

Hence

$$I_f N_f = \frac{1.35}{C_f} k_w \frac{IT_{ph}}{gp} \text{ (A-t/pole)} \quad (28.19)$$

Putting  $C_f$  at a typical value of 1.03, the rotor equivalent of the reaction m.m.f.  $F_a$  is

$$F_{af} = 4.31 N_f = 4.31 k_w \frac{IT_{ph}}{gp} \text{ (A-t/pole)} \quad (28.20)$$

With a salient pole rotor, with a distributed stator winding, a concentrated rotor winding, and a non-uniform gap reluctance, it is necessary in effect to calculate and equate the fundamental fluxes, not the m.m.f.s, along the direct axis.

Wieseman gives curves for estimating the factor  $C_{dl}$ , which is the ratio of the fundamental airgap flux produced by armature reaction m.m.f. directed along the direct axis to that which would be produced if the airgap were uniform and equal to the effective gap at the pole centre line. Then the peak fundamental flux density produced on the d axis by  $F_a$  is proportional to  $C_{dl}F_a$ . For typical profiles  $C_{dl}$  lies between 0.85 and 0.95.

The peak fundamental d axis flux produced by a rotor m.m.f.  $I_f N_f$  is proportional to  $C_1 I_f N_f$ . The value of  $I_f N_f$  that makes  $C_1 I_f N_f = C_{dl} F_a = F_{at}$ , the rotor m.m.f. equivalent of  $F_a$ . Then

$$F_{af} = I_f N_f = \frac{C_{dl} F_a}{C_1} \quad (28.21) \Leftarrow$$

$$C_1 = \frac{\text{Peak of fundamental flux wave}}{\text{Peak of actual flux wave}}$$

Putting in typical values of  $C_{dl}$ , and  $C_1$

$$F_{af} = (1.08 \text{ to } 1.2) k_w \frac{I T_{ph}}{gp} \text{ (A-t/pole)} \quad (28.22) \Leftarrow$$

Figure 28.20 shows how  $F_{at}$  is combined with  $F_e$  to calculate  $F_f$ , the on-load ampere-turns per pole.

## 28.8 Reactances and time constants

11,83,84,86–91

In order to evaluate the steady-state behaviour of a synchronous generator or its response to changes of load, excitation and system disturbances, a mathematical model of the machine is required. Reactances have been defined which, with winding resistances where significant, can form an appropriate equivalent circuit for which behaviour equations can be written; these equations can then be solved to determine the performance of the machine.

The reactances commonly employed are described below. They are associated with a two-axis model, represented on the d axis by an equivalent stator winding, the field winding and a damper winding, and on the q axis by a second equivalent stator winding and one damper winding. Circuit impedances can normally be taken as reactances because the resistances are comparatively small; however, the resistance values directly influence the time constants.

Voltages, currents and reactances are usually expressed in per-unit (p.u.) terms of rated voltage and current; other values are put in p.u. by dividing actual voltage and current by the rated values. The unit reactance is the ratio rated phase voltage/rated phase current. Thus a reactance having a voltage drop of 0.2 p.u. when carrying 0.5 p.u. current has a value of 0.4 p.u. Stator voltages, currents and reactances are all per-phase values.

Each reactance is associated with a particular component of flux produced by either the d or the q axis component of current in the stator winding. A d axis current produces a d axis flux: as shown in Figure 28.7, the conductors in which it flows are near the q axis but they form coils magnetising on the d axis. Similarly a q axis current produces a q axis flux. The numerical value of each reactance is then the fundamental frequency e.m.f. per phase generated by the associated flux, divided by the corresponding component of current. Usually reactances are defined with rated current in the d or q axis and are termed 'rated' or 'unsaturated'

values. With the heavy currents occurring under short-circuit conditions, saturation reduces the flux per ampere, and the saturated reactance values are lower.

The reactance values can be derived from the machine geometry by calculating first the permeance of the associated flux path and then the inductance  $L$ , i.e. the flux linkage with the stator winding per ampere of stator current in the required axis. The reactance (in ohms) is  $2\pi/L$ . Difficulties arise in defining exactly the flux paths and permeances and in allowing for saturation at high flux densities, even though a large part of the leakage flux paths is in air.

### 28.8.1 Armature leakage reactance

The armature leakage reactance  $X_1$  results from stator leakage flux that crosses the stator slots, flux that passes circumferentially from tooth to tooth round the airgap without entering the rotor and flux linking the stator endwinding.  $X_1$  is a component of all the positive- and negative-sequence reactances. Since the flux paths are independent of the rotor, the reactance has the same value for both axes; and since the flux paths are the same for positive- and negative-sequence currents,  $X_1$  has the same value for both.

### 28.8.2 Magnetisation (armature reaction) reactances

The magnetisation (armature-reaction) reactances are associated with the synchronously rotating flux set up by positive-sequence current in the stator winding, i.e. by balanced phase currents. Suppose the field winding is rotating synchronously but is open-circuited, and a three-phase e.m.f. ( $V$ ) of correct phase sequence is applied to the stator winding. After the initial damper circuit currents have delayed, a steady stator current  $I$  flows. If the e.m.f. is phased so that  $I$  produces flux along the pole axis, i.e.  $I = I_d$ , then  $I_d$  has a value sufficient to establish an airgap flux that induces a stator e.m.f.  $= V$  (neglecting the stator resistance and leakage reactance drops).  $V/I_d$  is the direct axis magnetising reactance  $X_{ad}$ . If the phasing is such that  $I$  produces only q axis flux, i.e.  $I = I_q$ , then  $V/I_q$  is the corresponding reactance  $X_{aq}$ . In most generators,  $X_{ad}$  lies between 1 and 2.2 p.u. In salient-pole machines,  $X_{aq}$  is typically 0.6  $X_{ad}$ . In cylindrical-rotor machines the airgap is of uniform length, but the rotor slots slightly increase the q axis reluctance, so  $X_{aq}$  is usually approximately 0.9  $X_{ad}$ .

### 28.8.3 Synchronous reactances

The synchronous reactances are the total reactances presented to the applied stator voltage when the rotor is running synchronously but unexcited:

$$X_d = X_{ad} + X_1 \text{ and } X_q = X_{aq} + X_1 \quad (28.23) \Leftarrow$$

The magnetising and synchronous reactances are steady-state values applicable with balanced phase currents of constant r.m.s. value. They are defined by considering the machine to be excited by stator current only. The two axis reactances can be represented by the equivalent circuits in Figure 28.8.

### 28.8.4 Transient and subtransient reactances

The transient and subtransient reactances relate to conditions that arise when the m.m.f. on the magnetic circuit of the machine is suddenly changed. Consider the conditions

**Figure 28.8** Equivalent circuits for d- and q-axis armature reaction reactances

following the sudden application of a three-phase supply of voltage  $V$  to the stator winding, with the rotor running synchronously and its field winding closed but unexcited. The three-phase stator currents develop an m.m.f. that rotates synchronously with the rotor. (There are direct-current (d.c.) components as well, but they are not relevant here.) Suppose that the instant of switching is such that the stator m.m.f. is impressed on the pole axis. The flux linkages of the stator winding must induce an e.m.f. that balances  $V$  (neglecting resistance). If there were no current paths on the rotor, the stator would immediately carry currents necessary to magnetise the machine to the required flux level, i.e.  $I = \mathcal{F}/X_d$ . However, if there are closed rotor circuits available (i.e. the field windings, damper windings and solid iron poleshoes), currents are induced in them, inhibiting the rise of flux through the rotor poles and so forcing the flux into rotor leakage paths of high reluctance. Hence the initial stator current must be larger than  $V/X_d$ . The leakage paths are largely circumferential in the pole faces, from pole to pole in the gap between adjacent salient poles, and across the wedges and tooth tips in a turbogenerator rotor. This path adds only a small permeance to that of the stator leakage paths alone, so the effective reactance is not much more than  $X_l$ .

$I^2R$  losses in the damper circuits cause these currents to decay rapidly, enabling the flux to penetrate past the dampers into the pole and field winding region. The permeance of the available flux path therefore increases, decreasing the stator current needed to maintain the required stator flux linkage. Thus the induced rotor currents, and the stator current, decrease in unison, at first rapidly as the damper currents decay, then for a time more slowly, until eventually the induced current in the field winding has disappeared, the flux is fully established along the main flux paths and the stator current is settled at its magnetising value  $I = \mathcal{F}/X_d$ . The main decay time is called the transient period, and the brief initial decay period is the *subtransient*.

The machine as seen from the supply system can be represented by the equivalent circuit shown in *Figure 28.9(a)*, where  $I_{kd}$  and  $I_f$  are the components of  $I_d$  needed to balance the induced damper and field currents respectively. The effective impedance increases progressively from its initial value of  $X_l$  in series with the other three circuits in parallel, through  $X_l$  in series with  $X_{ad}$  and the field circuit in parallel when  $I_{kd}$  has reached zero, to  $X_l + X_{ad}$  in the steady state. Thus the transient reactance  $X'_d$  and subtransient reactance  $X''_d$  are

$$X'_d = X_l + \frac{1}{1/X_{ad} + \mathcal{F}/X_f} \quad (28.24a)$$

and

$$X''_d = X_l + \frac{1}{1/X_{ad} + \mathcal{F}/X_f + \mathcal{F}/X_{kd}} \quad (28.24b)$$

**(a) Direct axis**

**(b) Quadrature axis**

**Figure 28.9** Equivalent circuits for d- and q-axis reactances

If the moment of switching is such that flux is established along the quadrature axis, similar arguments apply except that q axis flux has no net linkage with the field winding. There is, therefore, no q axis reactance corresponding to  $X'_f$  on the d axis, and in this simple model the q axis circuit is as shown in *Figure 28.9(b)*.

The q axis subtransient reactance is

$$X''_q = X_l + \frac{X_{aq}X_{kq}}{X_{aq} + X_{kq}} \quad (28.25)$$

In practice, the induced current paths in the iron on the d and q axes change as the flux distributions change, so neither axis can be accurately represented by a single damper circuit, with fixed  $X$  and  $R$  and therefore one fixed time constant. This is especially true of solid cylindrical rotors, in which the tooth tops and slot wedges form a surface damper cage of relatively high resistance with a time constant typically less than 50 ms. As surface currents decay, lower resistance current paths in the poles and beneath the slots become effective, introducing higher reactances with time constants up to a few seconds. Hence the machine can be represented more closely by having two damper windings on each axis. Traditionally the direct axis reactances  $X'_d$  and  $X''_d$  and associated time constants have been deduced from oscillograms of a sudden symmetrical three-phase short-circuit test, assuming only one damper circuit. Values appropriate to different levels of magnetic saturation can be found by testing at a number of voltages (tests at or near full voltage are rarely done because they cause very heavy forces on the windings). The short-circuit test measures only d axis values; other tests for these, and for q axis quantities, are given in IEEE Publication 115: 1983 and IEC Publication 34-4 1985; IEEE 115A 1987, describes frequency response tests (see Section 28.8.1).

In a salient pole rotor with laminated poles and specific damper cages, the damper circuits are more clearly defined, and a model with one damper on each axis (as well as the d axis field) is accurate enough for many purposes. Such a model has in the past been used for turbogenerators too, but advances in design and test procedures, and in computer analysis, have encouraged the use of the more elaborate models.

### 28.8.5 Negative-sequence reactance

Unbalanced load or fault conditions are usually analysed by the method of symmetrical positive, negative and zero phase-sequence components (p.p.s., n.p.s. and z.p.s. components). Currents of n.p.s. in the stator produce an m.m.f. rotating at synchronous speed in a direction opposite to that of the rotor. This m.m.f. acts upon the d and q axes in turn, inducing double-frequency currents in any available rotor circuit. The stator presents a low reactance to n.p.s. current, taken to be the mean of the subtransient d and q axis values, i.e.

$$X_2 = \frac{1}{2}(X_d'' + X_q'') \quad (28.26)$$

### 28.8.6 Zero-sequence reactance

Zero-sequence currents in the three phases are equal and in time phase, and their combined effect is to produce a stationary field alternating at supply frequency, therefore inducing a stator e.m.f. of that frequency. The m.m.f. and therefore the flux are small compared with the p.p.s. and n.p.s. components, and they depend heavily on the coil-span, falling from a maximum value to zero as the span decreases from full pitch to 2/3 pitch. Accordingly  $X_0$  is usually quite small.

### 28.8.7 Reactance values

Ranges of typical values of reactances and time-constants are given in *Table 28.4*. Since the ranges all depend on the details of the machine design, there will be exceptions to the following generalisations, which do however indicate normal trends.

For a given output and speed, the physically smaller machine will have a higher current loading, so all reactances will be higher than those of a larger, and therefore 'slacker', design. At a given speed, reactances tend to rise with

increasing rated output, since higher electrical loading and more intensive cooling are needed to attain more output per unit volume of active material. For a given output, low-speed machines are physically larger, and tend to have higher reactances, than high-speed designs.

### 28.8.8 Reactances and time constants

The reactances and time constants are based on equivalent circuits, such as those in *Figure 28.9*. Time constants are given by inductance/resistance ratios, i.e. the ratio of  $X/2\pi f$  to  $R$ . In the formulae below,  $2\pi f$  is written as  $\omega$ , the angular frequency. All time constants are in seconds if all  $X$  and  $R$  values are expressed consistently in per-unit or ohmic values.

#### 28.8.8.1 Open-circuit

With the stator winding open-circuited, the leakage impedance ( $X_1$  and  $R_a$ ) has no influence and the transient behaviour is determined by the inductance and resistance of the field winding. The open-circuit transient time constant is

$$T_{do}' = (X_{ad} + X_f)/\omega R_f \quad (28.27)$$

The subtransient duration depends primarily on damper-circuit currents: if we neglect the effect of  $R_f$ , the time constant is

$$T_{do}'' = \left( X_{kd} + \frac{X_{ad}X_f}{X_{ad} + X_f} \right) \frac{1}{\omega R_{kd}} \quad (28.28)$$

#### 28.8.8.2 Short circuit

With the stator short circuited, current and flux changes are influenced by  $X_1$ , but  $R_a$  is usually negligible. The transient time constant is

**Table 28.4** Synchronous generators: typical reactances (p.u.) and time constants (s)

Parameter	Symbol	Turbogenerator	Salient-pole generator		Compensator
			With dampers	Without dampers	
Synchronous reactance					
d axis	$X_d$	1.0–2.5		1.0–2.0	0.8–2.0
q axis	$X_q$	1.0–2.5		0.6–1.2	0.5–1.5
Armature leakage reactance	$X_l$	0.1–0.2		0.1–0.2	0.1–0.2
Transient reactance					
d axis	$X_d^{\prime \leq}$	0.2–0.35	0.2–0.45	0.2–0.45	0.2–0.35
q axis	$X_q^{\prime \leq}$	0.5–1.0	0.25–0.8	0.5–1.0	0.25–0.8
Subtransient reactance					
d axis	$X_d^{\prime \prime \leq}$	0.1–0.25	0.15–0.25	0.15–0.3	0.1–0.25
q axis	$X_q^{\prime \prime \leq}$	0.1–0.25	0.2–0.8	0.5–1.0	0.2–0.8
Negative-sequence reactance	$X_2$	0.1–0.25	0.15–0.6	0.25–0.65	0.15–0.5
Zero-sequence reactance	$X_0$	0.01–0.15		0.04–0.2	0.03–0.2
Time-constants					
Time-constants					
D.c.	$T_a$	0.1–0.2		0.1–0.2	0.1–0.2
Transient	$T_d^{\prime \leq}$	1.0–1.5		1.5–2.0	1.5–2.5
Subtransient	$T_d^{\prime \prime \leq}$	0.03–0.1		0.03–0.1	0.03–0.1
Open-circuit transient	$T_{do}^{\prime \leq}$	4.5–13		3–8	5–8

$$T_d'' = \left( X_f + \frac{X_1 X_{ad}}{X_1 + X_{ad}} \right) \frac{1}{\omega R_f} \quad (28.29)$$

The subtransient short circuit time constant depends primarily on damper-circuit parameters:

$$T_d'' = \left( X_{kd} + \frac{X_{ad} X_f X_1}{X_{ad} X_f + X_f X_1 + X_1 X_{ad}} \right) \frac{1}{\omega R_{kd}} \quad (28.30)$$

The armature short circuit time constant relates to the rate of decay of d.c. components of stator current that occur from the beginning of a sudden short circuit:

$$T_a = \frac{X_2}{\omega R_a} = \frac{X_d'' + X_q''}{2\omega R_a} \quad (28.31) \Leftarrow$$

### 28.8.8.3 q Axis

If the machine is represented by the simple model with only one q axis damper circuit, only subtransient time constants occur. These are

$$T_{qo}'' = \left( X_{aq} + X_{kq} \right) \omega R_{kq} \quad \text{open circuit} \quad (28.32)$$

$$T_q'' = \left( X_{kq} + \frac{X_{aq} X_1}{X_{aq} + X_1} \right) / \omega R_{kq} \quad \text{short circuit} \quad (28.33) \Leftarrow$$

### 28.8.8.4 Other relations

From the foregoing, it is found that

$$T_d' \neq T_{do}' = X_d' / X_d \quad (28.34) \Leftarrow$$

$$T_q' \neq T_{qo}' = X_q' / X_q \quad (28.35)$$

$$T_d'' \neq T_{do}'' = X_d'' / X_d' \quad (28.36)$$

## 28.8.9 Potier reactance

The Potier reactance  $X_p$  is an estimate of armature leakage reactance deduced from the open-circuit and zero-power factor (z.p.f.) curves; it is used in one method of calculating the on-load field current allowing for saturation.  $X_p$  is slightly higher than the true  $X_1$ , especially for salient-pole machines where pole saturation is greater than on normal load because of the greater pole-to-pole leakage flux for the z.p.f. conditions. Hence using  $X_p$  somewhat overestimates the load excitation.

### 28.8.10 Frequency-response tests<sup>87-89</sup>

The d and q axis parameters can be measured by injecting one-phase current into the stator winding over a frequency range (typically 1 mHz to 1 kHz), the rotor being stationary with its d and q axes in turn aligned with the stator field. By fitting an expression in the Laplace form

$$X_d(s) = \frac{(1 + sT_d')(1 + sT_d'')}{(1 + sT_{do}') (1 + sT_{do}'')} \quad (28.37) \Leftarrow$$

to the curve of d axis reactance against frequency,  $X_d$  and the time constants can be found, and the corresponding  $X_d''$

and  $X_d''$  values derived, appropriate to a machine model with one damper circuit on the d axis.

To fit the q axis reactance-frequency curve reasonably closely, it is necessary to assume two damper circuits, which give an expression similar to the d axis expression quoted, but with q axis quantities. Thus  $X_q'$  and  $T_q'$  values are deduced, as well as  $X_q''$  and  $T_q''$ , despite the absence of a field winding on the q axis.

More accurate fits to the measured frequency-response curves may be obtained by using an equivalent with more damper circuits and corresponding time-constants. Techniques have been developed for taking frequency-response curves on the machine in service in order to obtain values more appropriate to the load condition. There is an extensive literature in the *IEEE Journal (Power Apparatus and Systems)*. A review of the subject, and some specific papers are contained in IEEE Publication 83TH0101-6-PWR, Symposium on Synchronous Machine Modelling for Power System Studies, February 1983.

ANSI/IEEE 115A—1995 describes 'Standard procedures for obtaining synchronous machine parameters by standstill frequency response testing'. It contains eight references, and an appendix showing how operational impedances transfer functions and the  $R$  and  $L$  values of the equivalent circuit can be deduced from the measurements.

Measurements of the behaviour of machines and systems when they are subjected to test disturbances have shown that for some stability calculations the simpler circuits, even with the subtransient effects neglected, are adequate. However, for calculating short-circuit torques, the subtransients must be included; and for detailed analysis of the effects of excitation control, more elaborate models are needed.

## 28.9 Steady-state operation

### 28.9.1 Open- and short-circuit characteristics

Prediction of the operation of a generator in the steady state is based on the open- and short-circuit characteristics shown in Figure 28.10.

With the stator winding on *open circuit*, the field current  $I_f$  produces a mutual flux linking the stator and rotor windings, plus a relatively small rotor leakage flux linking the rotor winding only. The corresponding stator winding flux

Figure 28.10 Open- and short-circuit characteristics

linkage per phase  $\Psi_0$  generates the stator e.m.f. At rated speed, the value of  $I_f$  represented by  $0b$  generates rated e.m.f.  $E_0$  represented by  $bg$ ;  $0a$  is the current needed to overcome the reluctance of the airgap, and  $ab$  is required for the iron parts of the magnetic circuit.

With the stator winding *short circuited*, field current  $0d$  circulates rated stator current  $I_{sc}$ , represented by  $hd$ . Armature-reaction m.m.f. produced by  $I_{sc}$  is wholly demagnetising, and the difference between it and the field m.m.f. ( $0d$ ) develops a mutual flux  $\Phi_{sc}$ , sufficient to induce an e.m.f.  $E_{sc}$  equal to the stator leakage reactance drop  $I_{sc}X_1$ . This neglects the stator winding resistance  $R_a$  and any harmonic fluxes developed by the stator and rotor m.m.f.s.

The flux  $\Phi_{sc}$  is too small to cause magnetic saturation; hence  $I_{sc}$  is proportional to  $I_f$ . As both  $E_{sc}$  and  $X_1$  are proportional to frequency, the short-circuit characteristic is almost independent of speed; nevertheless, it is usual to obtain it at rated speed.

Still neglecting saturation and armature resistance, a field current  $I_f = 0a$  gives  $E_0 = af$  on open circuit and  $I_{sc} = ak$  on short circuit. Thus on short circuit the stator appears to present a reactance  $X_{du} = E_a/I_{sc} = af/ak$ , a constant representing the *unsaturated* d axis synchronous reactance  $X_{ad} + X_1$ .  $X_{du}$  is usually defined in terms of  $I_f$  as the ratio  $0d/0a$  in Figure 28.10. The short-circuit ratio is defined as  $0b/0d$  which from the geometry is  $(0b/0a)(l/X_{du})$ . Here  $0b/0a$  is a saturation factor, usually in the range 1.1–1.2.

### 28.9.2 Phasor diagram and power output

The resultant m.m.f. of the stator current  $I$  and the held current  $I_f$  develops an airgap flux  $\Phi$  which induces the stator phase e.m.f.  $E_{ph}$ . The stator leakage flux  $\Phi_1$  induces the e.m.f.  $E_1$ .

Detailed analysis allowing for local flux distribution and the variation of magnetic permeability in ferromagnetic parts of the magnetic circuit is necessary in design. However, the performance of a generator on load and under fault conditions can be examined conveniently (and, for many purposes, adequately) by combining the e.m.f.s considered to be produced by  $I_f$  alone and  $I$  alone, taken separately. Neglecting saturation, the machine can be represented by an equivalent circuit of constant reactances, and with e.m.f.s proportional to their respective currents. Usually the effect of stator-winding resistance can be neglected. Further, by assuming the airgap flux distribution to be sinusoidal, phasor diagrams can be employed. Finally, for a cylindrical-rotor machine the uniform gap length makes it permissible to assume that the d and q axes have equal reluctances. In practice,  $X_q$  is usually  $0.85X_d$  to  $0.95X_d$ .

Adopting the conventions of IEC Publication 34–10, the basis is generator action, with power positive when it flows from generator to load. An induced e.m.f. is  $e = -d\Psi/dt$ , where  $\Psi$  is the linkage between flux and stator winding. This means that the e.m.f. phasor lags the flux (or linkage) phasor by  $90^\circ$  electrical. Then, since the flux linking a stator phase winding is in time phase with the current, the phasor diagram in Figure 28.11 applies for a generator on inductive load, and Figure 28.12 shows the corresponding equivalent circuit. Here  $\Psi_f$  is the stator linkage produced by the field current  $I_f$  alone; it would induce on open circuit the e.m.f.  $E_f$ . The load current  $I$  produces the linkage  $\Psi_a$  (the armature-reaction effect) reducing  $E_f$  to the airgap e.m.f.  $E_g$ . Stator leakage flux produces the linkage  $\Psi_1$  and the e.m.f.  $E_1$ , and the total induced e.m.f. is  $E$ . Subtraction of the volt drop  $IR_a$  gives the terminal voltage  $V$ . With the convention

Figure 28.11 Phasor diagram for a cylindrical-rotor generator on load

Figure 28.12 Equivalent circuit for a cylindrical-rotor generator

Figure 28.13 Simplified phasor diagram

that the inductive voltage drop leads the current by  $90^\circ$ , the two equivalent equations in phasor terms are

$$V = E_f + E_a - E_1 - IR_a \quad \text{or} \quad V = E_f - I(X_a + X_1) - IR_a$$

If, as is usually permissible,  $R_a$  is neglected, then  $V$  and  $E$  coincide, simplifying the diagram to that in Figure 28.13. Here  $ab$  on a voltage scale represents  $IX_d$ . If the scale is divided by  $X_d$  then  $ab$  represents  $I$ . The angle  $abc$  is  $\phi$ , the power-factor angle;  $bc$  represents the active-power component of  $I$ ; but  $bc$  is also  $E_f \sin \delta$ , and hence the power per phase is  $(VE_f/X_d) \sin \delta$ .

**Figure 28.15** Power-angle relationships for a salient-pole generator on load

(3) the machine and bus-bar voltages must be momentarily in phase, or within  $\pm 5^\circ$  of phase coincidence.

In manual synchronising, condition (3) involves the use of a synchroscope to indicate to the operator the relative phase positions. Allowance must be made by the operator for the 0.2–0.4 s time-lag between initiation of switch closure and the actual closure of the switch contacts.

Alternatively, the process may be carried out by automatic means which monitor the conditions and initiate switch closure at the proper instant.

### 28.10.2 Synchronising power and torque

If a generator running in parallel with others is disturbed from its steady state, for example by a small change in system voltage, the electromagnetic torque no longer balances the driving torque (presumed constant), and the rotor swings from load angle  $\delta_1$  to a new angle  $\delta_2$  at which the balance is restored. The equal-area graphical criterion for stability is useful to give a picture of the oscillation process with a single machine,<sup>172,173</sup> but is inadequate for accurate calculation. In *Figure 28.16* the initial operating point *a* moves to *b* as the terminal voltage drops from  $V_1$  to  $V_2$ , reducing the electrical output. The rotor oscillates between  $\delta_1$  and  $\delta_3$  before settling at  $\delta_2$ , again delivering output  $P_{e1}$  equal to the mechanical power input. Areas *abc* and *cde* represent the energy interchanged between rotor kinetic energy and electrical energy.

If  $P_{e1}$  is too close to the peak of the  $V_2$  power curve, area *cdf* is less than *abc*, so the rotor can never be slowed to synchronous speed on its forward swing. It rises to a mean speed a little above synchronous, say up to 1%, delivering rather less than the initial load as an induction generator. As the rotor poles slip past the stator m.m.f. wave the speed fluctuates, and there are large swings in current, power, reactive and voltage. An e.m.f. at slip frequency is induced into the field winding, and may reach four or five times the excitation voltage needed at rated load. This forms one of the design criteria for the diodes or thyristors of the excitation system. In a turbine-generator, increased leakage flux in the end regions causes rapid heating of the core ends. E.m.f.s induced between the laminations have in a few

**Figure 28.16** Equal-area criterion

machines initiated local damage to the core-plate insulation, and serious core faults have developed in subsequent service. Many machines have pole-slip protection to trip the machine if synchronous running is not restored very quickly.

If  $\Delta\delta$  is a small deviation from  $\delta_2$ , the accelerating, or retarding, torque  $\Delta T$  is approximately  $\Delta\delta$ (slope of the  $T$ - $\delta$  curve at  $\delta_2$ ) =  $\Delta\delta T_s$  where  $T_s$  is the synchronising torque coefficient. The corresponding synchronising power  $\Delta P = \omega_m \Delta T = \Delta\delta P_s$  where  $\omega_m$  is the synchronous speed (in mechanical rad/s =  $2\pi$  rev/s) and  $P_s$  is the synchronising coefficient.

If the rotor swing were very slow the appropriate  $P$ - $\delta$  curve would be the steady-state curve such as in *Figure 28.15* and

$$P_s = \frac{dP}{d\delta} = \frac{VE_f}{X_d} \cos \delta + \frac{V^2(X_d - X_q)}{X_d X_q} \cos 2\delta \quad (28.39)$$

where  $P_s$ , the total for three phases, is in watts/electrical radian if  $V$  and  $E_f$  are line voltages (not phase) and reactances are in ohms/phase.  $T_s$  is then in newton-metres/electrical radian. Usually per unit (p.u.) values are more convenient, using rated apparent power and phase voltage and current as bases. Then  $P_s$  is in p.u. power/electrical radian, and  $T_s$  p.u. is numerically the same.

### 28.10.3 Rotor oscillation

The synchronising torque acting on the inertia of the coupled rotors constitutes an oscillatory system with a natural frequency

$$f_n = \frac{1}{2\pi\sqrt{J}} \sqrt{T_{spu}\omega_s} \quad (\text{hertz}) \quad (28.40)$$

where  $\omega_s = 2\pi f_s = 314$  for  $f_s = 50$  Hz and 377 for 60 Hz.

This formula ignores the effect on the frequency of the damping torques and, more significantly, the additional synchronising torques developed by currents induced in damper cages and solid iron.

In practice too, the natural frequency for almost any machine and system lies in the range 1–3 Hz, within which the time of a half-cycle of oscillation is comparable with,

Instability at all loads occurs when the generator (being underexcited) absorbs the reactive power 0a of value  $1/X_d$  p.u. The line 0a to the current scale is the zero-power-factor component of stator current; considered as delivered to the power system, 0a leads the terminal voltage  $V$ .

Stable operation in practice is not possible up to the theoretical steady-state limit line 0m. It is usual to construct a practical stability line such as 0fk on which, from each point such as  $k_1$ , operation for a given excitation  $0s = 0k_1$  is not permissible in the region  $rk_1$ . The load increment rs may be a fixed fraction of rated load or may change progressively between no load and full load. Often, a minimum acceptable field current is defined to avoid pole-slip at low load when a system voltage drop occurs (for the synchronising torque depends on  $V/I_f$ ). The minimum excitation is typically 20% of that needed on no load giving the limiting arc ef.

With a constant active-power output, the stator leakage flux in end-winding spaces increases as the power factor becomes more leading. This increases the loss, and the temperature in the end core packets and clamping plates will rise. Hence an end-heating limit line ln may be specified. Either the practical stability or the end-of-core temperature may set the limit on the reactive power that can be absorbed.

The operating chart can form the dial of a  $P$ - $Q$  meter having a pointer moving parallel to each axis. Where the pointers cross indicates the load point, and the margins between the output and the several limits are readily observed.

The effect of reactance  $X_e$  (of, say, a transformer or power line) between the generator and the fixed-voltage bus-bar is allowed for by adding  $X_e$  to  $X_d$  and  $X_q$ . Then for a cylindrical rotor machine the steady-state stability limit is reached where  $\delta_B = 90^\circ$ : the reactive power  $Q_L$  is  $V_B^2/(X_d + X_e)$  and the maximum real power  $P_L$  is  $V_B E_f / (X_d + X_e)$ . At any stable load condition

$$P = \frac{V_B E_f \sin \delta_B}{X_d + X_e} \quad (28.44)$$

and

$$Q = \frac{V_B (E_f \cos \delta_B - X_B)}{X_d + X_e} \quad (28.45)$$

The phasor diagram in Figure 28.18(b) shows that the presence of  $X_e$  requires the generator to operate over a range of terminal voltage. Generators are usually designed to deliver rated megavolt-amperes at rated power factor over a voltage range of  $\pm 5\%$ , and a frequency range of  $\pm 2\%$  or so. As  $V_T$  and  $f$  move away from the rated (1 p.u.) values, the rotor or stator temperature rises will increase. If  $V_T$  or  $f$  goes outside the design range, load may have to be reduced to avoid unacceptably high temperatures. See, for example, IEC 34-3 (Section 28.21).

To provide a voltage range of, say, 10% rather than 5% adds significantly to the size and cost of a large machine. In service the p.u. reactances increase as the voltage decreases, and this reduces the stability margin. Hence many generator transformers have on-load tap-changers, to reduce the range of generator voltage needed.

### 28.11.2 Salient-pole generator

From the phasor diagram the  $P$ - $Q$  chart for operation at fixed  $V_T$  of 1 p.u. can be drawn as in Figure 28.19; ab, ad and ag are the stator current or volt-ampere quantities, as before;  $ac/ab = X_q/X_d$ ;  $a0 = 4/X_d$ ;  $as = 4/X_q$ ;  $be \perp oe$ ;

Figure 28.18 Effect of system reactance

Figure 28.19 Operating chart for a salient-pole generator

$slb \parallel oe$ ; and  $lb = oe$ . Hence  $ols = 90^\circ$ , and the semi-circle constructed on diameter  $0s$  represents a zero-excitation boundary. Angle  $bs0 = \theta = \delta$  the load angle. At any load,  $E_f$  and  $I_f$  are represented by a length such as  $lb$ , on the line through  $s$ . (For any constant  $E_f$  and  $I_f$ , the locus of  $b$  is not quite a circular arc, but this becomes evident only with low excitations near the stability limit.)

$ad_1$  is the power contributed by  $E_f$ , and  $d_1d = \frac{1}{2}d$  is the reluctance power derived from the difference between  $X_d$  and  $X_q$ .

The theoretical steady-state stability limit is the line skb<sub>1</sub>m. One method of finding the line is to use the expression  $dP/d\delta = 4E_f \cos \delta / X_d + V^2(X_d - X_q) \cos 2\delta / X_d X_q$  to find consistent values of  $E_f$  and  $\delta$  that make  $dP/d\delta = 0$  (or see reference 8, article 6.5). A practical limit such as ptf can be constructed as for the round rotor generator, but with modern excitation controllers operation even beyond the theoretical limit, or with negative excitation, may be accepted, at least as a temporary condition.

With external reactance  $X_e$ , the intercepts of the zero-excitation circle lie at  $a_0 = \frac{1}{2}(X_d + X_e)$ , and  $a_s = \frac{1}{2}(X_q + X_e)$ . For a given  $E_f$  the peak power at the stability limit is also reduced.

## 28.12 On-load excitation

Use of the constant unsaturated value of  $X_d$  leads to values of  $E_f$  higher than those that occur for a practical machine. Thus a cylindrical-rotor generator with  $X_{du} = 2$  p.u. and carrying rated load at p.f. 0.85 lagging would have  $E_f = 2.67$  p.u. while a practical machine would saturate at around 1.5 p.u. If  $I_f$  were read from the airgap line for  $E_f = 2.67$  p.u. it would be about 15% low. At leading power factor, for which saturation levels are low, the error would be small. However, a more accurate estimate of the field current  $I_f$  is needed in the design of the excitation system and its cooling, and to determine the open-circuit e.m.f. that would be reached if the automatic voltage regulator failed to limit the excitation on sudden load rejection.

Flux distributions can now be calculated in considerable detail using computer programs that contain information on the geometry of the magnetic circuit, m.m.f.s of stator and rotor currents and values of iron permeabilities appropriate to the local flux densities. Hence, open-circuit curves and excitation on load can be calculated without much labour from design data once a program has been proved. However, methods based on phasor diagrams and adjusted reactances, making separate allowance for saturation, are still of value if a suitable program or the detailed design information, is not available. They are also needed when calculating excitation from test results on built machines.

Such methods add the rotor m.m.f. phasor needed to generate the no-load voltage to that needed to balance armature reaction. They differ in the choice of the voltage and in the way allowance is made for the effects of saturation.

The open-circuit short-circuit and zero-power-factor characteristics (o.c.c., s.c.c. and z.p.f.c.) are required, either by test or from design calculations. All the methods should give the full-load excitation to within  $\pm 5\%$ , or closer at leading power factor. We consider three methods here.

### 28.12.1 M.m.f. phasor diagram (Figure 28.20)

The e.m.f.  $E$  behind the leakage reactance  $X_1$  requires a field m.m.f.  $F_c$ , read from the calculated or tested o.c.c.  $F_{ar}$  is the armature-reaction m.m.f. in rotor terms, obtained by using the equations in Section 28.7 or (if  $X_1$  is known) by calculation from the tested s.c.c. as follows. To circulate stator current  $I$  on short circuit, excitation  $I_n$  is needed; to generate an e.m.f. to balance  $IX_1$  drop,  $I_{f2}$  is needed; hence the armature-reaction m.m.f. is  $F_{ar} = \frac{1}{2}I_{f1} - I_{f2}$ .  $E_f$  is the excitation m.m.f. required for the load current  $I$  at terminal voltage  $V$  and p.f. angle  $\phi$ . Figure 28.20(c) shows the diagram for a salient-pole machine with a leading p.f. load. As in Figure 28.14,  $ab$  is divided at  $c$  such that  $ac/ab = X_q/X_d$  to find point  $f$ .

### 28.12.2 The ANSI Potier reactance method (Figure 28.21)

ANSI Potier reactance method (ANSI/IEEE Publication 115, Section 4) requires the tested o.c. and z.p.f. characteristics, and is limited to machines that can be loaded for a z.p.f. test. In Figure 28.21(a), A is the rated-current short-circuit point and D is the rated-current rated-voltage point: to reach D the field current exceeds the rated-load excitation level. Draw  $DC = \frac{1}{2}AD$ , and draw  $CF$  parallel to the airgap line  $OBH$ . Drop  $FL$  perpendicular to  $DC$ , and draw triangle  $OBAM$  similar to  $CFDL$ . Then  $FL$  is the Potier voltage-age drop  $IX_p$ , and  $DL$  is the armature-reaction m.m.f.

The argument is that for a given stator current the armature-reaction and leakage-reactance voltage drops are constant, but the latter requires more excitation at the higher levels of saturation.

$OG$ ,  $OA$  and  $FH$  in Figure 28.20(b) are excitation currents as in (a), with  $OG$  for rated voltage on the airgap line.  $GH$  is the total excitation required.

The z.p.f. test may have to be performed at less than rated stator current; the z.p.f.c. is then closer to the o.c.c., and  $DL$  and  $FL$  are smaller. Nevertheless, the Potier reactance is still considered to be  $X_p = FL/I$  up to rated value.

Given only the o.c.c. and s.c.c., and no facility for adequately loading the machine, one procedure is to measure the d axis subtransient reactance from a sudden-short-circuit test (or by the IEEE method below) and to use it as  $X_p$ .

**Figure 28.20** M.m.f. excitation diagrams: (a) open- and short-circuit characteristics; (b) cylindrical-rotor, power factor lagging; (c) salient pole, power factor leading

Figure 28.21 Potier reactance excitation diagram

The test method for  $X_d''$  in ANSI/IEEE 115, Clause 7.30.25, is to apply a voltage  $E$  of normal frequency to each pair of stator terminals in turn and to observe the current  $I$  with the rotor stationary. Let the three quotients of  $E/I$  be  $A$ ,  $B$  and  $C$ . Then with  $E$  and  $I$  in per-unit values of rated phase voltage and current,  $X_d'' = (A + B + C)/6$  to an approximation. To avoid rotor overheating, the duration of the test should not exceed the maker's recommendations (e.g. 0.2 p.u. for a time sufficient to read the meters).

### 28.12.3 Use of design calculation (Figure 28.22)

Methods can be refined by allowing for the rotor pole-to-pole leakage. From a knowledge of the airgap flux, the m.m.f.s required for the gap, stator teeth and stator core are calculated. The m.m.f. for the rotor pole and body are calculated from the gap flux and pole leakage. The component phasors are added as in the diagram, where the total rotor m.m.f. per pole  $bc$  is obtained from  $0a$  (armature-reaction),  $0b$  (gap, teeth and core) and  $ac$  (pole and body). Saliency can be allowed for by dividing  $0a$  at  $d$  such that  $0d/0a = X_q/X_d$ . Then the total rotor m.m.f. is  $bc'$ . This differs very little from  $bc$ , but the load angle  $\delta'$  is more accurate.

Figure 28.22 M.m.f. excitation diagram from design calculations

### 28.13 Sudden three-phase short circuit<sup>6,7,11,19</sup>

If a three-phase generator is initially excited to a phase e.m.f.  $E_o$  on open circuit, and then the three phases are suddenly short circuited together, the stator winding carries balanced three-phase currents of up to several times full-load value depending on the magnitude of  $E_o$ . These currents produce a m.m.f. that rotates synchronously with the rotor, with its axis along the main pole axis, tending to reduce the mutual flux from its initial value. Change of flux linkage in a closed circuit induces therein a current opposing the change. Hence large direct currents are induced in the rotor damper circuits and field winding.

The combined effect of the large and opposing stator and rotor currents is to produce large leakage fluxes around the stator winding, the damper circuits and the field winding while the mutual flux along the main flux axis decreases correspondingly, so that the *total* flux linkage with each winding remains momentarily unchanged.  $I^2R$  losses rapidly dissipate stored magnetic energy and the damper currents rapidly decay. Typically, the induced field current reaches its peak a period or two after the short-circuit instant and then decays relatively slowly (Figure 28.23).

In the stator, each phase current is asymmetric to an extent depending on how near the phase voltage was to zero at the instant of short circuit; zero instantaneous voltage produces full asymmetry. Thus each phase carries a d.c. component which, at the instant of short circuit, is equal and opposite to the instantaneous a.c. component. These d.c. components produce a stationary m.m.f. sufficient to hold the stator flux linkage momentarily unchanged, i.e. fixed relative to the stator in the position the stator flux linkage occupied at the short-circuit instant. The d.c. rapidly decays, and with it the stationary field; while it persists, however, the rotation of the rotor within it induces rotational-frequency currents in the rotor damper and field circuits. The a.c. in the field is clearly seen in Figure 28.23; it is the greater, the less effective the damper circuits are. With no damper at all, the induced d.c. and the zero-to-peak amplitude of the a.c. would initially be equal.

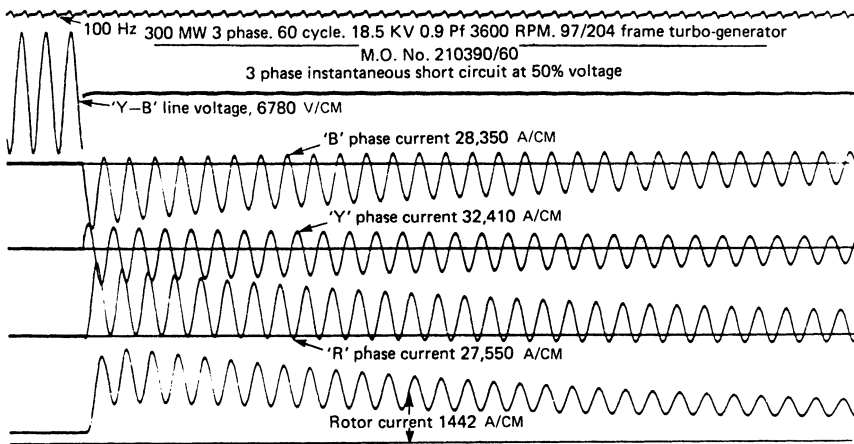

Figure 28.23 Short-circuit oscillogram

The path taken in the rotor by the stationary airgap flux has a greater permeance when the d axis coincides with the stationary flux axis than when the q axis coincides. Hence the flux fluctuates at twice fundamental frequency, and double-frequency current is induced in the stator winding. This current and the a.c. in the rotor decay as the stator d.c. component decays. The magnitude of the second-harmonic stator current depends on the difference between  $X_d''$  and  $X_d'$ ; it is small in turbogenerators and in salient-pole machines with good interconnected damper windings.

In summary, the a.c. components in the stator give rise to the d.c. components in the rotor circuits; after the subtransient period, stator a.c. and field d.c. decay together with the transient short-circuit time constant,  $T_d'$ . The stator d.c. components produce the rotor a.c., and these decay together with the armature short-circuit time constant  $T_a$ .

Direct-axis reactances and time constants are derived from the oscillograms of a three-phase short circuit as follows (see Figure 28.24 and Section 28.22: BS EN 60034-4:1995 and ANSI/IEEE Std 115-1995). The oscillograms should record for not less than 0.5 s;  $I_d$  can be measured by instruments or by taking a second oscillogram after the steady state has been reached. Speed and field current should be constant throughout.  $E_o$  is the open circuit phase e.m.f. corresponding to the rotor excitation.

The modern testing technique includes also digitally recording voltages and currents, and using computer programs to analyse the results and to present values of reactances and time constants. The principles are the same as for the analysis of the oscillograms described below.

- (1) Draw the envelopes abc and a'b'c' of one phase-current oscillogram. Then aa' is the double-amplitude of the prospective current at the instant  $t=0$  of short circuit. (The first current peak is slightly less than  $\frac{1}{2}aa'$  because of the rapid subtransient decrement.) Taking aa' as scaled in per-unit terms, the r.m.s. current is  $I_d'' = aa'/(2\sqrt{2})$  and

$$X_d'' = E_o / I_d''$$

- (2) Project the envelopes in the transient region, cb and c'b', back respectively to d and d', ignoring the initial rapid subtransient decrement (this cannot be done with great accuracy). Then  $I_d' = dd'/(2\sqrt{2})$  and  $X_d' = E_o / I_d'$

- (3) Repeat steps (1) and (2) for the other two phases and derive the mean values of  $X_d''$  and  $X_d'$ .
- (4) For a closer estimate, the equation relating the r.m.s. value of the a.c. short-circuit current  $I_t$  to time may be used:

$$I_t = I_d + (I_d' - I_d) \exp(-t/T_d') + (I_d'' - I_d') \exp(-t/T_d'') \quad (28.46)$$

where  $I_d = ee'/(2\sqrt{2})$  is the sustained steady-state short-circuit current, and  $I_d'$  and  $I_d''$  are the transient and subtransient r.m.s. currents respectively, corresponding to dd' and aa', respectively, at  $t=0$ .

- (5) Measure (e.g. in centimetres) the double-amplitude between the envelopes at each current peak and subtract ee' from each. Plot the results as ordinates on a logarithmic scale, to a linear base of time. This gives the curve abc in Figure 28.24(b).
- (6) Project cb by a straight line to d at  $t=0$ . Then

$$[d \text{ (cm)} / (2\sqrt{2})] \times \text{current scale of oscillogram} + I_d = I_d''$$

whence

$$X_d' = E_o / I_d'$$

[If bc is not linear, the decay is not exponential and  $I_d''$  is not a constant.  $I_d'$  and  $T_d'$  can be estimated from a straight line drawn through chosen points on the curve bc where the transient current components are b and 0.368b (see IEC 34-4: 1985).]

- (7) The subtransient r.m.s. current at  $t=0$  is  $I_d'' = I_d' +$  the rapidly decaying component represented by da. Thus

$$I_d'' = I_d' + \frac{\text{Intercept da}}{2\sqrt{2}} \text{ (cm)} \times \text{Current scale}$$

and

$$X_d'' = E_o / I_d''$$

The intercepts between ab and db are drawn to extended current and time scales in the lower part of Figure 28.24(b). Point f on the ordinate scale corresponds to da.

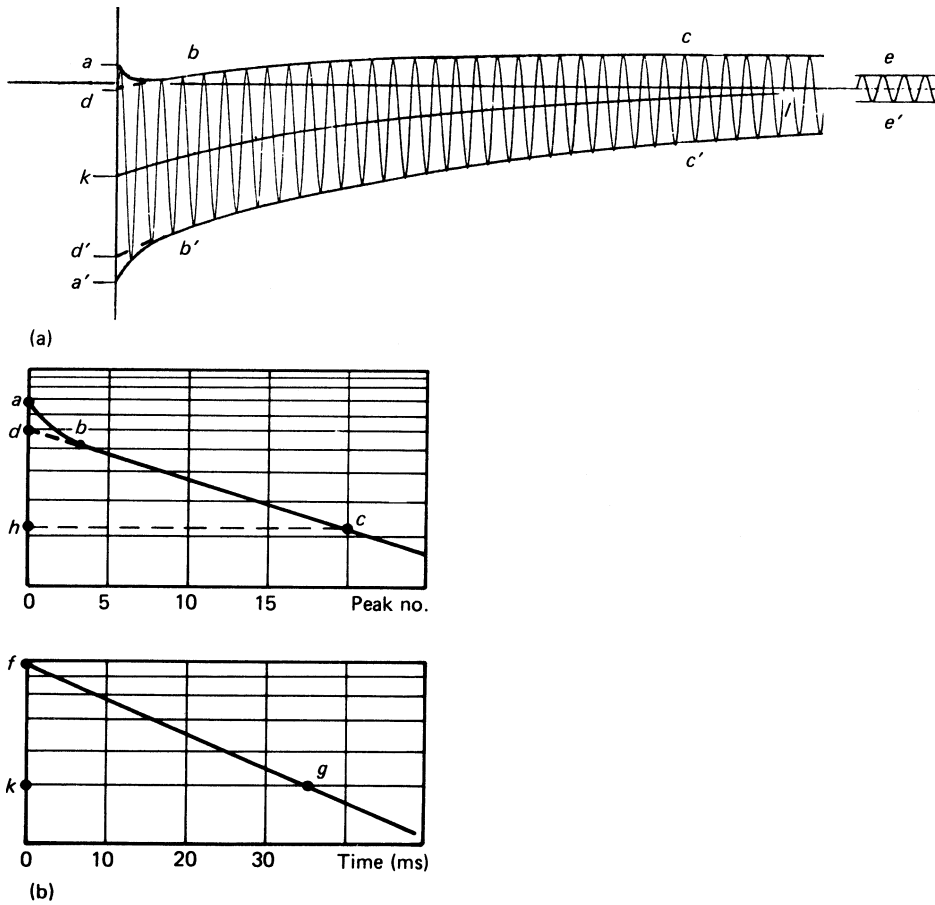

Figure 28.24 Analysis of a short-circuit current oscillogram: (a) current envelope; (b) logarithmic plot

- (8) Time constants are obtained from the slopes of the current-time plots. At  $c$  on line  $dc$  the transient component at time  $t$  is represented by  $h$  on the logarithmic ordinate (centimetre) scale and by  $hc$  on the time scale. It is related to  $I_d'$  at  $t=0$  by

$$I_t - I_d = (I_d' - I_d) \exp(-t/T_d') \quad (28.47)$$

$$\text{i.e. } hc = I_d' \exp(-t/T_d') \text{ consequently}$$

$$T_d' = (hc) / \ln(d/h) \quad (28.48)$$

where  $hc$  is in seconds and  $d$  and  $h$  are in centimetres.  $T_d''$  is obtained similarly from the extended-scale plot in Figure 28.24(b). The  $T_d'' = kg / (\ln f - \ln k)$ .

- (9) The procedure (5)–(8) is repeated for the other two phases and the mean values are obtained.
- (10) The reactance values decrease with increasing short-circuit current (and therefore with increasing open-circuit voltage  $E_o$ ). Rated-current values are obtained when at  $t=0$  the transient current  $I_d'$  is equal to rated current. A range of short-circuit tests spanning the expected  $X_d'$  will give a plot of reactance to a base of transient current  $I_d'$  from which the appropriate value can be found. A rated-voltage value, if required, is obtained by testing at 1 p.u. voltage for a small machine without a transformer, but the electromechanical forces on the stator endwindings would be excessive

in a large generator. Tests up to 0.7 p.u. voltage simulate a fault on the h.v. side of the transformer in a generator-transformer unit and are more relevant to the service conditions of a large machine.

- (11) The armature short-circuit time-constant  $T_a$  is determined from the decay of the d.c. components of stator current or from the decay of the a.c. component of induced field current. The latter method is simple: it requires only a log-linear plot of the a.c. component to a base of time, similar to the plot in Figure 28.24(b). The stator d.c. component is represented by the median line  $kl$  of the current envelopes in Figure 28.24(a). However, if there are significant even-order harmonics then the median is displaced and a waveform analysis is necessary to find the harmonic effect. This will occur in a salient pole machine that has no effective damper winding, and so is not common.

## 28.14 Excitation systems

A synchronous machine requires an excitation system to provide the field current for magnetising the machine to the desired voltage and, when it is running in parallel with others, determining the lagging reactive power generated or received. It is customary for each generator to have its own self-contained excitation system, which provides the power

required to supply the  $I^2R$  loss in the field circuit. This varies between about 10 kW/MVA for small machines and 5 kW/MVA for very large units.

Excitation voltage and currents are chosen: (i) to give field winding conductors that are mechanically robust in small machines and not too massive in large ones, (ii) to suit the ratings of available diodes or thyristors, and (iii) to give convenient designs of exciter, and also of slip-rings where these are used. Values range from a few score amperes and volts on very small machines up to say 8 kA at 600 V on the largest turbogenerators. At no load or with leading power factor, control of the exciting current is needed down to about one-third of the value for rated load.

The excitation system must respond to applied signals quickly enough to have the desired effect on the generator flux. Its duties can be broadly classified as:

- (1) to control the generator voltage accurately as slow changes of power and reactive loading occur;
- (2) to limit the fluctuations of voltage when loads are suddenly imposed or removed;
- (3) to maintain steady-state stability; and
- (4) to maintain transient stability.

(See references 168, 172 and 173.) These duties require different characteristics of the excitation system: these must be reconciled to provide proper control.

The performance of an excitation system is represented by its response ratio, or its response time and ceiling voltage. BS EN 60034-1:1998 gives definitions, and ANSI/IEEE Standard 421.1 gives definitions and methods of test for these and for other characteristics. In Figure 28.25,  $abdm$  is the voltage-time curve obtained, starting from the voltage  $V_e$  needed on the generator field winding at rated load, when the control is suddenly changed to cause ceiling voltage  $V_c$  to be reached as quickly as possible. Definitions are, where area  $abdf$  equals area  $agf$ :

Characteristic	ANSI/ IEEE 421.1	BS EN 60034-1:1998
Response time (s)	$t_2$	—
Response ratio measured over 0.5 s	$\frac{2gf \text{ in volts}}{V_e}$	$\frac{2gf \text{ in volts}}{V_e}$
Initial response/second	—	$\frac{1}{V_e} \left( \frac{\text{slope of } V-t \text{ curve}}{\text{at } t=0.5 \text{ s}} \right)^*$
High initial response system	A curve such as $ak$	—

\*The initial response is  $(V_c - V_e)/(t_1 V_e)$  per second if curve  $abd$  is exponential.

The measurements are conveniently made with the exciter on open circuit, but for analysing the generator behaviour values are needed with the exciter supplying the rotor winding. Where such testing is impractical, the on-load values must be calculated using known parameters of the machine(s).

Any system with a response time of 0.1 s or less is called a 'high initial response system'. A thyristor system<sup>166,171</sup> supplied from a transformer (or from an exciter machine that runs continuously at ceiling voltage) is inherently a high initial response system. A brushless exciter

Figure 28.25 Excitation response definitions

system<sup>165,167</sup> can be given high initial response by forcing the exciter field current with a pilot exciter voltage that may be 5–10 times that needed for rated generator output. The exciter field must be designed to have a short time constant; the whole magnetic circuit must be laminated, and damper windings, both deliberate and incidental, must be avoided. For example, clamping bolts and plates should not form closed loops linking flux. The exciter output voltage can be forced to a ceiling value of, say, 2–3 times  $V_e$  in less than 0.1 s. The output current rises more slowly, depending on the effective time constant of the generator field circuit. The controller may limit the exciter field current to say  $2\frac{1}{2}$  times the rated load value. In service such forcing would usually occur only for a few periods of up to about 0.5 s each as the rotor swings and returns to synchronism after a system fault.

A heavily forced main exciter with  $V_c$  about  $2V_e$  may provide the required *initial* response more cheaply than would a bigger exciter with yet higher  $V_c$  but a longer time constant.

Whatever the performance of the excitation system, the change in generator flux is delayed by eddy currents induced in its field winding and any available damper circuits. It is not practicable to constrain the design to avoid these: for mechanical reasons a turbogenerator needs a solid forged rotor (except very small ones), whilst a hydrogenerator with laminated poles needs pole-face dampers. Hence the natural generator time constants have to be accepted, and the excitation system designed to suit them. The extra cost of excitation systems to achieve more and more rapid response may become unjustifiably great in relation to the control actually achieved on the generator.

For the duties (1) to (4) listed above, the characteristics of the excitation system need to be as follows.

- (1) To hold the generator voltage within specified limits, which may be between  $\pm 3\%$ , and  $\pm 0.5\%$  of the set voltage, the excitation system needs a high d.c. gain, but a moderate ceiling voltage is enough to supply the small and slow changes of excitation needed.
- (2) To limit the fluctuation of voltage when load is suddenly applied or removed, a large, rapid and well damped response is needed. However a high initial response system, as defined above is often not necessary. For example, starting a large motor demands first a large reactive output from the generator, then increasing real power as the motor runs up. On a small generator or generator group, to avoid the voltage dip being too great and too prolonged, the generator needs a low  $X_d'$ , and the excitation must be kept high

for perhaps several seconds. A high ceiling voltage and a response time of say 0.2 s is more useful than a high initial response system with a lower ceiling.

- (3) Following a fault and its clearance on a high voltage power system, or a serious sudden loss of generation, a large and rapid response is needed to maintain transient stability, i.e. to restore the voltage and synchronising power flow to hold the several generators in step. Whether or not a high initial response system is essential depends on the particular circumstances, including the inertias of the generator sets and the post-fault reactances of the system. Very low frequency swinging, at 0.5 Hz or less, can occur between generating areas, requiring higher than rated excitation currents to be maintained for several seconds.
- (4) Steady-state stability can be improved, in the sense that the generator can run safely close to, or even beyond, the fixed excitation stability limit, if the controller has no dead band, and is designed to have the desired speed of response without introducing a phase shift that causes positive feedback. Such feedback encourages oscillations of rotor angle, etc., which can become intolerable. This is more likely with high-reactance power lines. Long lines with series capacitance inserted to compensate for the line inductance introduce the possible hazard of subsynchronous resonance.<sup>128–133</sup> A minor disturbance, for example normal switching of lines, can cause transient current to flow at the line natural frequency  $f_n$  (hertz), often in the range 20–40 Hz. Torque is developed on a generator rotor at system frequency  $f_s - f_n$  (hertz). If this is close to a natural frequency of torsional oscillation of some part of a turbogenerator shaft system, the oscillation may increase, sustaining the subsynchronous current. Fatigue damage has occurred on a few turbogenerator sets in this way.

Where stability problems are judged likely, the excitation controller is supplemented by a power system stabiliser. This acts in response to input signals such as voltage, power, rotor angle, or derivatives of these. They cause the controller to adjust the excitation so that torque is developed in the correct sense to damp the oscillations.

Because of its inherently fast response, and because of the mechanical advantages noted in Section 28.17 the self-excited thyristor excitation system is almost always used for hydrogenerators on long lines.

#### 28.14.1 D.c. exciters

These have been superseded by brushless or static thyristor a.c. systems. The exciter was a d.c. generator coupled to the shaft of the synchronous machine, feeding its output to the main field through slip-rings. For high-speed generators of more than about 50 MW, the exciter had to be driven at a lower speed (typically 1000 or 750 rev/min) through gears, or separately by a motor, in order to avoid difficulties of construction and of commutation. On very-low-speed hydrogenerators a directly coupled exciter would be excessively large, so a higher-speed exciter, driven by a motor or perhaps a small water turbine, was used.

For small ratings, the exciter was shunt excited; however, most were separately excited from a directly coupled shunt-excited pilot exciter. Control of the generator excitation was provided by controlling the field current of the main exciter.

#### 28.14.2 A.c. exciters with static rectifiers

Satisfactory service experience with brushless and static thyristor systems has made these early (diode) systems

obsolescent. Many remain in service, but many have been replaced by modern equipment. The advent of solid-state rectifiers made it possible to avoid commutators by using an a.c. exciter, directly coupled to the generator and feeding its output via floor-mounted rectifiers to the generator held winding through slip-rings. The exciter can operate at any economically convenient frequency, usually between 50 and 250 Hz, and the system is suitable for generators up to the largest ratings.

The diode cubicles may be cooled by natural convection or forced air flow. Alternatively, especially for large ratings, the diodes may be mounted on water-cooled bus-bars; this greatly reduces the size of the cubicles so that they can, if desired, be mounted on the sides of the main exciter frame, thus avoiding the need for long runs of a.c. and d.c. bus-bars or cables.

The main exciter field is supplied by an a.c. pilot exciter, often a permanent-magnet generator. The excitation of the main generator is controlled by controlling the main exciter field current via the automatic voltage regulator.

The main exciter is usually three-phase, and the diodes are connected in the six-arm bridge circuit, usually with a fuse in series with each diode to interrupt the fault current should a diode break down (which almost always causes it to conduct in both directions, i.e. to act as a short circuit). Diodes are available with current ratings up to 1000 A mean d.c., and peak inverse voltage up to 5 kV (but not both together in one diode). For other than small ratings, each bridge arm has several diodes in parallel; all the diodes are fused and have sufficient current margin to enable the bridge to carry full-load excitation continuously with one or more of the diodes failed and isolated by their fuses. Hence the generator can remain in service until maintenance can be carried out conveniently. Some installations on large generators had a.c. and d.c. isolators to allow parts of the bridge to be worked on without taking the generator out of service.

The diodes must be able to withstand induced transient currents and voltages resulting from system short circuits, asynchronous running, pole-slip and faulty synchronising, as well as from faults in the excitation system itself. Their continuous duty rating must leave some margin for imperfect sharing between parallel paths and for the possible loss of one or more paths, as noted above.

The fuse characteristic is co-ordinated with that of the diode so that fuses should not blow unless a diode fails or there is a short circuit on the d.c. output. The fuses must clear the fault current under the most onerous condition, which is usually that of a failure with the exciter at ceiling voltage. Fuse blowing is easily indicated by a microswitch operated by a striker pin that is ejected from an indicator fuse in parallel with the main fuse.

#### 28.14.3 Brushless excitation

The a.c. exciter has a rotating armature with three or more phases and a stationary field system. It usually is designed for a frequency of 0–5 times the power system frequency. The pilot exciter, when there is one, is usually a permanent magnet generator operating at around 6–8 times system frequency. The diodes and fuses are mounted on the rotor, and the rectified output is led directly to the generator field winding without need of brushes and slip-rings. The diodes are mounted on well-ventilated heat sinks, and special designs of fuse are used to withstand the centrifugal force on the fusible link.

On units small enough to require only one diode and fuse per arm, failure of one diode or fuse leaves the exciter with one phase unloaded; exciters are usually designed to supply full-load excitation in this condition without damage, so that the generator can remain in service until the fault can be repaired conveniently. However, experience shows that the failure rate of diodes is extremely low and that more often fuse links fail mechanically. Hence some makers supply salient-pole generators, up to say 25 MW, with no fuses at all, but use generously rated diodes to provide a large margin. These generators would use up to three diodes in parallel per bridge arm. For turbogenerators up to about 70 MW, some designs use two diodes in series—each of full duty, with one, two or more series pairs in parallel per bridge arm—and no fuses. On large units, redundant parallel paths, individually fused, are provided as in static equipments.

For units that use fuses, the striker-pin indicator type can still be used, the pin being observed by causing it to interrupt a light beam falling on to a photoelectric cell, or it can be observed visually with a stroboscope. Alternatively a neon lamp is connected across the fuse and glows when the fuse blows.

When diodes are in parallel, whether fused or not, if one becomes open circuit the system will continue to function apparently normally unless the remaining diodes are overloaded and eventually fail also. If an unfused diode fails by short circuiting, the short-circuit current in the exciter armature induces fundamental (exciter) frequency current in the exciter field winding. This can be detected and used to trip the set before serious damage is done. Another method of detection is to use stationary pick-up coils to see whether the diode connections are carrying current as they should as they pass the coils.

More elaborate indication, perhaps coupled with measurements of current and voltage and indication of earth fault, can be arranged by telemetry, but the telemetry may be less reliable than the diodes. Frequently instrument slip-rings are used, with solenoid-operated brushes that make contact only when readings are required.

The diodes, and fuses too if they are used, must be rated for the normal duty, including field forcing, and to withstand the abnormal conditions noted in Section 28.14.2.

#### 28.14.4 Thyristor excitation

Direct control of the field current of the synchronous machine by thyristors gives quicker response than can be obtained by controlling the exciter field current, because the time delay in the exciter is eliminated and the machine field current can be forced down by using the thyristors to reverse the machine field voltage. (By contrast, with a diode bridge, the machine field voltage can only be reduced to zero by reversing the exciter field voltage.) This is valuable for generators and synchronous compensators in certain power-system situations: for example, to minimise the voltage dip caused by large and possibly frequent load changes; to maintain transient stability of a generator under short-circuit conditions on the power system; to enable a synchronous compensator to maintain close control of the system voltage by rapid change in its reactive load, to minimise the voltage rise following sudden load rejection; to reduce more quickly the current resulting from a fault between the generator and its nearest protective circuit-breaker when field suppression is the only means available.

The synchronous machine requires slip-rings and brushes, and this is a disadvantage, especially for large

machines for which brushgear maintenance may become a significant inconvenience.

The excitation power may be supplied by direct coupled main and pilot exciters, the main exciter working continuously at ceiling voltage. This makes the power supply independent of voltage fluctuations on the power system. Usually though the excitation is supplied from the generator terminals through a step down transformer. This is usually designed to provide the required ceiling voltage when its primary voltage is reduced to about 60% of normal. This ensures that some field forcing can be done even when the power system voltage is depressed by a fault. It does subject the generator field winding to a rather high peak voltage when the system voltage is normal. A lower ceiling is adequate if power-rated current transformers are added in order to derive some excitation from the machine output current, so boosting excitation during the fault. The set is shortened by the absence of the exciter, and this may save costs on foundations and building. For very-low-speed generators the scheme may well be cheaper than a direct-coupled exciter and diodes.

Some excitation systems use diodes and thyristors in combination, e.g. in a full-wave half-controlled bridge circuit. One patented scheme uses a full-wave diode bridge with thyristor 'trimmer' control fed from a special excitation winding on the generator stator and from compounding current transformers.

Rotating thyristor systems have not yet been developed commercially, mainly because of technical difficulties in transferring control signals from the stationary equipment and problems concerning the reliability of rotating control circuitry.

#### 28.14.5 Excitation systems circuits

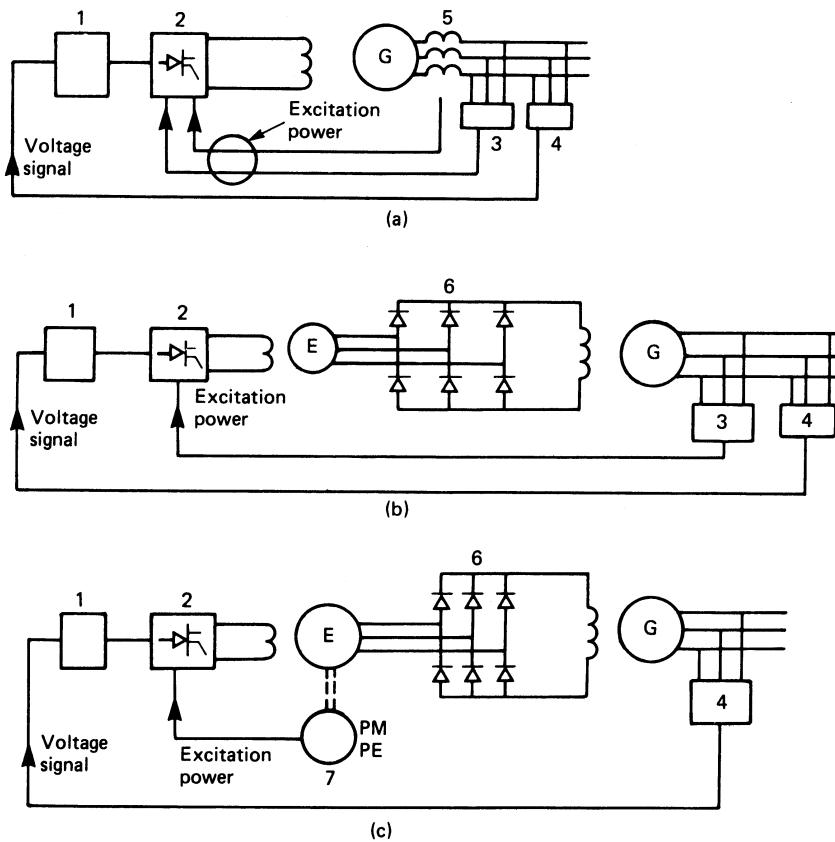

Typical systems are shown in *Figure 28.26*.

- (a) *Self-excitation* provides a simple and inexpensive scheme for generators up to about 3 MVA, using a one-phase thyristor output stage. With a three-phase thyristor bridge the scheme is applied for the highest ratings. The bridge rectifier may be half-controlled, with thyristors and diodes in combination. Another variant has a diode bridge that provides more exciting current than is demanded and thyristors to divert part of this current from the field winding.
- (b) *Self-excitation through an exciter* is convenient for brushless sets where the diodes are mounted on the generator-exciter shaft, and where the cost or mechanical complication of a pilot exciter is undesirable. A typical rating limit is 10 MVA.
- (c) *Separate excitation* provides excitation power independent of the generator output. It is commonly used for generators rated at 10 MVA up to the maximum.

Scheme (a) is capable of the most rapid response. In (b) and (c) some delay is introduced by the exciter time-constant; consequently a high exciter ceiling voltage and a large output from the pilot exciter are needed to obtain a more rapid response.

#### 28.14.6 Excitation control

When a generator operates alone the excitation is controlled to maintain the steady-state voltage within the necessary limits, and to prevent unacceptable variations of voltage when large and sudden changes of load occur. Generators running in parallel may need additional control signals to

**Figure 28.26** Excitation systems: (a) direct self-excitation; (b) self-excitation through an exciter; (c) separate excitation. 1, Control circuits; 2, power-output stage (a.v.r.); 3, excitation power transformer; 4, voltage transformer; 5, current transformers for excitation power; 6, diode rectifier (static or rotating); 7, permanent-magnet pilot exciter

share the total reactive load correctly between them. In an interconnected system, control of steady state and transient stability is a vital duty. Manual control of the excitation is inadequate, and automatic control is provided.

Electromechanical voltage regulators, in use only in old installations, may be of the carbon-pile, vibratory-contact (Tirrell) or rolling-sector (Brown Boveri) type. These have been superseded, initially by magnetic amplifiers, with or without amplidyne, and now by solid-state control systems using transistor amplifiers at low power levels, with thyristors for field-circuit power. The new systems are continuously acting (i.e. have no dead band) and can be arranged to respond to many control signals besides that from the terminal voltage, so the term 'automatic excitation controller' is more logical than 'automatic voltage regulator' (a.v.r.). Power supply for the control circuits is derived from the machine terminals or the pilot exciter.

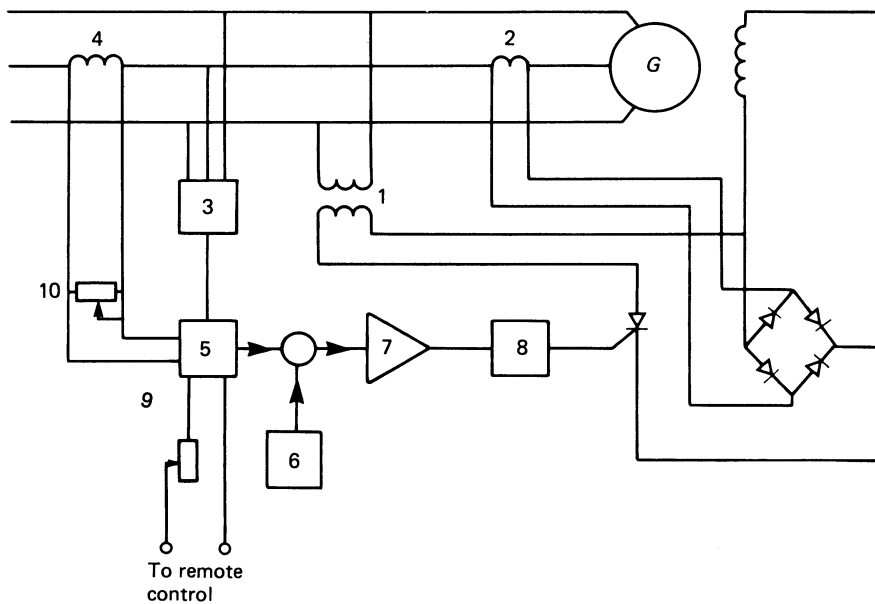

#### 28.14.7 Basic principles of voltage control

A direct voltage proportional to the generator average terminal voltage is derived via voltage transformers and a diode rectifier circuit. This voltage is compared with a stable reference voltage generated within the regulator. Any difference (the 'error voltage') is amplified and used to control the firing of a thyristor circuit which supplies the excitation, either to the field of the synchronous machine or to its main

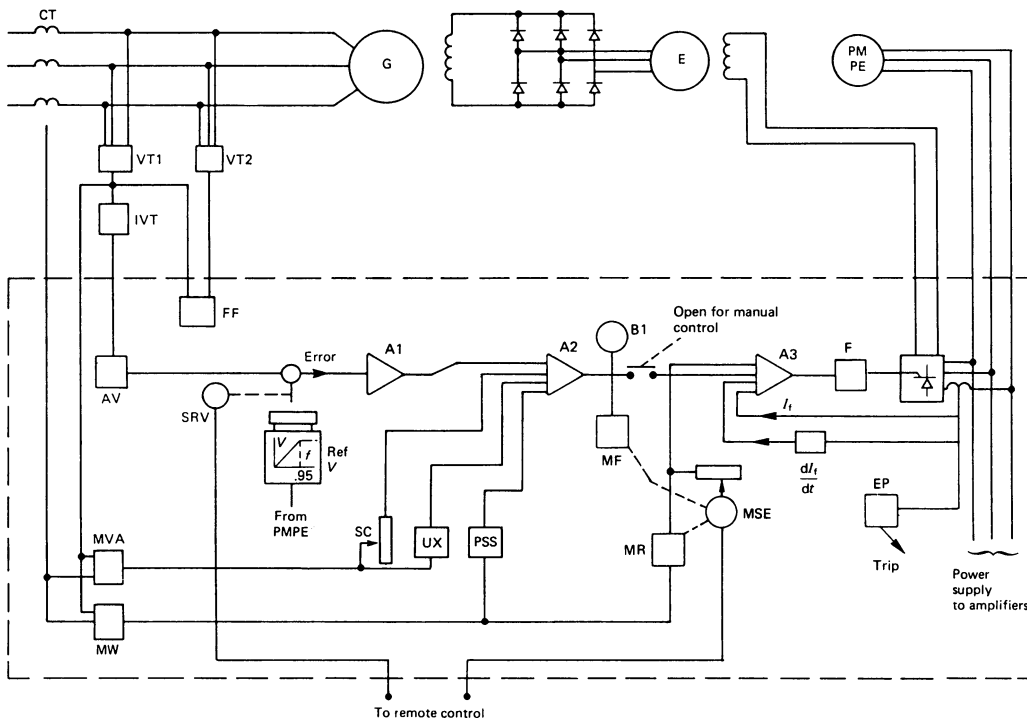

exciter-field winding. Thus the excitation is raised or lowered to restore the machine voltage to the desired level and the error voltage returns to near zero. The set level is obtained by adjusting the proportion of the machine voltage that is compared with the reference voltage or by adjusting the reference voltage itself. The basic circuit (Figure 28.27) is incorporated in Figures 28.28 and 28.29.

#### 28.14.7.1 Control range

Generators are usually designed to deliver any load from zero to rated output over a voltage range of  $\pm 5\%$ , at any power factor between rated (usually 0.8–0.9 lag) and say 0.95–0.9 lead. The a.v.r. setting controls must provide the corresponding range of excitation, and also provide say 85% of rated voltage on no load. Accuracy of control is usually within  $\pm 2.5$  or  $\pm 1.0\%$  of the set value over the load range.

#### 28.14.7.2 Manual control

Manual control is usually provided for use if the automatic control fails or for convenience when the set is being commissioned. In small units the manually controlled system may be entirely independent of the automatic one, but (especially for economy on large units) it uses the thyristor output stage and the associated firing circuits of the regulator.

Some regulators, when in auto control, drive the manual control so that, if it were in use, it would give the same excitation as the auto circuit. However, this follow-up must be prevented from driving the manual control down to excitation levels that are stable with continuously acting control but unstable with fixed excitation.

Some systems use the manual circuits continuously to control the steady-state excitation. The auto circuits continuously trim this to suit minor fluctuations of load, voltage, etc.; larger disturbances will cause rapid automatic changes of excitation voltage, up to full boost or full buck if necessary. If changed conditions persist for more than a few seconds, the follow-up circuit adjusts the manual control to the new steady state and the auto-circuit output falls to its usual low level.

#### 28.14.7.3 Manual-to-auto change-over

Whichever system is in control, it is necessary to adjust the other automatically or manually, so that a change-over can be made without causing a significant change in excitation. A balance meter is provided so that the outputs of the two systems can be matched before making the change. The manual rheostat and the voltage-setting rheostat are often motorised for control from a remote control room, and the balance-meter reading must be repeated there too, unless automatic matching is provided.

### 28.14.8 Additional control features

#### 28.14.8.1 Parallel operation

To ensure satisfactory sharing of reactive load between generators paralleled at their terminals, the a.v.r. can arrange for the terminal voltage to fall with increasing reactive load, usually by 2.5–4.0% at full load. For generators paralleled on the h.v. side of step-up transformers, the a.v.r. can either add to or partly compensate for the transformer impedance drop, as desired.

#### 28.14.8.2 Excitation limits

Fault conditions on the power system will cause the excitation to rise to ceiling value to try to maintain normal voltage. An adjustable timer is used to return to normal excitation after several seconds in order to avoid overheating the machines if the fault persists.

A reactive-power-limiting circuit can be used to prevent the excitation falling so low that the generator will not remain in step with the system. The reactive power (under-excited) at which this circuit operates is automatically varied in response to machine voltage and power output to maintain an adequate stability margin.

#### 28.14.8.3 Overfluxing protection

It is operationally desirable to be able to leave the a.v.r. in control when the generator is shut down or run up. To avoid overfluxing the machine and its associated transformer (if any) the reference voltage is arranged to decrease in proportion to frequency at speeds below about 95% of normal. This 'constant volts-per-cycle' control is needed also for generators that have to operate over a speed range, e.g. for ship propulsion.

#### 28.14.8.4 A.v.r. fault protection

Failure of a.v.r. components, or of other components in the excitation system, may cause excessive or insufficient excitation for safe operation. Either condition trips the a.v.r. to manual control and alerts the operator.

Voltage-transformer fuse failure is detected by comparing the voltages from two voltage transformers. If the a.v.r. voltage transformer fails, the system trips to manual control; if the comparison circuit fails, an alarm shows that fuse failure protection is no longer working.

#### 28.14.8.5 Double-channel a.v.r.

To enhance reliability of operation, large or vital generators frequently use regulators in which the automatic and manual control circuits are duplicated; often the thyristor output stage supplying the exciter field is duplicated too. Occasionally the much larger thyristor bridge that feeds the generator field directly may be duplicated. Each channel is able to perform the full excitation duty; the two channels may operate in parallel or in main and stand-by mode. If one channel fails, the other maintains the excitation unchanged. If the second channel fails subsequently, it trips to manual control. Alarms indicate the abnormal conditions.

### 28.14.9 Overall voltage response

The overall voltage response is defined in terms of steady-state and transient behaviour with the generator on open circuit and on no load, and under the control of the excitation system. For a generator operating *alone*, the following conditions may be relevant, their importance depending on the duty required of the generator:

- (1) *Steady state*: accuracy of voltage control over the range of load and power factor.
- (2) *Transient*: 1. Response of the open-circuit generator voltage to a step change in reference voltage; 2. Voltage response when a sudden increase or decrease of load occurs.

Conditions of importance under transient conditions are the voltage rise and recovery time of the generator voltage when load is suddenly removed, and the voltage dip and recovery time when a large motor is switched on to the generator terminals. For a generator running alone, BS 4999-140:1987, 'Specification for voltage regulation and parallel

operation of a.c. synchronous generators', specifies various grades of voltage regulation, for steady state and transient conditions. Accuracy of voltage control may conform to  $\pm 1\%$  or  $\pm 2.5\%$  or  $\pm 5\%$ . Voltage dip must not exceed 0.15 p.u. when a current of 0.35 or 0.6 or 1.0 p.u. of rated generator current is suddenly demanded. The voltage is required to recover to 0.94 or 0.97 p.u. within 1.5 or 1.0 or 0.5 s. Values of the temporary voltage rise that occur when rated load at p.f. 0.8 is thrown off are specified with a range 0.35–0.15 p.u. The more severe the conditions the more powerful the a.v.r. control must be. Also, the lower must be the generator  $X''_d$  and  $X'_d$  in order to reduce the immediate fall or rise in voltage that the a.v.r. cannot affect. There is a consequential increase in the short-circuit current and in the generator frame size; both these increases raise the cost of the generator and, perhaps, of its switchgear. The response under transient conditions is a convenient way of expressing the overall performance and of testing it during commissioning. The terms used are

$V_1$	initial voltage
$V_2$	final voltage
$V_1 - \mathcal{E}_2$	voltage step
$v$	voltage overshoot beyond $V_2$
$t_1$	rise time, that in which $V_2$ is first reached (and passed)
$t_2$	settling time, the shortest time after which the voltage remains within say $\pm 0.5\%$ of a steady value (which should be $V_2$ ). Figure 28.30 illustrates a step up of voltage.

Normally, either  $V_1$  or  $V_2$  is the rated voltage  $V_r$ , depending on whether a 'step-up' or a 'step-down' change is being tested. The voltage–time curve is a well-damped transient, settling at  $V_2$  after a few oscillations. Typical values of the quantities defined above are

$V_2 - \mathcal{E}_1$	0.1 p.u. of $V_r$	$v$	not more than $(V_2 - \mathcal{E}_1)/2$
$t_1$	0.2–0.6 s	$t_2$	1–5 s

For a given step change ( $V_2 - \mathcal{E}_1$ ),  $t_1$  is reduced by increasing the ceiling voltage  $V_c$ , by increasing the excitation system gain, and/or by reducing the system time constants. The parameters of the generator and exciter cannot be changed once the machines are made, but the a.v.r. parameters are designed to be adjustable. Changes that reduce  $t_1$  will increase the overshoot  $v$  and the settling time  $t_2$ ; hence settings of a.v.r. gain, time constants and feedback signals (if any, e.g. exciter voltage or exciter field current) are calculated to achieve the desired compromise, and performance is checked over a range of values of step change during commissioning (say steps of 1%, 5%, 10% and 20% of  $V_r$ ).

Figure 28.30 Voltage step change

When generators operate in parallel, as most do, the excitation systems must be designed and adjusted to achieve the best compromise between highly accurate voltage control, steady-state stability, and transient stability following a system disturbance. Thus some step-change tests, or tests by injecting low-frequency sinusoidal voltage into the reference circuit, are desirable, to confirm the calculated performance.

See IEEE Standard 421A, 'Guide for identification, testing and evaluation of the dynamic performance of excitation control systems'.

### 28.14.10 Digital control<sup>170</sup>

Increasing use is being made of a dedicated microprocessor to replace the analogue control system. The input signals (voltage, current, MW, MVAR, etc.) are converted to digital form, and the processor is programmed to respond to these to provide an analogue signal to the firing circuits. The characteristics needed in the excitation controller are reproduced digitally in the processor, and limits of relevant quantities are introduced. The whole can be set up and tested in the works, so that site commissioning is simpler and quicker. In service, settings do not drift or suffer from poor rheostat contacts, but can be readily changed, even while the set is in service, to suit changed operating conditions. If a component does fail, a new card can be inserted without repeating the commissioning tests.

There is a delay of up to 10 ms while the microprocessor scans the input signals and readjusts its output signal, if necessary, but this is very small compared with the machine time constants.

The thyristor firing pulses may also be generated digitally. Development is proceeding of adaptive controllers that will automatically tune their characteristics to suit the operating conditions.<sup>169</sup>

## 28.15 Turbogenerators<sup>92–137</sup>

The characteristic features of turbogenerators are their high speed to meet steam-turbine requirements and their large outputs to provide economy of capital and operating costs for the power station. Most are two-pole units running at 3000 or 3600 rev/min, but four-pole generators at 1500 or 1800 rev/min have become common for large outputs (1000 MW or more) from nuclear reactors of the boiling-water or pressurised-water type. These reactors deliver large volumes of steam at temperatures and pressures that are lower than those provided by fossil-fired boilers or some gas-cooled reactors. The low-speed turbine may handle these conditions with a greater efficiency that is sufficient to offset its higher capital cost compared with a high-speed unit. Design constraints are less exacting in the low-speed turbine and generator.

### 28.15.1 Main dimensions

The output coefficient  $C$  ranges typically from about 0.5 MVA s/m<sup>3</sup> for a rating of 20 MVA to about 2.0 MVA s/m<sup>3</sup> for a 1000 MVA unit. For 3000 rev/min machines these figures correspond to  $D^2L$  of 0.8 and 10 m<sup>3</sup>, respectively. Economic diameters for these outputs range from approximately 0.75 m to 1.3 m, the latter being a limit set by centrifugal stresses in the endrings and in the rotor teeth. Hence outputs range from approximately 17 to about 170 MVA per metre of core length. The higher values

of output coefficient are made possible by enhanced cooling techniques. Typical dimensions for a 660 MW two-pole hydrogen-cooled machine may be: rotor diameter, 1.15 m; core length, 6.8 m; overall shaft length, 13.5 m; core outside diameter, 2.7 m; outer casing, 4.8 m in diameter and 10.3 m long; total weight, 480 t.

### 28.15.2 Rotor body

The output available from a turbogenerator is largely determined by the excitation m.m.f. that can be carried on the rotor with acceptable winding temperatures. The high centrifugal stresses make cylindrical (i.e. non-salient-pole) construction essential.<sup>92,93</sup> Within the chosen diameter the number, shape, size and spacing of the winding slots have to be optimised to obtain the maximum m.m.f. capability with acceptable stresses in the teeth and slot wedges, with adequate insulation, with acceptable magnetic flux densities and with ducts for ventilation that enable temperature guarantees to be met. For air-cooled machines of medium output the manufacturing simplicity afforded by parallel-sided slots and solid copper conductors of rectangular cross-section may outweigh the loss of optimum performance and provide the cheapest design. For larger ratings tapered slots are used to accommodate more copper, while giving approximately constant mechanical stress and magnetic flux density along the radial length of the teeth.

A rotor is forged from a single steel ingot, the largest of which approach 500 t in weight; this would produce a rotor weighing 250 t, enough for a four-pole machine of about 1250 MW at 1500 rev/min. The forgings contain the alloying elements nickel, chromium, molybdenum and vanadium; according to size and speed, ultimate tensile strengths of the forgings range from 650 to 800 MN/m<sup>2</sup>, while their 0.2% proof stresses range from 550 to 700 MN/m<sup>2</sup>. The forgings are inspected with ultrasonics and magnetic-particle ink before use. Many generator makers now rely on these examinations and do not bore the forging axially along its centre line, except for large forgings or if ultrasonics reveals defects that can be removed by boring.

The endwindings (the parts projecting beyond the ends of the slots) must be supported against centrifugal forces by endrings (retaining rings) from which they are insulated by, for example, resin bonded fibreglass or aramid paper (Nomex) or combinations of synthetic insulating sheets. The endrings are steel forgings, usually shrunk on to the ends of the rotor body. In some older designs they were shrunk on to discs that were shrunk on to the shaft outboard of the windings, and they were not tight on the rotor body.

From the 1950s until 1982, the endrings<sup>106,107</sup> were of austenitic steel (18% Mn, 4–5% Cr, 0.3% C) warm worked to give high strength, up to 1100 MN/m<sup>2</sup> proof stress and 1220 MN/m<sup>2</sup> ultimate in the highest grade. This alloy is very susceptible to stress corrosion if it gets wet, e.g. by condensation from moist air or leakage of cooler water. In 1982 an austenitic alloy became available with 18% Mn, 18% Cr,<sup>108,109</sup> this is not subject to stress corrosion under any likely operating conditions, and has mechanical properties up to 1200 MN/m<sup>2</sup> proof stress (0.2% strain) and 1300 MN/m<sup>2</sup> ultimate strength. Endrings large enough for 1500 MVA two-pole or four-pole generators can be obtained, and higher strengths have been developed. Many endrings of the older alloy have been replaced, after some years in service, using the 18–18 material.<sup>106,116</sup>

Rotor vibration at running speed must be low—typically about 50  $\mu$ m peak-to-peak measured on the shaft near the

bearings, though up to twice this is commercially acceptable. Hence balance weights must be carefully positioned, axially as well as circumferentially, and the design of the rotor, its bearings and its supports must ensure that its critical speeds are sufficiently far from rated speed. Small 3000 rev/min rotors will have one critical speed below 3000 rev/min, say about 1700–2000 rev/min, but as ratings (and therefore the bearing span) increase, two or even three criticals will occur below 3000 rev/min (typically around 650, 1750 and 2500 rev/min). When the rotor is coupled to the turbine, the critical speeds are usually raised slightly, so that behaviour in both the coupled and the uncoupled condition must be acceptable, for site running and works testing (without the turbine) respectively.

Electrical faults on the power system or on the machine itself produce abnormally high oscillatory torques on the rotor, at system frequency and often at twice this frequency also. Where series capacitance is used in long lines to compensate for inductive reactance drop, electrical oscillation at the natural frequency  $f_n$  may cause torques on generator rotors at system frequency minus  $f_n$ . These torques may resonate with torsional natural frequencies of the shafts and produce unacceptable fatigue stresses. From all these causes, complex torsional oscillations develop in the shaft system, with components determined by the inertias and stiffnesses of the several shafts of the turbine, generator and exciter. The shaft dimensions must be chosen to avoid a serious loss of fatigue life during such incidents as well as to satisfy the critical speed criteria mentioned above. There are many articles on the subject; references 128–135 are a few of these.

Bearings are of the white-metalled cylindrical type, with forced oil lubrication and, except on small sets, high-pressure oil jacking also. Jacking allows the set to run slowly (typically 3–20 rev/min) on the turning gear to cool off the turbine and generator rotors before the unit is finally stopped. Without this, the rotors would bend because temperature gradients would occur across the diameter of each rotor, and vibration would occur on the next run-up.

All turbogenerator rotors bend under their own weight, and with two-pole rotors for outputs more than about 30 MW the amount of bend would be significantly more when the pole axis is horizontal than when it is vertical. Hence a vibration would occur at a frequency corresponding to twice the running speed; it is caused by the changing stiffness of the rotor in the vertical plane, and therefore cannot be removed by mechanical balancing. The stiffnesses about the polar (direct) axis and the slot (quadrature) axis must be made as nearly equal as possible under running conditions (when centrifugal force on the windings increases the stiffness in the plane of the quadrature axis). This is done either by cutting axial slots along the pole areas (and filling them with magnetic steel if necessary to avoid magnetic saturation) or by cutting narrow arcuate grooves circumferentially across the poles, sufficient grooves being spaced down the length of the rotor to reduce the stiffness to match that in the quadrature plane.<sup>29,93</sup>

### 28.15.3 Rotor winding

Excitation currents range from say 400 A at 200 V for a 30 MW generator to 5.7 kA at 640 V for a 1000 MW two-pole machine and up to around 7 kA at 650 V for a 1500 MVA machine. For rotors using indirect cooling each coil is wound with a continuous length of copper strap, bent on edge at the four corners. The copper contains about 0.1% silver and is hard drawn to increase its strength

and so avoid the coil-shortening effect that occurred with plain soft copper as a result of heating while part of the copper was prevented (by centrifugal force) from expanding axially.

Directly cooled coils are usually made of larger section conductors of silver-bearing copper containing grooves and holes to provide gas passages. Half-turns are brazed together in the end regions after they have been positioned in the rotor slots. The slots may be parallel-sided, or tapered to contain more copper without increased tooth stress.

Insulation between turns is usually provided by interleaves of resin-bonded glass fabric or some other synthetic material. The coils are insulated from the rotor body by U- or L-shaped troughs of resin-bonded fibreglass, Nomex or melamine, or combinations of such materials. Similar insulating strips insulate the top conductor from the slot wedge; in direct-cooled rotors the strips must have through-holes to allow the cooling gas to escape from the rotor; they must be thick enough to provide adequate creepage distance to withstand the specified h.v. tests.

The end-windings are packed, partly or wholly, with blocks of insulating material to avoid distortion and the consequent risk of short circuits between turns.

### 28.15.4 Stator core

The stator core is built up of segments of electrical sheet steel, usually 2–3% silicon, 0.35 mm thick, cold rolled and non-oriented. To minimise weight, the core is worked at the highest flux density consistent with reasonable losses. In a two-pole machine the magnetic force across the airgap subjects the core to an elliptical distortion that rotates with the rotor, so producing a double-frequency ( $2f$ ) vibration. The core depth must be chosen so that its natural frequency of vibration in this elliptical mode is well away from  $2f$ ; usually  $3f$  or more is practicable without excessive depth of core. Grain-oriented steel has better permeability and lower losses than non-oriented steel, but as it has a lower modulus of elasticity its other advantages cannot be realised without accepting higher vibration. This, and its higher cost, severely limit its use in turbogenerators.

### 28.15.5 Stator casing

Air-cooled machines may have bearing pedestals on a bed-plate; the stator frame then merely supports the core and forms the ventilation enclosure. Alternatively, it may be a more rigid box frame with the rotor bearings carried in end-brackets.

A hydrogen-cooled machine must have a totally enclosed and gas-tight construction; the end-bracket bearing arrangement is adopted to minimise the bearing span and to raise the critical speeds. Hence the frame must be rigid enough to provide proper support for the bearings and to contain the gas pressure that might occur in the unlikely event of a hydrogen–air explosion inside the frame. This could produce pressures up to about 1400 kN/m<sup>2</sup>; therefore this pressure, rather than the continuous working pressure of hydrogen, becomes the design criterion.

In large two-pole machines (which are invariably hydrogen cooled) some form of flexible mounting is needed between the core and the casing, and the casing should not have any natural frequency near to  $2f$ . This is to avoid excessive magnetic noise and the risk of unacceptable vibration on the casing, coolers or pipework.

Where transport facilities are inadequate for handling the complete stator, the core and windings must be made separately from the outer casing, separately transported, and assembled on site before the rotor is inserted. By contrast, smaller machines can be transported complete to some sites, with the rotor clamped in temporary supports; this arrangement facilitates erection.

### 28.15.6 Stator winding

For small machines the voltage is usually fixed at a standard network voltage (e.g. 6.6 or 11 kV), but for large machines, where a generator-transformer is used, the designer has a free choice. A high voltage avoids difficulties due to high currents, but valuable space in the slots has to be sacrificed to insulation; a compromise is thus about 15 kV for 100 MW and 200 MW machines, and up to 22 or 25 kV for the larger sets. Even so, generators of more than about 50 MW rating will have two circuits in parallel per phase; for more than 1000 MW it may be necessary to use special winding arrangements to have four parallel paths in a two-pole machine. In four-pole generators, four circuits occur naturally and can be in parallel or in series-parallel.

The winding is of the two-layer basket type, almost always with integral slots per phase per pole, as described in Sections 28.3 and 28.4. In the slots<sup>27</sup> and in the endwindings<sup>101</sup> the coils must be supported to resist electromagnetic forces.<sup>93</sup> These are, on normal load, continuous though fairly low vibratory forces at twice supply frequency. When a short circuit occurs close to the generator, transient oscillatory forces occur, 50–100 or more times greater than those on load.

In the slots the forces are radial, directed towards the bottom of the slot, except where different phases occupy the same slot; there the force on the top conductor is towards the wedge for part of each cycle. To support the coils along the whole core length, conformable packing strips of, for example, resin impregnated polyester fleece are placed beneath and between the coil sides. Slot wedges are fitted that apply a known radial load to the coils, greater than the electromagnetic forces. Packing may be fitted down the sides of the coils, and there may be a fibreglass ripple spring between the wedge and the top coil side to take up any small shrinkage in service.<sup>27,29,93</sup>

The endwindings are secured to a strong structure of insulating materials,<sup>27,29,93,100</sup> fibreglass rings carried on brackets of resin-bonded wood laminate have been used very widely. For larger ratings a solid cone of filament-wound resin bonded fibreglass is used for greater strength and long-term rigidity. The coils are bedded to the structure with conformable packing material. Usually the slot and endwinding packings are cured while the coils are held by temporary wedges and clamps, which are then replaced by the permanent ones. The complete structure is bolted to the end of the core; some axial movement may be allowed, to accommodate expansion of the coils relative to the core.

### 28.15.7 Cooling

Efficiencies are between 96.5% and 99%, increasing with the rated output. However, the losses will be 0.5–15 MW, appearing as heat that must be removed by circulation of an appropriate cooling medium: oil for removing bearing-friction losses, and air, hydrogen or water for other losses. Details of the cooling media used for stator and rotor windings are given in Table 28.6. The heat transfer coefficients

**Table 28.6** Properties of cooling media

Medium heat	Absolute pressure (bar)	Specific heat (kJ/(kg K))	Density (kg/m <sup>3</sup> )	Relative volume flow	Relative thermal capacity	Relative heat transfer coefficient
Air	1.0	1.0	1.1	1.0	1.0	1.0
Hydrogen	1.0	14.3	0.076	1.0	0.99	1.45
	2.0	14.3	0.152	1.0	1.98	2.52
	4.0	14.3	0.304	1.0	3.96	4.38
Water	1.0	4.2	1000	0.01	38	60

are typical, but depend considerably on velocity and duct size.

Traditionally, indirect air cooling was adopted for outputs up to 70 MVA, and indirect hydrogen cooling for outputs above about 50 MVA. Direct hydrogen cooling of rotors developed rapidly for ratings from about 100 MVA up to the largest, about 1500 MVA, that have been built. Some manufacturers used hydrogen cooled stator coils up to about 650 MVA: others adopted water cooling above about 150 MVA where indirect cooling was becoming difficult. In recent years cheap and simple designs have been developed up to 200 MVA rating using air cooling, direct in the rotor winding and indirect for the stator.

#### 28.15.7.1 Indirect cooling

The cooling medium (air or hydrogen) is blown along the airgap, through ducts in the core and over the surface of the windings. Thus heat generated in the winding passes through the main insulation to the rotor and stator teeth,

respectively, and is picked up by the cooling gas mainly from the iron surfaces.

With air cooling, closed-circuit ventilation is universal except in the very smallest sizes, and coolers are separately mounted—usually in a basement beneath the generator, but occasionally above or at the side of the machine. With hydrogen cooling, however, there is no alternative but to build coolers within the gas-tight explosion-proof structure of the machine itself. *Figure 28.31* shows a simplified diagram of a hydrogen-cooled machine with its gas system.

It has directly cooled windings. The cooling gas is usually circulated by a fan at each end of the rotor, though many air-cooled generators (30–60 MW or so) had motor-driven fans mounted in the basement with the air coolers. The rotor fans may be of the centrifugal or the aerofoil (axial-flow) type. Their main purpose is to establish the gas flow through the stator frame, core and coolers; the flow through the rotor results mainly from its own rotation. Most indirectly cooled rotors have axial ventilation slots in the teeth that are closed by wedges

**Figure 28.31** Section of a turbogenerator with simplified hydrogen cooling and water-cooled stator winding

except near the middle of the rotor body where the flows from each end emerge into the gap and then pass through the radial ducts in the stator core to the back of the frame.

Pure hydrogen has a density approximately 1/14 that of air, while its specific heat is 14 times that of air; it has a higher heat transfer coefficient and much better thermal conductivity. In service there may be about 1% impurity consisting of air and carbon dioxide; this increases the density by about 13%, but has no significant effect on the cooling properties listed in *Table 28.6*. Windage losses are proportional to density, but even at an operating pressure of 5 bar (absolute) they are still only 40% of what they would be in air at atmospheric pressure.

Early hydrogen-cooled machines were designed to operate at just above atmospheric pressure, but raising the pressure to 2 bar (absolute) and then to 3 bar raised the output available from a given frame size by approximately 15% and then by a further 10% respectively. No worthwhile improvement occurs above 4 bar (absolute) because the temperature gradient across the winding insulation is a large part of the permissible temperature rise.

The auxiliary equipment for hydrogen-cooled generators divides into two main groups: gas control and seal-oil treatment.

The gas control system provides means for filling and emptying the casing without risk of forming an explosive hydrogen-air mixture. Carbon dioxide is used as a buffer, and mixtures containing more than 5% hydrogen in air, or more than 5% air in hydrogen, are avoided. In service the rate of hydrogen loss, though small, is sufficient for the purity to settle at 98–99% hydrogen as make-up is added to maintain the desired operating pressure.

The shaft seals, which prevent leakage of hydrogen along the shaft to the bearings, are supplied with oil maintained at a pressure above the gas pressure. Ring seals which encircle the shaft are simple and allow free axial expansion of the shaft; however, they also allow a significant rate of oil flow towards the hydrogen side of the seal, and rather more to the air side. The gas-side flow absorbs hydrogen, and would release air or moisture into the machine if it contained these in solution. To avoid the consequent pollution, and loss, of the hydrogen, the oil is vacuum treated before being fed to the seals, and the hydrogen-side oil passes through detrain- ing tanks to allow entrained hydrogen to return to the frame before the oil is vacuum treated and recirculated.

The face, or thrust, type of seal is a ring, usually of white metallised steel, which operates against the radial face of a collar on the shaft. The hydrogen-side oil flow is insignificant, so vacuum treating is unnecessary. The extremely thin hydrogen-side oil film (say 60  $\mu\text{m}$ ) makes the seal rather vulnerable to dirt particles, and if the ring does not slide freely to follow shaft expansion it will leave the collar and allow leakage or will suffer excessive face pressure and damage to the white metal. Both types of seal are in satisfactory operation. A doubly fed ring-type seal offers the advantages of both types, provided that the pressures of the two systems are kept accurately balanced so that the hydrogen- and air-side flows are kept separated.

A wide range of indicators fitted with audible and visible alarms is necessary to indicate any departure from normal operation of the various parts of the gas and oil systems.

#### 28.15.7.2 Direct cooling<sup>27,29,123–127</sup>

**Hydrogen** The winding conductors are much more effectively cooled by passing the coolant through them in direct,

or almost direct, contact with the copper. Hence much higher current density is possible with an acceptable temperature rise, and the output per unit volume of active material can be greatly increased. Furthermore, significant improvement in performance with hydrogen cooling is obtainable up to operating pressures of 5 or even 6 bar (absolute) (500–600 kN/m<sup>2</sup>).

In the rotor, several flow arrangements are used:

- (1) *Axial flow* The gas enters tubular, or axially grooved, conductors in the end-winding region and leaves radially through a group of holes through the conductors and wedges at the mid-length of the rotor.
- (2) *Axial flow* This is as for (1), but for longer rotors. The middle quarter (approximately) is fed from subslots, while the two end-portions are fed as in (1).
- (3) *Radial* The gas enters each end of a subslot cut beneath the winding slot and flows radially outwards through holes punched through the flat copper strips and insulation, distributed throughout the rotor length.
- (4) *Axial-radial* This is a combination of (1) and (3) using axially grooved conductors in which the radial exit holes are displaced axially from those that feed gas from the subslots.
- (5) *Gap pick-up* Specially shaped holes in the wedges 'scoop up' gas from the gap, and others eject it after it has passed through cooling ducts formed in the copper by punched holes or transverse grooves.

Types (1) and (2) require high-pressure axial-flow blowers, which may have three to seven stages of blades; (3) and (4) rely almost wholly on the self-ventilating action of the rotor; (5) may be applied by dividing the rotor into axially adjacent inlet and outlet zones, which may be co-ordinated with the stator ventilation zones. All these schemes are used for hydrogen-cooled machines up to the largest ratings. Type (3) is now common for air-cooled machines with totally enclosed air circuits.

Directly hydrogen-cooled stator coils are used by some makers up to ratings of 600 MW or more. The gas flows down thin-walled bronze or stainless steel tubes that are bonded among the conductor strips and lightly insulated from them. Entry and exit has to be at the ends of the coils, so a moderately high pressure differential is needed. The system co-ordinates well with rotor ventilation of type (1) or (2).

**Water** The high heat-removal capacity of water and its low viscosity allow it to be used in tubular subconductors that are still small enough to keep the eddy-current losses low.

At each end of the conductor the subconductors (tubes and strips, or all tubes) are brazed into a water box. The coil-to-coil current-carrying connection may be tubular to carry the water also, or separate connections may be made. The water boxes are connected to the inlet and outlet manifolds by insulating pipes of polytetrafluoroethylene (PTFE) or some other synthetic material. Water taken from the boiler make-up system is circulated by pumps around a closed pipework system containing the winding, coolers, filters, control valves and monitoring instruments. Water conductivity is easily maintained by using a demineraliser unit, usually of the resin-bead type; less than 10  $\mu\text{S-cm}$  is easily attained, and the leakage currents down the water columns are insignificant.

The temperature difference between copper and water is only about 2°C, and the water temperature rise between inlet and outlet is usually about 25–30°C. The inlet water

pressure is kept below the hydrogen pressure; if leakage does occur, it is leakage of hydrogen into the water (easily detected), and water does not enter the machine.

Water-cooling of the rotor winding increases the output available from given frame size; the slots can be smaller, leaving more room for magnetic flux, so the machine can be shorter provided the stator design is adjusted to suit. Constructional problems occur because of the need to convey water to and from the rotor, to accommodate water manifolds on the shaft, to support the water-pipes against centrifugal force, and to design them and the winding to withstand internal pressures (produced by rotation) up to around 15 MN/m<sup>2</sup>. Nevertheless, such rotors are in successful service though they have not yet been widely adopted.

Direct cooling allows the specific electric loading to be increased without exceeding the permitted limits of temperature rise. A smaller frame size can be used for a given output, but the leakage reactances are increased by the increase of leakage flux compared with main airgap flux. The values of  $X_d$  and short-circuit ratio can be maintained by lengthening the airgap, until the increased excitation on load pushes the rotor winding temperature rise to its limit.

### 28.16 Generator–transformer connection

For small ratings up to 3 MW, single-core cables are used. For ratings above this where the number of cables needed would be excessive or cannot be accommodated, solid copper or aluminium bus-bars are used. The bus-bars are supported on insulating cleats or ceramic post insulators and are enclosed in a surrounding duct which provides mechanical protection and sealing. The bars are spaced and supported to suit the operating voltage, the current to be carried (taking into account skin and proximity effects which raises the a.c. resistance and leads to extra heating) and the electromagnetic forces produced by short-circuit currents. The phases are sometimes segregated by insulating barriers to achieve the creepage and clearance distances required. For higher current ratings, each phase conductor usually consisted of two angle- or channel-section bars mounted face to face to form an open diamond or box-shaped section. These sections and arrangements give lower skin-effect losses than flat rectangular bars of the same weight, and natural air cooling may be adequate up to at least 200 MW (with a corresponding current of the order of 10 kA).

To avoid the possibility of phase-to-phase faults, however, phase-isolated bus-bars were adopted for ratings above about 200 MW, and now above 60 MW. Each line connection consists of two angle- or channel-section bars supported by post insulators inside an aluminium tube which is physically and electrically continuous along its length. The tubes of the three phases are connected together electrically at each end of the run and are joined mechanically to the generator and transformer frames. Thus only phase-to-earth faults are possible. Eddy currents induced in the aluminium tubes cause additional losses, but they confine the magnetic field largely within the tube, so that heating of the foundation steelwork or other structures is avoided.

For the higher ratings, say above 12 kA, each conductor bar may be of semi-hexagon or semi-octagon shape, so that the complete conductor approximates to the circular cross-section that gives minimum skin effect and minimum loss.

**Table 28.7** Typical dimensions of generator–transformer connections

	<i>Cooling</i>		
	<i>Natural air</i>	<i>Forced air</i>	<i>Pumped water</i>
Conductor shape	[ ]	[ ]	○⇐
Diameter of circumscribing circle (m)	0.9	0.5	0.13
Diameter of isolating trunking (m)	1.5	1.1	0.75
Total loss in conductor and trunking, for 3 phases (kW/m)	2.0	4.5	7.5

Natural air cooling is practicable up to about 20 kA, but a significant reduction in cross-section or an increase in current rating is made possible by forced-air cooling. A maximum conductor temperature rise of 55°C above the ambient air is usual. With this, and a continuous rating of 19.5 kA (660 MW at 23 kV, 0.85 p.f.), typical dimensions are as given in *Table 28.7*.

For forced-air cooling, the flow is usually from one end of the run to the other along one phase, half the flow returning along each of the other two phases. The air circuit is totally enclosed, with an air-to-water heat-exchanger extracting the loss. If the air circulation fails, the naturally cooled rating is about 60% of the forced-flow rating.

The use of water-cooled stator windings led to the development of water-cooled connections in solid tube or cable form. The water-cooling circuit is similar to, but usually separate from, that for the generator stator. The smaller dimensions are an advantage where space is limited, and the greater loss is not usually economically unacceptable. The system has not been widely adopted, however, because there is usually room for air-cooled connections, while the extra water-cooling auxiliaries introduce additional maintenance and extra complications of duplication and control to guard against shut-down of the generator if an auxiliary item fails.

### 28.17 Hydrogenerators

#### 28.17.1 Introduction<sup>26–28,30,53,138–156</sup>

The design of hydrogenerators is determined mainly by mechanical considerations. Outputs range from less than 1 MVA to over 800 MVA, and speeds from 50 to 1000 rev/min, depending on the water head available and the type and size of the turbine. The low speeds require the generators to be physically large, and it is often necessary to transport them to site in sections. The inertia required in the set is determined by turbine governing or speed regulation requirements, or by the transient stability of the associated power system. The turbine contributes little flywheel effect, so the generator inertia must often be more than that of a design that satisfies the electrical specification in the least expensive way. The diameter must be increased, or in extreme cases a separate flywheel coupled to the shaft. This is often the best arrangement in fairly small horizontal shaft units.

A water turbine runs up to a high overspeed when load is suddenly removed, because the flow of water cannot be

suddenly stopped without causing a high and probably damaging rise of pressure at the turbine gates or valves. The ratio of overspeed to normal speed is, approximately, for impulse turbines (Pelton) 1.7 to 1.9, for reaction (Francis) 1.8 to 2.1, and for propeller (Kaplan) 2 to 2.2. If the governor should fail during load rejection, a Kaplan turbine could run up to 3 times normal speed.

The rotors must be designed to be safe at overspeed, where the factor of safety on the proof stress of the material used is normally not less than 1.5. A figure closer to 1.1 is acceptable for the very rare runaway condition of a Kaplan unit.

The first critical speed is required to be above the overspeed.

## 28.17.2 Construction

### 28.17.2.1 General arrangements<sup>8,26,30</sup>

Horizontal and vertical shaft arrangements are used, the former usually for impulse turbines and small reaction turbines, the latter for large reaction and propeller turbines. Nevertheless, the vertical arrangement has been used up to 36 MVA and 1000 rev/min, and the horizontal shaft up to more than 100 MVA at 428 or 600 rev/min.

Horizontal generators are similar to those made for diesel engine or geared turbine drive, except that they must accept the higher overspeed, may carry a flywheel, and need a thrust bearing to carry any unbalanced hydraulic thrust. A turbine may be overhung at each end, or at one end only.

With a vertical shaft, five bearing arrangements are possible. These are shown in Figure 28.32. The umbrella arrangements of (d) and (e) are suitable for low-speed sets in which the ratio of core length to stator bore diameter does not exceed say 1/4. With a top guide bearing added as at (c), higher speeds and an  $L/D$  of 1/3 are practicable. The top thrust bearing arrangement of (a) and (b) is used, where necessary, for higher  $L/D$  ratios and speeds usually above 400 rev/min. The top bracket and the stator frame must be rigid enough to carry the thrust load, and so are more expensive than with a bottom bracket assembly. However, as the bearing is on a smaller diameter part of the shaft, its losses are less; if the contract places a high value on losses (as with pumped storage for example) the capitalised value of the lifetime losses may be enough to pay for the top-thrust layout. If the bracket is supported directly from the pit walls, the stator frame is relieved of the thrust load, and some problems of differential expansion and electromagnetic vibration are avoided.

### 28.17.2.2 Thrust and guide bearings

In large vertical machines the dead weight plus hydraulic thrust is several hundred tonnes. The thrust collar rests on segmental pads (usually of steel) faced with white metal. They are supported on a thrust ring at the bottom of the annular oil chamber that surrounds the shaft. The pads and the lower part of the collar are submerged, and careful design and assembly are needed to avoid leakage of oil and vapour.

The pads are supported so that they can tilt slightly to develop hydrodynamic lubrication. The Kingsbury pad is supported on a single spherical pivot; the Michel pad pivots on a radial ridge. Both supports are offset from the centre line of the pad if rotation is to be in only one direction: a pivot on the centre line is needed for a reversing pumped

**Figure 28.32** Hydroelectric generator bearing arrangements: (a) thrust bearing above rotor, two guide bearings—upper guide bearing separate from and below thrust bearing; (b) thrust bearing above rotor, two guide bearings—upper guide bearing combined with thrust bearing; (c) thrust bearing below rotor, two guide bearings (semi-umbrella machine); (d) thrust bearing and single guide bearing below rotor (umbrella machine in English, American and Continental literature); (e) thrust bearing mounted on turbine casing, single guide bearing below generator rotor (umbrella machine in German literature). (Reproduced, with permission, from Anscombe<sup>30</sup>)

storage set. Load sharing among the pads depends critically on the accuracy of dimensions or adjustment of the pad heights. This difficulty is much reduced if the pad sits on a mattress of closely spaced helical springs instead of a solid pivot. The specific bearing pressure can be quite high, up to 3.5 MPa average over the pad surface. Transient conditions on a pump/turbine unit may increase this at some times by a factor of about 1½. The peak oil pressure on the pad is about 1.5 times the average. The oil film thickness is usually between 0.1 and 0.05 mm. On such highly loaded bearings a high pressure oil supply is often fed through one or more small holes in the surface of the pad to provide oil jacking and hydrostatic lubrication at rest. This is especially needed to reduce the starting torque required when the unit is being motored for pumping duty.

The pumping action of the bearing is often enough to circulate the oil through water-cooled heat exchangers placed in the oil pot. If the pot is too small for this, or to improve accessibility to the pads, the coolers may be mounted separately below the bearing. The oil is then circulated by main (a.c.) and stand-by (d.c.) motor driven pumps.

With high bearing pressures and surface speeds cooling water may be circulated through channels in the pads themselves.

Vertical shaft machines have friction brakes operated by air pressure to bring the set to rest without protracted running at low speeds, when the lubrication of the thrust pads may become inadequate. To reduce wear on the brake pads they are not applied at or near the full speed except in an emergency. Dynamic braking is achieved by circulating up to full-load current through the stator winding short-circuited by a braking switch. The friction brakes are then applied at 15–20% of full speed.

The brakes can also be operated by oil pressure when the machine is stationary, to lift the thrust collar off the pads, either to flood the surfaces with oil after prolonged standing, or for maintenance such as inspection or removal of the thrust pads. If the shaft is to remain lifted for a long time, the jacks are locked mechanically to allow the oil pressure to be removed.

Guide bearings are usually of the pivoted-pad type, running on the outside of the thrust collar or a smaller diameter of the thrust block. Where the guide is remote from the thrust bearing, it runs on the shaft in its own oil enclosure.

If there is a bearing above the rotor, it needs to be insulated to prevent the flow of shaft currents caused by some asymmetry in the core flux, e.g. differences in reluctances at the joints in the core. With a top thrust bearing the thrust face, which is normally a renewable ring bolted to the collar, can be insulated from the collar.

### 28.17.2.3 Rotor

For large machines the cheapest construction is to secure a laminated rim<sup>143,149</sup> to a fabricated spider that is shrunk on the shaft. The rim must carry its own hoop stress plus the load of the poles and coils. Laminations of rolled steel plate commonly have 0.2% proof stress of 450 MPa, suitable for rim speeds up to about 170 m/s at overspeed. Proof stress up to 700 MPa can be obtained, if necessary.

Sheet can be obtained of quality and width suitable for rims up to approximately 1.5 m diameter, so these can be built of complete rings, shrunk and keyed to the spider with enough interference to maintain contact at overspeed. Larger diameter rims have to be segmental; they will come free at just above running speed, but are kept true to the spider by keys that allow radial growth but not tangential movement. Some designs rely upon this key location, and do not have a shrink fit.

Two kinds of rim are used. The so-called *chain rim* uses segments about 5 mm thick spanning two or more pole pitches, clamped axially by close-fitting bolts. By suitably overlapping the segments and distributing the bolts, the rim can have a hoop strength up to 75% of that of a solid rim. The *friction rim* is being increasingly used. It has segments about 2 mm thick, to increase the number of surfaces in contact. They are clamped with high pressure by high tensile bolts in holes with some clearance. To build a good rim of either type the segments must be flat and of uniform thickness, and accurately aligned to ensure accurate dimensions of the keyways and the axial T-slots for the pole fixings.

Smaller rotors for 600 rev/min or more, especially horizontal ones, are built of discs up to 150 mm thick, shrunk on to a shaft, or spigotted together and held by through bolts, with bolted-on stub shafts. The diameter is limited by the size of plate available of suitable thickness and quality.

Poles are now most frequently built up of laminations about 2 mm thick. They, like the rim, carry unidirectional flux, so tensile strength, flatness, uniform thickness and magnetic permeability are important. It is not usually

thought necessary to insulate the laminations, though this would reduce the surface losses caused by harmonic fluxes in the airgap. The laminations are clamped tightly between heavy steel endplates, cast, forged or fabricated depending on the load imposed by their own centrifugal force and the end turns of the field coil.

Poles are fixed to the rim by dovetail, or more often by T-head, projections. These are secured in corresponding axial slots in the rim by taper keys driven in from each end. These pull the base of the pole against the rim. Large rotors may use as many as nine T-heads per pole; detailed analysis of the stress distribution is needed, e.g. by a finite element technique, to ensure that they share the total centrifugal force reasonably equally.

Copper damper bars, usually uninsulated, are fitted reasonably tightly in semi-closed axial slots in the pole face. They are brazed at each end to a copper segment to form a closed grid. Currents induced in them help to reduce the oscillations of load angle when a disturbance occurs on the power system, and to counteract the negative sequence stator current of unbalanced loads. Pole-to-pole links are sometimes fitted to make the grids into a complete cage, but in large machines centrifugal force and fatigue stresses can cause mechanical failures. If interconnection is needed, it is usually sufficient to braze the bars to a few thick copper laminations next to the end clamps of the poles. These provide satisfactory contact to the rim, which completes the circuit between poles.

Field coils on very small machines have several layers wound with round or roughly square-section copper, enamelled and wrapped with resin impregnated insulating fibre or braid. Larger rotors have coils wound with bare copper strip, bent on edge, and larger rotors still<sup>143</sup> use coils fabricated from straight lengths of rectangular section copper strip, brazed together at the corners. The cooling surface is increased by making some strips wider than the others, and placing these, singly or say in pairs, every few turns. With continuously wound strip-on-edge coils the finned effect can be produced conveniently on the sides or the ends of the coil, but not on both.

Insulation between turns consists of two layers of polyimide or aramid paper, or woven glass, with a thermosetting resin. After the coil has been consolidated by baking it under pressure, the interturn insulation is approximately 0.3 mm thick.

Wire-wound coils may be wound directly on to the insulated pole. Strip-on-edge coils may go directly on to the insulated pole, or on to a separate insulated spool which is then secured to the pole. Thick washers of resin-synthetic paper or resin-glass insulate the coil from the rotor rim and from the pole shoe, unless the spool has insulated flanges that do this.

Coil-to-coil connections are secured to the rim, the connection to the top turn (i.e. the outermost one) of a strip-on-edge coil may be brought down inside the coil, between it and the pole, then out beneath the bottom turn. Connections should preferably be arranged to carry the field current equally clockwise and anticlockwise round the shaft. Otherwise it will be magnetised axially, and the bearing surfaces may be damaged by induced currents.

Centrifugal force on the sides of the coil has a component tending to bow the turns, i.e. to bend them on edge away from the pole. To resist this one or several V-blocks (depending on the axial length) are secured to the rim between the poles. Pieces of insulating board of course are fitted between the bare copper and the metal V-block. It is often required that poles may be removed without removing the rotor from the stator bore, and V-blocks make this

difficult to arrange. Therefore in some designs, the coils are held by clamps that are secured to the pole itself; the two parts of each clamp are tightened together after the coil and its insulation have been fitted. Then the pole, coil and clamps can be withdrawn as a unit after the pole keys have been released.

#### 28.17.2.4 Stator frame and core<sup>26,143</sup>

The frame is a fabricated assembly of rings of steel plate connected by axial members of tubular, angle or channel section. It is often necessary to split the frame and core of a large vertical shaft machine into several segments for transport to site. These must be bolted together accurately to form a true circle, with the joint faces of the core fitting extremely closely together.

The core joints are avoided if the core is built into the assembled frame sections on site.

The lower endplate of the frame is bolted to the foundations; if the machine has a top thrust bearing the frame may have to support the thrust load as well as the core and windings.

The wrapper plate round the outside of the frame will usually have openings to receive the air-to-water heat exchangers.

The core is built of cold-rolled silicon steel, usually 0.35 or 0.5 mm thick. The reduction of loss that could be obtained with oriented-grain sheet is small, and rarely enough to justify the higher cost of it. The coreplates are assembled with spacers to form radial ventilating ducts, and are clamped between strong endplates.

#### 28.17.2.5 Stator winding (see Section 28.4)<sup>26,53,143</sup>

This is usually of the two-layer, fractional-slot type, using diamond coils with either lap or wave connections. The number of slots is often chosen to permit two or more parallel paths per phase, depending on the number of poles. Coils may be pulled, formed or made as single bars, depending on size. In large high-voltage machines they must be firmly secured in the slots and endwindings, especially if they are to suffer much thermal cycling, e.g. in pumped-storage units. Proper earthing in the slots and stress grading for a distance beyond the slot ends are essential to avoid surface discharges. Large and important machines now often have permanent instruments to give warning of any increase in electrical discharges in service.

### 28.17.3 Cooling

Except for small machines, closed-circuit air cooling is used. Most hydrogenerators rotate in one direction only, and radial-flow or axial-flow fans mounted on the shaft are commonly used. The heat is removed by air-to-water heat exchangers mounted on the back of the stator frame. About 4 m<sup>3</sup>/s of air is required per kilowatt of loss removed. In cold climates, some of the hot air may be taken from the machine and used for heating the station.

Reversing sets for pumped storage would have to use radially bladed fans, which have poor performance and efficiency. For these machines, and for highly rated machines needing carefully controlled ventilation, several motor driven fans are used.

Hydrogen cooling has not been applied to hydrogenerators, mainly because of the cost and practical difficulties of making an explosion-proof casing. However, when inertia

is not a controlling factor, a useful reduction in physical size can be achieved by water cooling the stator or rotor windings, or both.<sup>26</sup> Water cooling of only the stator winding introduces a multiplicity of joints which must not leak, but greatly increases the current capacity, or conversely allows the slot size to be reduced for a given rating; this slightly reduces the outside diameter of the core and significantly reduces the leakage reactance.

Water cooling of the rotor winding introduces more constructional difficulties and affects the design more profoundly. The excitation capability is increased without risk of exceeding the specified temperature limits, so a higher short-circuit ratio (longer airgap) is possible, improving the underexcited (line charging) capability. Alternatively a smaller machine with higher electric loading is possible with the stator design suitably adjusted. However, it may be necessary to adopt a size larger than the smallest determined from purely thermal considerations. This larger size may be needed to attain the desired inertia constant, or the lower capitalised cost of its lower losses may be enough to offset the lower first cost of the smaller frame. In some circumstances, water-cooled stator and rotor windings may be economically justified at ratings as low as 150 MVA; conversely, water-cooled stator windings with some form of improved air cooling for the rotor may be preferred on grounds of adequacy and simplicity for ratings as high as 700 MW.

### 28.17.4 Excitation

Vertical-shaft generators may use main and pilot a.c. exciters mounted above the generator, or separate motor-driven exciters. These often have a flywheel to maintain the exciter speed and output during momentary interruptions or reduced voltage of the motor supply.

Static thyristor equipment is now more often used, because it simplifies the mechanical arrangement of the unit, reduces the height, and avoids the possibility of an unacceptable run-out at the top of a tall shaft assembly. Thyristors also have the advantage of inherently high response, which is valuable when the generator feeds along transmission lines.

Slip-rings and brushgear are rarely troublesome, as the peripheral speed can be fairly low; 40 to 50 m/s is a usual limit.

Horizontal-shaft generators may use brushless exciters, overhung or two bearing depending on size and speed. Again static thyristors simplify the mechanical layout, especially if the generator has a turbine at each end.

### 28.17.5 Pumped storage units

Pumped storage units were originally installed as peak-leveilling units, running as generators at times of high system load, and as motors pumping water up to the top reservoir during light-load periods. A unidirectional set has separate pump and turbine, whereas a reversing set uses the same hydraulic machine either as a pump or as a turbine, depending on the direction of rotation.

The original purpose has been extended to provide spinning reserve and to deliver power into the system at a 'few seconds' notice to assist in maintaining stability if other generation, or a system interconnection, is suddenly lost. This introduces particular problems of thermal cycling and mechanical fatigue, especially with reversing sets, which may be required to go from full-speed pumping to reversed full-speed generating within seconds, and to do this perhaps

several times a day. For reversing units, separately driven fans are usually provided because rotor-mounted fans designed for both directions of rotation have low efficiency. Water cooling may be applied, as for generators, and may be particularly valuable for the damper cage if this is used for 'induction-motor' starting.

Figure 28.33 shows a cross-section of one half of the motor/generator of a reversible pumped-storage unit rated at 330 MVA, 18 kV, 0.95 p.f., 500 rev/min. The design at this output and speed approaches the limit achievable with present materials and air cooling. The outside diameter of the stator core is 6.2 m, the rotor diameter 4.5 m and the active core length 3.6 m. The mechanical design of the rotor is dominated by centrifugal stresses and the fatigue effects of reversals. The rotating parts weigh about 440 t, and the hydraulic thrust raises the load on the thrust bearing to almost 600 t.

#### 28.17.5.1 Starting<sup>26, 146</sup>

Methods available for starting and run-up of a machine in the pumping mode are: (i) by a direct-coupled auxiliary starting turbine or pony motor, (ii) by back-to-back connection with another machine driven by its own turbine and acting as a generator; (iii) from the power network through a step-down transformer, using the rotor solid pole-shoes or the damper winding as a cage for an 'induction' start; and (iv) from the power network through a variable-frequency

thyristor converter controlled to give an output over the range of a few hertz up to normal system frequency. In (iii) the pole-shoes or damping windings must be designed to carry the induced currents without excessive rise in temperature. In (iv) the machine moves from rest by induction torque, but at a low frequency it synchronises with the converter and thereafter remains in synchronism up to normal frequency, to be then synchronised with the power network. The starting equipment is expensive, but run-up is more readily supervised, and the damping cage (or pole-shoe) design is not constrained. The method is preferred for large units.

## 28.18 Salient-pole generators other than hydrogenerators

These are made for synchronous speeds ranging from less than 100 rev/min to 1500 rev/min for 50 Hz and 1800 rev/min for 60 Hz supplies: hence they have from 4 to more than 72 poles. Small 2-pole generators are also made in large numbers. The outputs for salient pole generators range from a few kilovolt-amperes up to about 60 MVA. Prime movers range from internal combustion engines burning petrol, gas (either natural gas or methane obtained from land-fill sites or biomass schemes) or diesel fuel and steam or gas turbines. Direct drive by an internal combustion engine is practicable over the whole range, though at 1500 and 1800 rev/min the output is limited by the maximum engine available power of about 5 MW. Typical ratings for low-speed two-stroke diesel sets are 15–60 MVA at 150–100 rev/min. Diesels, often four-stroke, in the speed range 428–1200 rev/min (14–6 poles) are particularly common, with outputs of say 10–45 MW. Four-pole generators with outputs up to about 60 MVA are driven via a suitable gearbox by high speed (up to 15 000 rev/min) steam or gas turbines.

### 28.18.1 Applications

Salient-pole generators are used both for stand-by applications and to continuously supply power. They can therefore be connected to public power systems, incorporated in marine installations (ships and oil rigs) or in a great variety of industrial plants. Where a *public system* requires unit ratings up to about 40 MVA, high speed, medium speed or low speed diesel sets can be installed more cheaply and more quickly than a gas or steam turbine set with its boiler and auxiliaries. The internal combustion engine set can deliver full load within a few minutes of starting, which can be done remotely if necessary; it will respond rapidly to changing load demand, and will have better efficiency at part load than the turbine. The slow two-stroke diesel is particularly suitable for the larger outputs (15–60 MVA), running economically on low grade fuel and with low maintenance costs. The recent focus of attention on emissions has had a marked effect on the choice of type of i.c. engine to be used. Engines burning gas are able to achieve lower level emissions of nitrous and sulphur oxides and are therefore proving very popular for new installations. In contrast, achieving acceptable levels of emissions with 2 stroke diesel engines burning low grade fuel is more difficult and costly.

Combined cycle installations are being increasingly used to attain higher thermal efficiency. Exhaust heat from a gas turbine that drives one generator is used to supply steam to a turbine that drives another. The turbines are high speed, geared down to, usually, the four-pole speed. For outputs

Figure 28.33 Section of a pumped-storage motor/generator

greater than the gearbox limit of about 60 MW, two-pole cylindrical rotor generators are directly coupled to the turbines.

For *marine applications*, high-speed or medium-speed generators are used. These can either be driven by dedicated diesel engines, shaft driven from the engine used for propulsion or, in larger installations by gas turbines.

For *ship propulsion*, medium-speed diesel or gas turbine driven generators supply d.c. through rectifiers, or variable frequency a.c. to motors coupled to the propellers. The domestic load may be supplied from the same generators, but often separate generators are used—this has the advantage of isolating the domestic supply from the converter harmonics.

*Oil rigs* can either use internal combustion engine-driven generator sets or gas-turbine-driven generators for their power depending on their size. The generators are required to supply the large drilling motors and mud-pump motors, and the domestic supply. The number, rating and reactances of the generators are chosen to avoid excessive voltage dip when a large motor drive is started, so that other loads are not badly affected. Rated outputs can be around 15 MW where gear-driven generators running at 1800 rev/min would be used or up to 25 MW directly coupled to the power turbine at 3600 rev/min.

*Industrial power stations* commonly use steam turbines if there is need for process steam, which is delivered through a back-pressure or pass-out turbine; or if waste heat is available to raise steam for generating electricity.

Gas and diesel engines are often used, alone or in combined cycle installations. Gas turbines are expensive to run, and are used only if rapid response to load is essential, or the fuel is locally not so expensive, e.g. in an oil refinery.

## 28.18.2 Construction

The *rotor construction* for these salient pole machines is determined by the rating of the unit and its peripheral speed. High-speed rotors with four or six poles and ratings up to about 30 MW can have integral poles which are made up of a series of laminations. These can be punched from sheet material using a die or a nibbling type press; alternatively, they can be manufactured using a laser cutting machine. The thickness of punchings is normally limited to less than 3 mm if one of these processes is used, which has the advantage of limiting the pole-shoe losses. Thicker plates up to 100 mm thick can also be used, in which case the pole profile is cut using a numerically controlled flame cutting machine. With this type of construction, due consideration must then be given to the extra surface losses which will occur in the pole-shoes.

For larger machines, i.e. above 30 MW, with bigger diameter rotors, the peripheral speeds will result in rotational stresses in excess of the safe limits for the laminated type of rotor materials. In this case, forged solid rotors with pole pieces integral with the shaft are used. Solid forged pole-shoes are secured by high tensile strength bolts after the coils have been put on.

For the lower peripheral speeds associated with multi-pole rotors, separate laminated pole pieces may be secured by dovetails or T heads in slots in the square or hexagonal middle portion of the forged shaft. Alternatively, the laminated poles may be bolted or dovetailed to the wide cylindrical rim of a flywheel on the shaft; or they can be fixed by dovetails or T-head slots in a laminated rim.

The laminated-pole construction is cheaper than a forged rotor, and reduces the cost of the stator winding too,

because fewer, wider, stator slots can be used with acceptably low eddy current losses in the pole faces.

Generators may have one or two *bearings*. Many diesel driven generators have only an outboard bearing, the driving end of the shaft being solidly coupled to the engine crankshaft flange. This shortens the set and saves the cost of a drive end bearing and the flexible coupling. It also allows the generator to be partly supported on a Society of Automobile Engineers (SAE) flange on the engine crankcase. The crankshaft bearing must carry half the weight of the generator rotor. A gearbox bearing can rarely do this, so gear-driven generators normally have two bearings.

The generator may be supported on sole plates grouted into the foundations, or may be bolted directly to the engine base plate, where this has been designed for the purpose. If transport and site lifting facilities permit, the generator can be delivered complete on its own bed plate; this is to be preferred as it saves erection time on site.

Often it is desirable to limit the vibration transmitted to the foundations, especially when the driver is a diesel engine. A common method is to put flexible mountings beneath the combined bed plate. These need to be chosen, or tuned, to isolate the vibration and not to permit resonance at any of the disturbing frequencies.

Class F *insulation* is always used on high voltage stator and some rotor windings, although class B temperature limits are often specified to extend the life of the machine and give some margin for an overload capability. Class H systems are common on low voltage generators and also on some medium voltage machines. Often class F temperature rises will still be specified even for machines with class H insulation systems in order to achieve an extended life.

Stator coils are usually of the pulled diamond type (see Section 28.4.1). Rotor coils are generally similar to those of hydrogenerators, but as they are smaller they are more often of the wound on edge construction using rectangular strip copper rather than fabricated. Where the rotor has integral poles, the field copper is wound directly onto the pole pieces by rotating the complete rotor or the laminated rotor core-pack about its longitudinal axis.

## 28.18.3 Ventilation and cooling

These generators are always air-cooled. If an adequate supply of clean air is available, open ventilation with an appropriate class of protection is used. If the air is only slightly dirty, it may be ducted to and from the machine, with filters on the inlet side. In a short machine the air is drawn through from one end to the other by a single centrifugal shaft-mounted fan. Longer machines have radial ducts in the stator core; the air enters the stator bore at both ends and is expelled radially through the ducts to the back of the core. In this case, shaft mounted axial-flow fans are used to drive the air through the machine.

In dirtier surroundings a totally enclosed machine is used. The primary (internal) air is circulated by shaft fans through an air to air heat exchanger (c.a.c.a. arrangement). The secondary (external, ambient air) is driven through the heat exchanger by one or more separate motor driven fans. Alternatively a water-cooled heat exchanger is used (c.a.c.w. arrangement). The materials used in the heat exchanger must be chosen to suit the quality of the water, e.g. tubes of aluminium brass or cupro-nickel if the water is salty. The limits of temperature rise may be adjusted in accordance with the maximum temperature of the secondary coolant. (see Section 28.5.)

## 28.18.4 Particular design requirements

### 28.18.4.1 Machines for operation in hazardous atmospheres

As a result of a vast increase in power generation for the oil industry, and a few catastrophic accidents, generators are required to be designed to operate safely in potentially hazardous atmospheres. BS EN 60079-10:1996 defines the different levels of hazard. Generators, especially when driven by gas turbines, are considered to operate in a zone-2 area. They must be designed and made to prevent any gas that is present being ignited, and compliance with the requirements must be certified by a type-N certificate granted by one of the nominated inspecting authorities. The requirements are specified in BS 5000-16:1997. They are many and complicated, but the major ones can be summarised thus. For a particular group of gases, the surface temperatures of all bare live parts must not exceed an ignition temperature defined for that group. Mechanical clearances on fans, including separate motor-driven fan units, must be greater than usual to prevent any contact between the stationary and the rotating parts, to avoid sparking or excessive local temperatures. Auxiliary electrical devices, including terminals, heaters, fan motors, etc., must all be of certified origin, with certificates of conformity to demonstrate that they comply with the requirements.

### 28.18.4.2 Reactances

$X_d$ ,  $X'_d$  and  $X''_d$  are those that have most influence on the design and the operation of the generator. A maximum  $X_d$  or minimum short-circuit ratio is usually specified. A minimum value of  $X''_d$  or a maximum  $X'_d$  are either specified or implied by specifying the permissible fault megavolt-amperes or the grade of voltage regulation required. For example, BS 4999-140:1987 specifies voltage regulation grades in terms of

- (1) accuracy of voltage control under steady load;
- (2) voltage dip when specified loads are suddenly applied; and
- (3) voltage rise when full load is suddenly removed.

This performance is with the automatic voltage regulator in control of course, but implies lower  $X'_d$  to achieve the smaller voltage dips and rises. As implied in, Section 28.6.1.4 it becomes expensive to specify a closer grade of voltage regulation than is really needed. The grade may be unattainable if  $X''_d$  is high to limit the fault megavolt-amperes.

### 28.18.4.3 Generators driven by internal combustion engines

ISO standard 8528 (equivalent to BS 7698:1993) entitled 'Reciprocating internal combustion engine driven a.c. generating sets' is applicable to generators used in these applications. Most of the standard is concerned with the engines, controls, etc., but Parts 3, 5 and 9 contain requirements for the generator, including definitions and limit values of parameters to do with voltage control.

The mechanical design of such sets must consider the transverse vibration and critical speeds of the shaft assembly, and also the possible torsional modes. BS 5000-3:1980 and ISO 8528 place the responsibility for seeing that the torsional behaviour is investigated with the supplier of the set, assisted by the makers of the engine and the generator. Some cyclic irregularity of the generator speed is inevitable:

the rotor inertia may be enough to keep it acceptably small, but an extra flywheel may be needed.

Cyclic irregularity of torque will occur at frequencies determined by the number of firing impulses per second. In low-speed sets (100–150 rev/min) one of these harmonic frequencies may lie near to 10 Hz, and around this frequency the eye is very sensitive to light flicker caused by fluctuation of voltage as small as 0.5%. The fluctuation may affect the operation of electronic equipment, mains ripple control systems, etc. If it is impracticable, or too expensive, to reduce the speed fluctuation by adding more inertia, the voltage swing can be reduced with a high response excitation system, phase-controlled to swing the generator flux in opposition to the speed.

If the cylinder torques are not all equal, there will also be torque fluctuations at rotational frequency or low multiples of it, i.e. in the frequency range  $1\frac{1}{2}$  to  $4\frac{1}{4}$  Hz. For most sets the natural frequency of electromechanical oscillation relative to the power system lies in this range. The resonant, or near-resonant, swings of load angle, power, voltage, etc., may nevertheless be tolerably small if the generator has a sufficiently effective damper winding.

## 28.19 Synchronous compensators

Synchronous compensators are synchronous motors running without mechanical load; they are used to generate or absorb reactive power, in order to control the voltage of a power system. Hence they are usually installed near a load, or part way down a long transmission line to support the voltage at the intermediate point.

At times of heavy load, compensators run overexcited to supply the magnetising power demanded by the load (transformers and induction motors) or the inductive  $I^2X$  losses of the line. At light load they must run underexcited to take reactive power from the line to offset the capacitive line-charging current and so avoid excessive voltage rise. In many h.v. systems (200 kV and above), the line capacitive power exceeds the load magnetising power, even at times of heavy load.

Static inductors and capacitors, switched to suit the system conditions, can be used for the same purpose, but the synchronous compensator has the advantage of providing continuously variable control, and with thyristor excitation it can have a response fast enough for many contingencies.

Thyristor-controlled static compensators give rapid and continuously variable control, but require filters to limit harmonic generation in the power system. Lower maintenance and running costs give them an advantage over rotating machines in most new installations.

Synchronous compensators up to 300 MVAR are in service. Air cooling has been used up to ratings of 40 MVAR, but hydrogen cooling is now normal to reduce the size and the light-load losses, the latter by reducing windage. As the shaft-end need not emerge from the hydrogen-tight casing, no shaft seals are needed. Losses at full load (overexcited) are in the range 0.01–0.016 MW per MVAR of rating.

The underexcited capability is usually about half the overexcited rating; for this a short-circuit ratio of about 0.75 is desirable, to ensure that at the underexcited capability the rotor has sufficient positive excitation to maintain stability. A short-circuit ratio of 1.3–1.5 will provide an underexcited capability level equal to the overexcited level, but the machine is larger and has higher losses than the design with the lower short-circuit ratio. Water cooling has been used for stator and/or rotor windings at ratings of 200 MVAR or more.

The compensator may be run up to speed as an induction motor through a step-down transformer, by means of a direct-coupled pony motor, or by using a variable-frequency inverter.

## 28.20 Induction generators<sup>157–164</sup>

If an induction motor is driven above synchronous speed it will deliver power to the system, with a slip of about  $-0.05$  at full load. It has the advantage of simple construction, and needs no excitation, speed governing, or synchronising. This makes it cheaper than a synchronous machine and operationally more convenient, e.g. for unattended hydrostations or wind-driven generators. The disadvantage is that it must draw from the power system magnetising power of  $0.5\text{--}0.75$  of its rated active power output, and this has limited the size to about 5 MW.

Research in the USA has shown that, by using static var compensators to supply the reactive power, it should be practicable to run induction generators of a few hundred megawatts output either in parallel with synchronous generators or even as a separate supply system. Speed control would then be essential to fix the frequency of the separate system.

Connection to the power network can be made merely by closing the breaker when the machine is up to synchronous speed. To reduce the current surge in large machines, the machine can be allowed to build up to normal voltage by first connecting a capacitor and then synchronising in the usual way. By suitable design of the machine and the static compensator, efficiency and stability can be comparable to those of a synchronous machine.

The most suitable locations appear to be where transmission by h.v. cable is required, for the cable capacitance will contribute to the reactive-power requirement, and at points in the system where substantial var support is installed anyway, the generator being run when active power is also required.

To maintain stability following system faults requires considerable reactive-power capacity beyond that needed for steady full-load operation. Where the system is strong enough, however, this is not too costly, and the total cost of the induction generator installation can be less than that of a synchronous unit.

## 28.21 Standards

A selection of standards relevant to generators published by ANSI, BSI, Cenelec, IEC, IEEE and NEMA is listed below. Revisions are made every few years, so care must be taken to use the most recent issue, or an earlier one if that is relevant. Member countries of the European Economic Community are required not to have national standards that conflict with Cenelec Euronorms or Harmonised Documents. Some of these documents are technically equivalent to, or closely similar to, IEC standards that were adopted as the bases for harmonisation. British Standards are technically equivalent to relevant Cenelec documents, or to IEC standards if a corresponding Cenelec standard has not been published. BS EN 60034 parts 1 to 22 are numbered consistently with IEC 60034–1 to 60034–22. For a full comparison, see BS 4999: Part 0. The parts of BS 5000 relate to machines of particular types or for particular applications, and call for parts of BS 4999 where appropriate.

## 29.1 Introduction

Electrochemical science is an interdisciplinary subject, which is unique both in its concepts (the chemical interactions between matter and electrons particularly across interfaces) and general in its applications. Electrochemical reactors use electrical energy to isolate elements from their compounds, as in the electro winning of metals (copper, silver, aluminium) or chlorine, or the production of hydrogen and/or oxygen by the electrolysis of water. On the other hand electrochemical power sources, batteries and fuel cells store chemical energy, which can be instantly converted into d.c. electrical energy. Corrosion, an electrochemical process, wastes both energy and materials.

## 29.2 Cells and batteries

### 29.2.1 Definitions

The term 'battery' means an assembly of voltaic primary or secondary cells. Batteries of secondary cells are known also as storage batteries or accumulators.

- A primary cell is used once until it is discharged and then discarded.
- A secondary cell needs to be charged after it is made before use. Once discharged the cell can be recharged and used again.

#### 29.2.1.1 Terminology

*Open-circuit voltage* is the voltage at the terminal of the cell when no current flows, i.e. without an external loading circuit connected. It depends on the operating history of the cell, but cells are usually designed to have a relatively flat discharge curve until the cell is almost totally discharged after which the voltage drops quickly.

*Cell capacity* is the amount of energy, usually stated in ampere-hours that the cell can provide without the terminal voltage falling below a specified value. This is also stated as its 'C' rate which is the rate at which a fully charged cell would be discharged in one hour, i.e. a 5Ah cell would have a C rating of 5A.

*Depth of discharge* is the percentage of the cell's capacity which has been discharged.

*Shelf life* is a measure of the ability of the cell to retain its charge under the storage conditions encountered.

*Cycle life* is the number of charge/discharge cycles a secondary cell can tolerate before performance failure.

*Charge acceptance* is the proportion of the charge input which the cell can give out again without the voltage falling below a specified value, i.e. is a measure of the ability of a cell to accept charge.

*Charge voltage* is the voltage developed across a secondary cell when it is under charge. This voltage can be up to 50% higher than the rated discharge voltage of the cell. It increases with the charge rate and with low temperatures.

### 29.2.2 Principles

In both primary and secondary batteries the individual cells consist of a positive and negative electrode immersed in an ion-conducting medium called the electrolyte and generally separated by a porous non-conducting diaphragm, called the separator. The electrodes, which must be electrically conducting, may consist of a single rod or plate, or a number of these welded or bolted together in parallel. In some cells (for example, the conventional primary 'dry' cell) the outer metal container may constitute one of the electrodes. The two electrodes have different electrical potentials when immersed in the common electrolyte and the difference between these potentials represents the e.m.f., or open-circuit voltage, of the cell.

In both primary and secondary cells the electrical energy released during discharge is derived from the chemical energy liberated as a result of the chemical reactions taking place in the cell. These reactions involve charged particles in the electrolyte, known as 'ions'. Ions, if positively charged, have a deficiency of electrons, and if negatively charged, carry an excess of electrons. As indicated below, certain ions tend to react with the electrode in their vicinity, causing a transfer of electrons from ions to electrode, or vice versa. If this reaction is allowed to proceed (for example, by closing the external circuit to which the battery is connected), the transfer of electrons from one electrode to the other gives rise to an electric current flowing in the external circuit conventionally from the positive to the negative electrode: the flow of electrons is in the opposite direction. Thus, an *anodic* reaction involving the release of electrons occurs at the *negative* electrode, and a *cathodic* reaction involving the capture of electrons at the *positive* terminal of the battery. In electrochemical reactors the reverse is true, i.e. *anodic* reaction at the *positive* and *cathodic* at the *negative* electrode.

### 29.2.3 Redox process

The chemical reactions at the electrodes are either 'reduction' or 'oxidation', i.e. 'redox' processes. The basic feature of such reactions is the gain or loss, respectively, of one or more electrons, e.g.

Here  $e$  represents the electron. H, Cu, Zn and Pb represent atoms, or (when charged) ions of hydrogen, copper, zinc and lead. The sign + indicates a deficiency of one electron; 2+ indicates a deficiency of two electrons.

The gaseous hydrogen formed by the first reduction process, if allowed to accumulate, would rapidly polarise the electrode, and the electrochemical reaction would virtually cease. To overcome this, the positive electrodes of many kinds of batteries are selected from substances which readily undergo a depolarising reaction with hydrogen. Typical examples are manganese dioxide ( $\text{MnO}_2$ ), used in the primary dry battery, and lead dioxide ( $\text{PbO}_2$ ), used in the lead/acid storage battery. Negative electrodes must be readily oxidisable, and for these active metals such as zinc, lead and cadmium are generally chosen.

Electrode potentials and redox reactions are not confined to metals, but include such elements as hydrogen, oxygen, chlorine or fluorine, either in the gaseous form or in combination with some metal in the form of an inorganic salt.

Electrode potentials are generally expressed with respect to hydrogen, which for standard conditions is assigned a potential of zero. It is an advantage to have at the two electrodes redox reactions widely spaced on the potential scale to give the highest cell e.m.f. But the choice is restricted by other factors—in particular, the type of electrolyte. Formerly electrolytes were aqueous solutions of salts, acids or bases. Organic electrolytes (e.g. propylene carbonate containing ionic conductors) and molten salts (e.g. LiCl–KCl eutectic, which melts at 352°C) are now being used, so that more active ‘anodes’ such as lithium or its alloys, which react with aqueous solutions, can be incorporated.

## 29.3 Primary cells

Primary cells differ from secondary cells in that the electrochemical reactions are not reversible, or, if so, only to a very limited extent. This may be primarily due to physical factors such as a loss of electrical contact by the chemical products of the discharge. In the case of the primary conventional ‘dry’ cell, for example, failure often occurs through excessive corrosion of the zinc can which forms one of the electrodes. In secondary cells or accumulators the reactions are readily reversible. The original chemical compounds can be re-formed by passing a direct current through the cell in the reverse direction, and accumulators can generally be submitted to many cycles of discharge and charge in this way.

The simplest primary cell, and one of the earliest (1836), is the *Daniell* cell, named after its inventor. Since many of the principles involved are common to other systems, this cell will be described in some detail. The electrodes are copper and zinc, and the electrolyte is a solution containing sulphate ions. The copper electrode is immersed in a solution of copper sulphate held in an inner porous pot, and the zinc electrode is held in a solution of zinc sulphate or dilute sulphuric acid in the outer glass vessel. The cell is shown diagrammatically in *Figure 29.1*.

The chemical reactions on discharge can be represented as follows:

Early forms of this cell were made with both electrodes immersed in dilute sulphuric acid, and had somewhat

Figure 29.1 Daniell cell

different reactions: the main reaction at the negative electrode was (as above) the formation of positively charged Zn ions, but in the presence of the acid ( $\text{H}_2\text{SO}_4$ ) hydrogen was also produced, by a corrosion reaction. At the positive electrode the reaction was  $2\text{H}^+ + 2e^- \rightarrow \text{H}_2$ ; and as the discharge reaction proceeded, hydrogen gas accumulated on the electrode surface, polarising the cell and depressing the terminal voltage. Other factors in the voltage ‘fall-off’ are (a) over-voltages arising from the kinetic limitations of the electrode reactions themselves, (b) the slow diffusive mass transfer of the ions up to the electrode surfaces, and (c) the ohmic resistance of the electrolyte. Substituting sulphuric acid by copper sulphate ensured that copper and not hydrogen ions were discharged at the positive electrode, eliminating the counter-e.m.f. By placing the zinc electrode in its own zinc sulphate electrolyte, the evolution of hydrogen was eliminated; but this made it necessary to enclose the copper electrode and its electrolyte in a porous pot, increasing the ohmic resistance of the cell.

### 29.3.1 Leclanché (zinc–carbon) cell

In its ‘dry’ form, the Leclanché cell is the most common. A zinc plate or container forms the negative, a carbon plate or rod the positive electrode. The electrolyte is aqueous ammonium chloride. Through ionisation of the water, hydrogen and hydroxyl ions are produced ( $\text{H}_2\text{O} \rightarrow \text{H}^+ + (\text{OH})^-$ ). During the discharge the zinc electrode is oxidised in the reaction

and hydrogen migrates to the carbon. Polarisation is avoided by surrounding the carbon by manganese dioxide, which participates in the redox reaction

and the complete cell reaction, in which the electrolyte is also involved is

corresponding to an open-circuit e.m.f. of about 1.5 V. The presence of zinc and ammonium chlorides in the electrolyte keeps the acidity at the right level and helps to reduce polarisation of the zinc electrode by the flocculent jelly-like zinc hydroxide that would otherwise coat the surface. In practice, the cells are not strictly ‘dry’, as the electrolyte is a thick paste. The cell (*Figure 29.2*) comprises: (a) a central rod forming the positive terminal; (b) a depolariser of manganese dioxide (mixed with graphite or a highly active form of carbon black known as acetylene black to improve its

Figure 29.2 ‘Dry’ Leclanché cell

conductivity) that is liberally moistened by the electrolyte; (c) a thin layer of jellified electrolyte; (d) a hard-drawn zinc outer can forming the negative terminal; and (e) a seal, such as a card disc covered by a layer of bitumastic compound. Recent improvements, particularly in high rate performance, have been achieved by the replacement of the bulk of the ammonium chloride in the electrolyte with zinc chloride.

### 29.3.1.1 Performance

In many applications the use is intermittent. Polarisation develops as the current flows; during rest periods the cell recovers. *Figure 29.3* shows typical curves for a U2 cell discharging continuously through a lamp, the resistance of which varied from 1.32 to 1.03  $\Omega$  during the discharge. The cell dimensions are 32 mm diameter, 57 mm height and 0.1 kg mass. Cell behaviour in store and in transit ('shelf life') is lengthened by adding a soluble mercury salt to the electrolyte, which lightly amalgamates the active surface of the zinc container. Shelf life is reduced with high, and extended with low, ambient temperatures.

### 29.3.1.2 Flat and layer cells

Flat and layer cells have been developed for transistorised electronic equipments. In a duplex type the positive and the negative electrodes are placed on opposite sides of an electrically conducting diaphragm impermeable to the electrolyte. In the layer-built battery the zinc plate serves as the conducting diaphragm as well as the negative plate. On the opposite side this is first coated with a thin adherent layer of carbon mixed with a plastic resin, which functions much as the carbon rod in the cylindrical cell. Against this carbon layer is placed a moulded cake of the usual black depolariser mix and next to it a layer of absorbent material, such as filter paper, impregnated with the electrolyte. Another duplex electrode is placed on top of the first, and in this way a multicell battery of any desired voltage can be built up.

Sealing presents a particular difficulty with layer-built batteries. Obviously, there must be no electrical contact between the electrolytes of neighbouring cells, as this would permit leakage current. Also, some provision must be made for the release of adventitious gas from each cell. One means of sealing is to separate the adjoining duplex electrodes with annular spacing pieces and to cover the edges of the whole battery in wax or a suitable cold-setting plastic resin. Another way is to encapsulate the unit in a tightly stretched plastic stocking which is shrunk into position by gentle heat after application. Yet another method is

Figure 29.3 Discharge of a U2 cell

to enclose the edges of each duplex diaphragm in an annular envelope of rubber or a plastic material, shrunk into position by heat. To reduce the risk of leakage, such envelopes may be cemented to the diaphragm and the assembled unit sealed together or firmly wrapped with plastic tape. Thin strips of rubber or suitable plastic materials in this form are sufficiently permeable to hydrogen to allow the release of gas, and the construction allows for sufficient expansion to release any internal pressures that may develop, without permitting significant leakage of electrolyte.

### 29.3.2 Standard cells

The Weston standard cell (*Figure 29.4*) has a cadmium/cadmium sulphate negative electrode, an electrolyte of cadmium sulphate and a mercury/mercurous sulphate positive electrode. To give added stability, the cadmium is amalgamated with mercury and the cell assembled in an H-shaped glass vessel with platinum leads to the terminals. The cadmium and mercury sulphates are usually prepared as thick pastes by digesting fine crystals of the salts with cadmium sulphate solution. Small quantities of sulphuric acid are added to reduce any tendency of the salts to hydrolyse.

When a saturated solution is used for the electrolyte, the cell is termed 'normal' and has an e.m.f. of 1.01862 V at 20°C (for e.m.f.s at other temperatures see reference 2).

### 29.3.3 Alkaline cells

Three alkaline cells use zinc for the negative electrode.

#### 29.3.3.1 Copper oxide/zinc

The positive electrode or depolariser is CuO, the electrolyte a solution of caustic soda of relative density about 1.2. The cell was formerly common in railway signalling, being cheap to make and able to deliver intermittent currents over considerable periods. The open-circuit e.m.f. is about 1.0 V, and on load 0.5–0.7 V. The reaction at the positive electrode involves the reduction of the copper oxide, while at the negative the zinc is oxidised:

#### 29.3.3.2 Silver oxide/zinc

The silver oxide/zinc cell has military and other special fields of application. With appropriate modifications this couple will also function as a reversible cell, at any rate for a limited number of cycles. Batteries of cells have outputs four to five times those of any other system for the same weight and

Figure 29.4 Weston standard cell

volume, and they are particularly in demand where very high currents and a low weight and volume are required, as in torpedo batteries, guided missiles and space satellites. In the primary form the batteries may be stored dry for long periods and brought into action by priming with electrolyte either by some pressure device or simply under the influence of gravity. To reduce polarisation, the electrodes are generally made porous. In one method of manufacture the positive electrode is made by sintering silver powder, the porous compact then being anodised to convert it to silver peroxide ( $\text{Ag}_2\text{O}_2$ ). The zinc electrode is made from a paste of zinc oxide and caustic potash solution which is pressed into a screen of a suitable metal, such as silver or silver-plated copper. This is then reduced electrolytically to spongy zinc in dilute alkali solution. The electrolyte is caustic potash solution of about 30% concentration. A thin separator made of cellophane or paper may be used to prevent the plates from coming into contact and causing a short-circuit.

The discharge reactions at the electrodes are analogous to those already described for the copper oxide/zinc cell, but the silver peroxide passes through an intermediate stage to silver oxide ( $\text{Ag}_2\text{O}$ ) before being reduced completely to metallic silver. The two separate reduction stages each have their own characteristic potential, so the discharge voltage curve of the cell with freshly prepared electrodes has two plateaux, a short one at about 1.80 V and a much longer one at about 1.50 V. The second portion of the discharge at about 1.50 V per cell or less, depending on the rate, remains remarkably steady until the active materials are exhausted, when the cell voltage falls sharply.

#### 29.3.3.3 Mercury oxide/zinc

The electrolyte is caustic potash, but the elements are merely moistened. Known as the Ruben-Mallory cell, the mercury oxide/zinc cell has very low standing loss and gives steady voltages for long periods on low discharge rates. For such applications as hearing aids it is made in the form of a small metal button; as batteries of 6–8 V the applications are to portable transistorised radio receivers and 'walkie-talkie' sets. Mercuric oxide ( $\text{HgO}$ ), mixed with 5–10% graphite to increase conductivity, acts as the positive depolariser. The mixture is compressed into a pellet, and in the button form this is placed in contact with the steel cup that makes one half of the button. A pellet of compressed zinc powder with a small amount of mercury is in contact with the other metal half of the button, which may be of copper. The separator may be a layer of absorbent paper saturated with the caustic potash solution. The outer surfaces of the two metals are insulated from each other by a plastic grommet, and form the terminals. Such sealed buttons have a capacity of a few milliampere-hours. In other forms the zinc electrode may be a coiled strip or perforated sheet, and the electrolyte is a jelly with gelling agents such as carboxymethylcellulose. The reactions are similar to those of other alkaline couples:

positive:  $\text{HgO} + \text{H}_2\text{O} + 2e^- \rightarrow \text{Hg} + 2(\text{OH})^{--}$

negative:  $\text{Zn} + 2(\text{OH})^- \rightarrow \text{Zn}(\text{OH})_2 + 2e^{--}$

The open-circuit cell e.m.f. is 1.35 V, and the terminal voltage on load is 1.25–1.0 V. Prolonged low-rate discharges are obtainable. Standing losses are very low.

#### 29.3.3.4 Air depolarised

These systems are essentially hybrids between true batteries which contain both electrode materials within themselves

and fuel cells (see Section 29.5) which contain neither. In principle, they exhibit very high energy densities. In practice, however, various problems have been encountered, such as polarisation of the air cathode.

Zinc-air batteries (see below) have been the most successful, but aluminium-air, iron-air and lithium-air systems all have their protagonists. Lithium must be employed in strongly alkaline solutions to avoid reactions with the aqueous cell electrolyte. Aluminium-air systems are particularly attractive, at least in principle. In this case it is envisaged that the aluminate solutions which are produced as the batteries are discharged would be recycled to the aluminium smelters and 'fuel' (e.g. aluminium foil) would, if the batteries were used for traction, be obtained at suitable aluminium filling stations(!) during a journey to replace that used in the cells. The aluminate solutions could be tapped off at the same time.

Analogous to the carbon/zinc Leclanché cell, the air depolarised cell uses atmospheric oxygen as depolariser for the porous carbon electrode, which is made by roasting finely divided carbon and charcoal with a binder and then wet-proofing (e.g. by paraffin wax) to render the interior hydrophobic. The carbon electrode is only partially immersed in the electrolyte, and oxygen is readily adsorbed from the air. The negative electrode, of large plates of zinc lightly amalgamated with mercury, is completely immersed. A cell generally consists of two zinc plates flanking one carbon electrode, with capacities up to several hundred ampere-hours.

One range of cells has as electrolyte a solution of caustic soda. The essential reaction at the positive (oxygen) electrode is the reduction of oxygen with the production of  $(\text{OH})^{--}$  ions, and at the negative (zinc) electrode these contribute to the usual oxidation reaction, as in the copper oxide/zinc cell. The open-circuit e.m.f. is about 1.45 V; the terminal voltage on load for small currents is about 1.3 V, reducing to about 1.1 V at the end of the discharge.

The Le Carbone AD cell has as electrolyte a solution of ammonium chloride, which reduces polarisation at the zinc electrode by the action of zinc hydroxide. Large batteries of this type have been used in European railway signalling.

#### 29.3.3.5 Alkaline manganese batteries

Another important recent development, providing up to 50% more power than Leclanché cells of the same volume uses dilute KOH electrolyte in a manganese dioxide/zinc cell with a reverse type of electrode assembly. The zinc anode paste is held in a porous tubular separator surrounding the centrally placed current-collecting nail anode. The cathode mixture of  $\text{MnO}_2$  and graphite is highly compressed in the form of annular tablets and these are packed concentrically around the zinc anode. The whole assembly is contained in a thin-walled steel can, with the usual plastic disc-bitumen closure. The extra capacity over standard cells is due to the greater amount of  $\text{MnO}_2$  (40–70%) the absence of solid  $\text{NH}_4\text{Cl}$  and the higher conductivity of the KOH electrolyte.

### 29.3.4 Water activated cells

Water activated cells are stored dry for long periods, then activated by filling with (or immersion in) salt or fresh water; in the latter case, sodium or potassium chloride is included in the cell to increase its conductivity.

#### 29.3.4.1 Silver chloride/magnesium

Silver chloride/magnesium cells are costly, but can deliver very large currents for short periods, typically for electric

torpedoes. When flooded with sea water, they become immediately active. The positive electrode (silver chloride) is a thin plate obtained by rolling a slab cast from the molten salt or by chloridising thin sheets of silver. The negative electrode is formed from magnesium strip or sheet. The electrodes are separated by rubber bands, absorbent paper, ebonite forks, or glass beads cemented to the electrode surface. Cylindrical cells with coiled plates have been used in batteries for meteorological pilot balloons. During discharge, silver chloride is reduced to metallic silver and the chloride ions  $\text{Cl}^-$  migrate through the aqueous electrolyte to the negative (magnesium) electrode, which is oxidised to magnesium chloride ( $\text{MgCl}_2 \cdot 6\text{H}_2\text{O}$ ), with the transfer of electric charge. The formation of silver raises the conductivity during discharge: this counteracts polarisation and tends to stabilise the terminal voltage. The e.m.f. is about 1.7 V, and the terminal voltage during discharge falls from 1.5 V to 1.0 V.

#### 29.3.4.2 Copper chloride/magnesium

The chemical reactions are similar to those in the foregoing; the cell is cheaper, but the voltage is lower. Batteries of this type have been used in radar-sonde and other meteorological equipment. For higher voltage at low discharge currents a bipolar construction with duplex electrodes has been used. Positive plates are made by pressing the pelleted salt into copper screens or by dipping into molten chloride. Duplex electrodes are made by pressing or welding positive and negative electrodes to opposite sides of a thin copper foil.

#### 29.3.4.3 Lead oxide/magnesium

The lead oxide/magnesium cell is simple, and comprises a fully formed lead dioxide positive plate (as in a lead/acid secondary cell), flanked by a U-shaped magnesium negative plate, with absorbent paper separators. The paper is impregnated with potassium chloride solution, then dried before assembly. The base of the element is left open and the cell is activated by dipping into fresh water for about 30 s. The electrode reactions are the reduction of lead dioxide to lead at the positive, and oxidation of magnesium to magnesium hydroxide at the negative, electrode. A two-cell battery for a pilot balloon lamp gives typically 0.3 A at 3.0 V for 30 min at temperatures down to 0°C. As the discharge reactions are exothermic, batteries can still operate in ambient temperatures of  $-40^\circ\text{C}$ .

### 29.3.5 Acid cells

Primary cells with acid electrolytes have been developed for special military and meteorological requirements.

#### 29.3.5.1 Lead oxide/zinc (or cadmium)/sulphuric acid

These cells can be stored 'dry' for long periods and activated as required, an advantage in radio-sonde equipment, meteorological balloons, telemetering in experimental guided missiles and similar special applications. Batteries are referred to as 'short-duration reserve'. Lead dioxide electrodes (like those in lead/acid secondary cells) are welded in parallel according to the capacity required, interleaved with sheets of zinc or cadmium, and separated by thick strips of absorbent paper. The sulphuric acid electrolyte, of relative density 1.270 at 15.5°C, can be introduced some hours before use. The chemical reactions involve the reduction of lead dioxide to lead sulphate and oxidation of the negative electrode to zinc (or cadmium) sulphate. The

cell e.m.f. is 2.5 V (with zinc) or 2.2 V (with cadmium). Corrosion of the zinc is reduced by amalgamation obtained by adding about 1% of mercuric sulphate to the electrolyte. The zinc couple gives higher voltage and discharge rate but at temperatures below 10°C, the zinc is polarised by the build up of a reaction product; and at higher temperatures local action is acute, standing loss is high and accelerated activity on discharge can lead to gas polarisation. The cadmium negative is less temperature sensitive, does not require amalgamation and gives satisfactory performance over the range 0–60°C. Typical voltages for a three-cell battery at 3 A discharge for 3 min are 6.8–6.5 V (zinc) and 6.3–6.0 V (cadmium).

#### 29.3.5.2 Lead dioxide/lead/perchloric acid

Excellent discharge reactions are obtainable with perchloric (or fluoboric or fluosilicic) acid producing soluble lead compounds. Polarisation by the build up of reaction products is considerably reduced, so that it is not necessary to increase the surface of the electrodes by making them porous, as in a secondary cell. Nearly all of the active electrode material is usable, giving a high output/mass ratio. But for the same reason the cells must be used soon after priming, to avoid high standing loss. The cells are useful where they can be stored dry and primed immediately before use, and where low-mass batteries are required for large currents for relatively short periods. The positive plate is made by electrodepositing a thin non-porous film of lead dioxide on a sheet of nickel, iron or copper from a bath of lead perchlorate, lead nitrate or sodium plumbate. The negative plate may be made by electrodepositing thin layers of lead on a similar metal conductor, or directly from lead sheet. The plates are connected in parallel packs, the interleaved negatives being separated from the positives by spacers allowing rapid ingress of the electrolyte. The latter is held in compartments above the cell and allowed to enter the cell when the cell is primed. During discharge, lead dioxide is reduced to lead monoxide which is at once converted to lead perchlorate; the lead negative is oxidised to the same final product. Batteries have been constructed on the bipolar principle, the lead and lead dioxide being deposited on opposite sides of a nickel sheet. The e.m.f.s with electrolytes of 40–60% concentration range from 2.1 V (perchloric acid) to 1.9 V (fluoboric and fluosilicic acids). Perchloric acid in high concentration can become explosive in the presence of organic materials such as paper, sawdust, etc. Cells with the alternative electrolytes present no such risk, but have lower outputs.

## 29.4 Secondary cells and batteries

A secondary (or storage or accumulator) cell consists essentially of two electrodes held apart by separators and immersed in an electrolyte, the assembly being fitted into a suitable container. In the lead/acid cell the positive electrode is lead dioxide and the negative is pure lead in spongy form. In the alkaline cell the positive is nickel hydroxide and the negative is iron or cadmium. The electrolyte for the former cell is dilute sulphuric acid and for the latter, dilute potassium hydroxide.

### 29.4.1 Lead/acid cells

The chemical reactions follow the redox pattern (see Section 29.2.3). The current in the external circuit flows conventionally

from the positive to the negative electrode. The two reactions can be written as follows:

The reversible potentials are  $E_+ = +1.685 \text{ V}$  and  $E_- = -0.356 \text{ V}$ , giving an open-circuit e.m.f.  $E = 2.041 \text{ V}$ .

#### 29.4.1.1 Charge and discharge reactions

A secondary cell must be connected to a d.c. supply for charging, positive to positive and negative to negative. During *charging* the reactions are

The fully charged cell has

and the overall cell reactions are

During *discharge* the active parts of both electrodes are converted to lead sulphate, and the concentration of the electrolyte is reduced by both the removal of sulphate ions and the formation of water. During *charge* the lead sulphate at the negative plate is reduced to spongy lead, and at the positive electrode to lead dioxide with the release of sulphate ions at both plates and an increase in the concentration of the electrolyte. Measurement of the concentration indicates the state of the electrodes: the relative density of the electrolyte is read by a hydrometer.

Typical charge/discharge cell voltages are shown in Figure 29.5. Lead sulphate, the product of the discharge reaction, is practically insoluble in the electrolyte, a factor that endows the cell with its high degree of reversibility. During cycling the lead sulphate remains where it is formed, and the structure of the active materials is relatively undisturbed.

#### 29.4.1.2 Materials

Lead dioxide and spongy lead are the active materials, but it is necessary to provide metallic frames or supports for them. The success of the modern secondary cell depends on plate design and manufacture, and on the separators that prevent internal short-circuits and help to retain the active material in position.

**Figure 29.5** Typical charge and discharge voltages of a lead-acid cell

## Plates

**Planté (formed) plate** The positive plate has its effective surface area increased ten-fold by forming close-pitched fins on the surface of a pure lead plate. The negative plate was commonly of a 'box' form.

**Faure (pasted) plate** The active material applied to open-mesh grids cast in antimonial lead is a paste made by mixing lead oxide with water and sulphuric acid. The plate is seasoned, dried and then electrochemically converted to lead dioxide or spongy lead by charging in dilute sulphuric acid. The grid acts both as a support for the active material and as the conductor of the current to and from the active material. The merit of the pasted plate is that the grid can be cast in precisely defined thin sections as low as 1.5 mm or less, and the ratio between active material and carrier grid is high. In addition to the standard gravity die-casting process, in modern developments, thin grids are made by stamping or punching suitable patterns from thin pure lead or lead-calcium alloy sheet. The red lead and litharge originally used for the positive and negative plates have been superseded by a grey oxide containing one-third fine metallic lead particles and two-thirds lead monoxide.

Reference has already been made to the box type of pasted negative plate used with Planté positive plates, in which the paste is held in the grid by thin sheets of perforated lead covering both surfaces. The box negative plate is however costly, both on materials and manufacture, and has now been largely superseded by the common pasted negative plate.

**Separators** In some cells the separators serve only to keep the plates equidistant; in others they act as diaphragms to prevent internal short-circuit or to retain the active material.

Earlier wood separators have been almost entirely superseded by artificially made forms. One of the most successful is a microporous polyvinyl chloride (PVC). It has a high degree of diffusability, a low electrical resistance in acid and great durability under normal battery conditions. It is used in all types of lead/acid batteries. Another type of separator is made by sintering fine particles of PVC, and yet another by impregnating an absorbent paper with an acid-resistant resin such as phenol formaldehyde which both stiffens the paper and protects it against attack by the acid.

The profile of the separator is of interest. One product of the chemical reaction at the positive plate is water, the other being lead sulphate, which removes  $\text{SO}_4$  ions from the electrolyte. The acid is doubly diluted at the positive plate, whereas at the negative only lead sulphate is formed. It is, consequently, necessary to provide a greater reservoir of acid adjacent to the positive plate, and in cells where the amount of acid is minimised it is usual to make separators with ribs which rest against the plate surface.

**Electrolyte** Different concentrations of the sulphuric acid electrolyte may be used, depending on the application for which the particular battery has been designed. The voltage of the cell depends on the concentration of the electrolyte, being higher for higher concentrations. Also, the minimum electrical resistivity at  $20^\circ\text{C}$  occurs at a concentration of about 31%, equivalent to a density of 1.225; and the minimum freezing point at a relative density of 1.300. Taking these and other factors into account, stationary cells are generally filled with acid of relative density 1.200–1.215; automobile and traction batteries, 1.275–1.285, or in tropical climates 1.240–1.260.

One important operational aspect of the electrolyte concerns *impurities*. Impurities such as chloride and acetic or nitric acid attack the positive grids and are generally kept to a minimum in both the filling-in acid and the 'topping-up' water which is added to replace water lost by evaporation and by electrolysis during charging. Metals such as iron and manganese cause self-discharge of both positive and negative plates, while nickel and copper are 'plated out' on the negative and also cause self-discharge. Limits for various impurities are given in British Standards. For topping up, it is generally advisable to use only distilled water.

### 29.4.1.3 Construction

Battery design and construction is considerably influenced by the application.

**Road vehicle starting, lighting and ignition** A battery which is used for starting, lighting and ignition (SLI) must, *inter alia*, be able to deliver up to 100 A/h of electrical energy at the 20-h rate and be able to supply high currents (e.g. 400–450 A) for up to half a minute without too much voltage fall-off for engine start-up purposes. Faure plates have a special advantage where high currents are required. The larger the plate surface area, the lower the polarisation and the higher the cell voltage. Batteries normally comprise three-cell (6 V), six-cell (12 V) and 12-cell (24 V) assemblies, with plates connected in parallel groups in moulded containers.

In the past, batteries were supplied which, after filling with acid, required an extended first charge to reduce the active spongy lead negative plate. More recently, a dry-charged automobile battery has been developed to give about 75% of its nominal capacity shortly after filling, even after lengthy storage. The basic requirement in manufacture is to ensure a high percentage of lead dioxide in the positive plates and a minimum (e.g. 10%) of lead monoxide in the negative plates. This is achieved by the inclusion in the plates of an antioxidant, or by drying the plates after formation in an oven in which they cannot come into contact with atmospheric oxygen.

**Traction** These batteries often have larger voltages and higher capacities than the SLI type. Batteries for electric vehicles may have a flat-plate or an iron-clad tubular form. The application involves deeper cycling and causes shedding of the active material. In the Faure plate design, 'retainers' (generally of thickly matted glass-wool fibres) are placed in close contact with the surfaces of the positive plates. Batteries of this type (*Figure 29.6*) have lives of 6 years or more. With tubular plates (*Figure 29.7*) tubes of high porosity are fitted: one such plate uses non-woven fibres of a plastic inert to sulphuric acid, such as Terylene. Another type uses an inner woven stocking of glass fibre, strengthened by individual thin-walled perforated PVC tubes. By raising the permeability to acid, these designs have enabled the output/mass and output/volume ratios to be increased by 30% without loss of durability and cycling life.

### 29.4.2 Nickel/cadmium and nickel/iron alkaline cells

Both of these commercially available alkaline cells have the same electrolyte, dilute potassium hydroxide, and the same positive active material, nickel hydroxide. The nickel/cadmium cell has a negative plate of cadmium with a small proportion of iron. Both have an e.m.f. of about 1.2 V. Cadmium gives the nickel/cadmium cell a lower charging voltage and reduced ohmic resistance, and its characteristics

Figure 29.6 Sectional view of a traction cell

Figure 29.7 Iron clad cell with tubular positive plates

resemble those of the lead/acid cell. Use of the nickel/iron cell is mainly in traction, where the higher charging voltage and internal resistance are less important.

#### 29.4.2.1 Charge and discharge reactions

The chemical reactions are complicated. The following gives a general guide:

The reversible potentials of these reactions are respectively  $E_+ = +0.49 \text{ V}$  and  $E_- = -0.81 \text{ V}$ , giving an open-circuit e.m.f. per cell of  $E = 1.30 \text{ V}$ . The overall reaction is

These reactions apply to the nickel/cadmium cell. In the nickel/iron cell the cadmium (Cd) is replaced by iron (Fe).

**Figure 29.8** Charge and discharge characteristics of a low resistance nickel/cadmium cell

The electrolyte is a solution of pure potassium hydroxide (KOH) of relative density about 1.200, a small amount of lithium hydroxide being sometimes added. The electrolyte takes no apparent part in the reactions and its density remains substantially constant. Cells can stand indefinitely in any state of charge, provided that the plates are kept immersed. As in the lead/acid cell, water is lost during gassing on charge and is made up with distilled water. Electrolyte is added only to make good accidental spillage.

Typical charge and discharge characteristics are shown in *Figure 29.8*. The time for a full charge is 7 h, the voltage per cell rising from about 1.4 V at the start to about 1.8 V (nickel/iron) or 1.7 V (nickel/cadmium) after about 5½ h, and then remaining constant for the remainder of the charge. The input (in ampere-hours) should be 1.4–1.5 times as great as the previous discharge. Filler caps or vents should be kept closed except when topping up or taking gravity readings.

As alkaline cells are not damaged by overcharging, a full normal charge can be given irrespective of the state of the cells.

#### 29.4.2.2 Construction

Nickel hydroxide forms the active material of positive plates, the form being 'tubular' for the nickel/cadmium and 'pocket' for the nickel/cadmium cell. Negative plates are of the pocket form for both: the active material is first pelleted, and the pellets then firmly enclosed in pockets of this nickel-plated steel, perforated with many minute holes. In tubular plates helically wound tubes of similar perforated material are constructed, and active material interspersed by layers of thin nickel flake is tamped into them. Groups of plates of the same polarity are bolted or welded to steel terminal pillars. Plates are kept apart by ebonite rod separators. The cell assembly is fitted into a welded sheet-steel container, the terminals being brought out through the lid in suitably insulated glands.

The construction (*Figure 29.9*) produces sturdy, robust cells, unaffected by vibration and shock. Batteries are built up by assembling cells in hardwood crates.

The need to increase the electrical conductivity of the nickel hydroxide positive active material of the alkaline cell was recognised at an early stage of its development. In the tubular plate this was done by introducing small pockets of

**Figure 29.9** Nickel/iron cell

extremely thin metallic nickel flake at regular intervals in the positive active material as it was tamped into the tube. In the pocket type of plate graphite powder is mixed with nickel hydroxide before it is pressed into a pellet. The same object was achieved in a *sintered* plate developed in the late 1930s. The plate grid or support was prepared in the form of a highly porous sintered nickel plaque and the active materials (nickel hydroxide for the positive plate and cadmium hydroxide for the negative) were deposited in the fine pores from suitable solutions of their salts. In this way the active materials were distributed evenly over a very large conducting surface and relatively high coefficients of use were obtained. By this method also very thin plates could be made in closely controlled thicknesses of 0.75 mm or less, and when these were interleaved with thin separators of woven or felted cloth, close-packed assemblies were produced capable of delivering very high currents, particularly at low temperatures.

Sintered plate batteries have been extensively used in aircraft and in other applications calling for high discharge currents.

It was later discovered that if the amount of electrolyte were reduced to such a point that there appeared to be no free potassium hydroxide, the cell could be submitted to overcharge in a fully sealed condition without any risk of the container bursting. The chemistry of this reaction can be explained simply by saying that any oxygen produced at the positive electrode during charge is immediately absorbed by the cadmium in the negative electrode and this is converted to cadmium oxide. The negative charge is therefore used to reduce this cadmium oxide and no gaseous hydrogen is evolved.

Sealed cells require no topping up, evolve no vapour or spray, and can be installed in equipments without hazard. But occasionally they partially dry out, so it is the custom to fit release valves. Batteries of sealed cells have found application in aircraft.

Development has resulted in small cells of capacities less than 1 A-h. They are made in the form of a large button or in cylindrical shape. The former generally have compressed pellets of the active materials; the latter have thin sintered electrodes. Both have restricted amounts of electrolyte and function as fully sealed cells. They are applied to transistor radio receivers and other electronic devices.

### 29.4.3 Silver/zinc alkaline cells

Silver/zinc alkaline cells have recently come to the fore in applications where very high outputs per unit of weight and volume are required. In these respects they give outputs from four to five times those of the equivalent lead/acid and nickel/cadmium alkaline cells. Thus, a 100 A-h cell may be only 10 cm × 5 cm in plan and 20 cm in height, and have a mass of 1.5 kg. The silver is costly, and in view of the relatively low reversibility of multicell batteries, silver/zinc batteries have found few commercial applications. They have been used in aircraft, in guided missiles and to supply power to the communication systems in satellites.

#### 29.4.3.1 Charge and discharge reactions

As in the conventional alkaline system, potassium hydroxide of about 1.200 relative density is used as the electrolyte. The silver oxide used as the depolariser in the positive plate passes through two stages of oxidation (AgO and Ag<sub>2</sub>O) each of which has a characteristic electrode potential. During discharge the following reactions take place:

The overall cell reactions are therefore

For the former reaction the open-circuit cell voltage is 1.81 V and for the latter it is 1.58 V.

The discharge voltage curves of silver/zinc cells therefore generally show two plateaux, a relatively short one at about 1.8 V and a relatively long one at about 1.5 V. With some pre-treatment, as, for example, a very short preliminary high-rate discharge, it is possible almost to eliminate the first plateau, and the discharge voltage then remains fairly steady at about 1.5 V per cell. A curve of this type is shown in Figure 29.10.

The nominal cell voltage is 1.5 V, and this is held (at normal discharge rates) substantially constant over most of the discharge period, as shown. High output currents and charge rates can be employed with little sacrifice in effective capacity. Normal ampere-hour efficiency is 90–95% and watt-hour efficiency 80–85%. Practically no gassing takes place. The electrolyte is to a major degree absorbed in the active materials and almost completely immobilised.

Owing to the slight solubility in potassium hydroxide of the higher silver oxide, overcharging of reversible silver/zinc

Figure 29.10 Discharge voltage of a silver/zinc alkaline cell

batteries should be avoided. In general, charging should be stopped when the voltage reaches 2.1 V per cell and, for this reason, recharging is best carried out with constant-voltage control. If this is not done, short-circuits may develop through the separators. To reduce this risk, manufacturers generally enclose the zinc negative plates in several layers of the separator material, which is usually of a cellulosic base. Single cells of this type have a fair degree of reversibility, but in a multicell battery the irregularity between cells, which is difficult to eliminate, has an adverse effect on reliability. And the greater the number of cells in the battery, the shorter the cycling life becomes.

### 29.4.4 Secondary battery technology

#### 29.4.4.1 Voltage

The open-circuit voltage of a fully charged secondary cell is the same, however large or small, but varies according to the type, i.e. lead/acid or alkaline. That of a fully charged lead/acid cell is approximately 2 V; that of an alkaline cell is about 1.2 V.

Because of the difference in cell terminal voltages (2.0 V for lead/acid and 1.2 V for Ni/Cd), five Ni/Cd cells are required to replace batteries with three lead/acid cells.

#### 29.4.4.2 Capacity

The capacity of the lead acid battery increases with decreasing rates of discharge (currents) and increasing durations (hours). It is therefore usual to state the rate of discharge for any declared capacity, e.g. at the 10-h rate, the 5-h rate, the 1-h rate and so on. Figure 29.11 shows families of discharge- and charge-voltage curves for a typical lead/acid cell on discharge at constant current in each case. The salient properties are:

Discharge time (h)	10	7.5	5.0	3.0	2.0	1.0	0.5
Current rate (A)	11	14	19	29	40	65	118
Mean voltage (V)	2.0	2.0	1.98	1.94	1.90	1.84	1.70
Energy (A-h)	110	105	96	88	79	65	59
Power (W-h)	220	210	190	170	150	120	100

Points to note are: (a) the O/C voltage is about 2.0 V; (b) the discharge voltage curves all start with a relatively flat plateau which ends with a sharp decline, usually referred to as the 'knee' of the curve, beyond which little further capacity is available; (c) the slope of the discharge curves becomes steeper as the rate (current) increases and the knee becomes less prominent; and (d) the 'energy' capacity is represented by the product of the current and the duration (A-h) and the 'power' capacity by the product of energy and the mean voltage (W-h).

The theoretical amounts of the active materials consumed per A-h of discharge energy are: PbO<sub>2</sub>, 4.45 g, Pb, 3.86 g and H<sub>2</sub>SO<sub>4</sub>, 3.68 g. The actual amounts are considerably greater as the coefficients of use fall very much below 100%, as indicated below:

	5-h rate	1-h rate	5-min rate
Positive, PbO <sub>2</sub>	52%	33%	16%
Negative, Pb	66%	40%	19%

Figure 29.11 Representative curves of charge and discharge

The capacity is related to the amounts of the active materials and to their porosity and intrinsic surface area. The main product of the discharge in both positive and negative active materials is lead sulphate. This has a very high electrical resistivity. It polarises the active material and, by clogging the pores restricts diffusion of the electrolyte into the reaction zones. Planté positive grids are cast with a developed area at least 10 times the superficial area and the anodically prepared active material— $\text{PbO}_2$  is spread in a thin layer over a large area. In Faure pasted plates on the other hand, the porosity of the active material must be adequate to permit rapid diffusion of the sulphuric acid electrolyte, particularly during discharges at high rates.

Thus, it is found that (a) for stationary batteries of the lead/acid type, on the score of durability and efficiency it is best to use a Planté positive with a large surface area lightly coated with active material; (b) for automobile or diesel engine starter batteries it is best to use a large number of comparatively thin pasted plates; and (c) for traction battery service, where lower rates are usual, thicker plates with denser material can be used.

#### 29.4.4.3 Charging

All secondary batteries require a supply of direct current for recharging. The method of charging is important in its effect on battery performance and service life. The three principal methods are as follows.

**System control** The batteries work in parallel with a generator across the load. Typical applications include motor vehicles, in which the battery forms an essential standstill reserve for ignition, lighting, signalling, etc. Most small motor cars employ a d.c. generator with control gear for cutting out the generator when its speed is too low, and for voltage regulation for operation over the wide range of active speed. Larger cars and road vehicles employ a.c. generators (alternators) with rectifiers and appropriate automatic control equipment.

**Manual or semi-automatic control** Here the battery is recharged from a separate source, such as a transformer/

Figure 29.12 Charger waveforms

rectifier. Typical applications are to electric vehicles, in some cases with the transformer/rectifier carried on the vehicle.

Since the performance and life of motive power batteries largely depend on the efficiency of the charging system, these will be described in more detail. Three forms of charger are in general use, the single-step taper charger, the two-step taper charger and the pulse-control charger, of which the Chloride Spiegel is a typical example. The voltage-current-time relationships for these three types are shown in Figure 29.12. With the single step charger, the voltage is held constant just below the battery gassing point, 2.4 V per cell. When the battery voltage reaches this point, the current is allowed to decay until the battery becomes fully charged. With the two step process, the first stage follows the same line as with the single step; the current is then reduced to a pre-determined value and charging continued for a pre-determined period. The pulse type of charger is devised more to keep the battery fully charged. When the main charge is stopped, the battery receives short pulses of charge, controlled by the decay in the battery voltage during the intervening open-circuit period.

**Float-and-trickle control** Large stationary batteries in generating stations and (for emergency lighting) in hospitals are connected permanently to a charger, and may also be connected across the load. In normal operation the battery receives a trickle charge to keep it fully charged and ready for intermittent loading. Such a battery requires ventilation and ready access for servicing.

#### 29.4.4.4 Maintenance-free, gas recombination technology

One of the most important developments in storage batteries during the past 20 years or so has been the production of maintenance-free (MF) systems. The primary object was to reduce or eliminate altogether the need to replace water lost through three main factors; (a) evaporation; (b) local electrochemical action at lead negative plates due to the deposition of metals, such as antimony having a lower hydrogen overvoltage than lead; and (c) electrolysis of the aqueous electrolyte towards the end of each recharge. With well-stoppered cells, (a) presented few problems. So far as (b) was concerned, from the earliest days of manufacture, antimony has been the favourite hardener for the lead grids used to support the active materials and to collect the current. But, because of their different hydrogen overvoltages, when lead and antimony come in contact in the electrolyte, hydrogen is evolved, water in the electrolyte is decomposed, some of the lead active material is oxidised causing a corresponding loss of capacity—the so-called ‘standing loss’. Many metals have been tested in lead alloys for this application

and the most successful has been lead-calcium alloy, containing 0.08% calcium and small amounts of tin. With grids cast in this metal, standing losses are negligible. Losses by the third factor (c) proved more difficult to contain, but following the route taken for alkaline cells, the principle of gas re-combination has now been fully established for lead-acid batteries. The main requirements are: (a) no free electrolyte (to permit rapid diffusion of oxygen to the negative plate surfaces, the elements should be 'starved' of electrolyte); (b) the bulk of the electrolyte should be retained by the porous separators; and (c) there should be excess negative capacity. Oxygen is evolved from the positive group before the negative is fully charged. It diffuses to the negative plates where it is absorbed causing discharge of the active material. The negative plates are, therefore, never fully charged and hydrogen is not evolved. This principle is now being applied to cells of various types from small button cells to batteries for SLI, traction and stationary service. Cells can be fully sealed, though it is usual to incorporate a pressure-controlled safety valve.

### 29.4.5 Lithium cells

In recent years there has been much activity on the part of the battery companies directed towards developing cells having lithium electrodes. These electrodes have many potential advantages in battery technology, including high cell voltages, high energy densities, high power densities and rechargeability. Thus they give rise to both primary and secondary batteries. Lithium as an electrode gives a high energy/mass ratio and an inherently high power density. The standard electrode potential is over  $-3.0\text{ V}$  and when allied with, say, a fluorine electrode ( $E_0 = +2.87\text{ V}$ ), the resulting cell should theoretically have an O/C voltage of over  $6.0\text{ V}$ . However, problems arise in practice because of the extreme reactivity of lithium which is stable only in certain non-aqueous media (see below) and even in these it is often the formation of surface films on the lithium which determines the performance of the battery.

There are many different types of lithium cell, having both different electrolyte solutions and different positive electrodes, but with a common lithium negative electrode. The solvents include organic materials such as propylene carbonate containing lithium salts, inorganic materials such as thionyl chloride, molten salts such as the lithium chloride/potassium chloride eutectic and solid electrolytes such as lithium iodide and organic polymers, e.g. polyethylene oxide.

Lithium/thionyl chloride battery technology is both well advanced and well established. Notable features of these batteries are their very flat discharge characteristics, long shelf-life and applicability over wide temperature ranges.

Although a wide range of primary lithium batteries are now commercially available it has not been straightforward to produce viable secondary cells. The problems mainly arise in subjecting both the negative and positive electrodes to charge/discharge cycles in these cells.

The following couples have been employed with organic electrolytes:  $\text{Li}/\text{MnO}_2$ ,  $\text{Li}/\text{SO}_2$ ,  $\text{Li}/(\text{CF}_3)_m$ ,  $\text{Li}/\text{MoS}_2$ ,  $\text{Li}/\text{Ag}_2\text{CrO}_4$ ,  $\text{Li}/\text{CuO}$ ,  $\text{Li}/\text{FeS}_2$  and  $\text{Li}/\text{TiS}_2$ . Unfortunately, the electrical resistance of these organic electrolytes, even when improved by inorganic salt additives, is relatively high and cells of this type are only suitable for low rate discharges.

With molten  $\text{LiCl-KCl}$ , the alloys  $\text{Li-Al}$  and  $\text{Li-Si}$  have been used as negative electrodes, and  $\text{FeS}$  and  $\text{FeS}_2$  as positive electrodes. Operational temperatures may be as high as  $400^\circ\text{C}$ .

The  $\text{Li}/\text{SO}_2$  and  $\text{Li}/\text{SOCl}_2$  couples have inorganic electrolyte and can be operated at high discharge rates at ambient temperatures. They have, in fact been tested for possible torpedo propulsion.

### 29.4.6 Sodium/sulphur cells

Another high-temperature contender ( $300/375^\circ\text{C}$ ) is the sodium/sulphur cell, which employs liquid sodium and sulphur as the negative and positive electrodes, respectively, with the solid electrolyte  $\beta$ -alumina which is a sodium ion ( $\text{Na}^+$ ) conductor. It is envisaged that this system would be used for load levelling and car traction. The open circuit voltage of a single cell is  $2.1\text{ V}$  and its theoretical energy density  $756\text{ W-h/kg}$ . Safety is a major concern. In practice, cells have capacities of about  $150\text{ A-h}$  with practical energy densities in the  $100\text{--}150\text{ W-h/kg}$  range. Heat management is also very important; it is desirable to employ the batteries for applications which enable them to remain molten during on and off periods. In the UK a company (Chloride Silent Power) set up by the Electricity Council and the Chloride Group is exploiting the sodium/sulphur battery for large-scale application.

## 29.5 Battery applications

### 29.5.1 Stationary or standby power batteries

Batteries in large installations having capacities of hundreds of ampere-hours, which supply power in emergency or auxiliary situations, are referred to as stationary or standby batteries. Standby power supply is needed when the mains source of electricity fails. The choice of standby supply is usually between lead-acid or nickel-cadmium batteries or auxiliary generators, or a combination of both sources. Applications include emergency lighting in department stores, offices, factories, cinemas and other public places, power to keep burglar alarms and other communications working, emergency power for important production processes and equipment such as in hospitals, mines, airports, power stations, telephone exchanges, lighthouses and, more recently, computer operations especially in the financial service sector.

#### 29.5.1.1 Lead-acid batteries

Various types of lead-acid secondary batteries are used for stationary or standby purposes:

- Plante cells giving a long life of 20–35 years or even longer with high reliability which are kept on continuous trickle charge. Cell capacities are rated by relating current flow to time in ampere-hours. High performance cells up to  $2000\text{ Ah}$  are usually in transparent containers allowing acid levels to be checked.
- Flat plate cells provide a cheaper but short-lived alternative to Plante cells. Pasted flat plate cells, again in transparent containers are available in capacities of up to  $500\text{ Ah}$  with a life expectancy of 10–12 years to meet emergency lighting regulations. Car batteries are based on this design but are totally unsuitable as an emergency power source being designed instead to give a high current for a short time.
- Tubular cells are normally used to power electric trucks on which daily recharging is needed, but are suitable for standby applications requiring frequent charge/discharge cycles. When on standby they have a life expectancy of 10–12 years compared to 5 years when powering electric trucks.

### 29.5.1.2 Nickel-cadmium batteries

Large nickel-cadmium secondary batteries, open and semi-open or sealed are made in a variety of designs to meet many purposes including those of stationary or standby batteries. Their uses cover the application areas mentioned above. Other applications include engine starting for motor-generating sets as required for standby power systems where bad weather, low temperature conditions might prevail. Under these circumstances engine-starting batteries must be highly reliable, have a high performance capability and be free from the effects of high stress and vibration, such as occurs in vehicles or engine rooms of ships. A similar requirement is for emergency batteries in trains for lighting at stations or in the case of a power supply failure. Nickel-cadmium cells are used also for the uninterrupted emergency power supply (UPS) to railway mainline stations and signalling systems. Marine applications include UPS systems for radar, communications, steering and navigation and for the emergency lighting on board. In air transport these batteries provide ground power supplies, the support battery systems on board aircraft and at airports all the essential lighting and communications depend on batteries. UPS systems operate in standby mode, providing power only in the event of mains failure.

### 29.5.2 Self-contained power supplies

Applications as self-contained power supplies include a wide range of portable devices such as transceivers, razors, portable equipment and tools, radios, torches, toys, hearing aids, cameras, calculators, computers, clocks, etc.

Sealed nickel-cadmium secondary batteries have a range of uses in these markets resulting from their favourable characteristics including:

- (1) total absence of maintenance;
- (2) very long operational life;
- (3) ability to accept permanent overcharge;
- (4) prolonged storage without deterioration;
- (5) ability to be overcharged at high rates;
- (6) constant discharge voltage characteristic;
- (7) mechanically robust; and
- (8) operation over a wide temperature range of  $-40^{\circ}\text{C}$  to  $+50^{\circ}\text{C}$ .

If the application requires a low initial cost, or the life of the equipment is short, however, then primary batteries are the obvious choice. Secondary batteries can prove cheaper in the long run because they can be recharged and reused, but they require a charger, so the initial cost of the battery system is high.

Of the primary cells zinc-carbon is cheap and readily available. It is particularly useful in applications having a light, intermittent duty cycle, but the battery has a low shelf life and a drooping discharge characteristic. For heavy-duty applications needing continuous operation at high current, alkaline manganese dioxide batteries are preferred to zinc-carbon. They have 50–100% more energy for the same weight and a longer shelf life, but are more expensive at low currents, e.g. below 200 mA. The mercury-oxide battery has a flat discharge characteristic and a high energy to weight ratio. It is often used in voltage reference applications. Lithium batteries are used in applications that require a long shelf life or a wide operating temperature range, or a high energy density.

### 29.5.3 Traction batteries

Much of the recent interest in battery development has been linked to traction purposes. There have been a number of obstacles to the widespread introduction of electric vehicles (EVs) based on batteries alone:

- Inability to store sufficient energy for long distance travel;
- Time taken to recharge the battery;
- Lack of supporting infrastructure of fore-court services and maintenance facilities;
- Replacement costs of battery pack; and
- Additional vehicle weight of battery pack.

Lead-acid and nickel-cadmium store too little energy per unit weight and volume to be viable for electric traction; therefore the development of the electric vehicle is critically dependent on designing advanced batteries which can store two to three times the amount of energy per unit weight and volume compared with these conventional rechargeable batteries. Significant advances have been made in electrochemical battery development, however, over traditional lead-acid battery performance. Advanced battery technologies such as room temperature lithium ion and high temperature sodium nickel chloride have energy densities of 2.5 to 3 times that of lead acid, resulting in electric vehicle ranges of possibly 150–250 km at 100 km/h, i.e. suburban use, with sufficient energy to power normal levels of auxiliary equipment. The high temperature sodium nickel chloride battery (sodium metal negative electrode—nickel chloride positive electrode separated by an ion conducting  $\beta$ -alumina ceramic) is a robust technology with demonstrated cycle life, performs well in cold weather, but would not be energy efficient in vehicles with low mileage because of the self discharge needed to keep the battery heated. The lithium ion battery has good energy performance, is safe, but has relatively low specific power and requires considerably more development; nevertheless the development of high-power systems are anticipated in the future.

The state of development of secondary batteries along with the targets set by electric passenger vehicle (EV) requirements is summarised in *Table 29.1*. The data does not account for improvements which can be made by properly designed engine-management systems. The use of ultracapacitors, for example, can supplement power supplied. A battery's life could be as much as doubled by the use of ultracapacitors for load-levelling purposes. This technology is well suited for delivering high power to EV's during acceleration and generating new energy supply during braking using power electronics for four-quadrant control.

## 29.6 Anodising

Anodising is the production of a film of oxide or hydrated oxide on the surface of aluminium or of its alloys, to prevent corrosion of aircraft metal and other surfaces likely to be exposed to the effects of the sea. The anodic film is usually of a light grey colour. When newly formed, it can absorb dye, a property of use for decorative purposes.

### 29.6.1 Process

The workpiece is made the anode in a bath of chromic or sulphuric acid, through which a direct current is passed at a voltage of about 50 V for the former acid bath and 10 V for the latter. In large installations a current of 1–2 kA may be required from a rectified a.c. supply. The action produces on the aluminium workpiece a semi-insulating film, and

the vat voltage is increased as the action proceeds. Non-aluminium parts must be screened by plastics materials. The current density is 0.5–0.7 A/cm<sup>2</sup> of active anode surface. In a typical process about 10 V is initially applied, the current being 1.5 kA; after 30 min the voltage is steadily raised in 5 min to 50 V, and maintained for a further 5 min. The work is then removed from the vat and washed.

The liquid carries the anodising process into every bare recess so long as there is no exclusion by gas. A tube 2 m long and of 5 mm internal diameter can be satisfactorily anodised over its entire surface. The effectiveness of the surface can be tested by applying 50 V between the workpiece and a 25 mm diameter steel ball. Anodising is best carried out at a standard temperature (e.g. 40°C).

### 29.6.2 Vats

In small baths the cathodes are carbon plates or rods hung from the cathode connection. Current is conveyed to the cathodes and the anode workpiece by round copper rods resting on porcelain insulators attached to the rim of the wooden or metal vat. A typical vat is  $6\text{ m} \times 2\text{ m}$  with a depth of about 2 m, sunk into a concrete floor for convenient access. The cost of filling a bath with diluted acid is considerable, making necessary scrupulous attention to cleanliness and the avoidance of contamination. Precipitates must be allowed to settle or be filtered off. Gentle agitation of the liquid by means of compressed air from a small motor-driven pump is applied to avoid slight pitting of the workpiece at the liquid surface level: this keeps foreign bodies in suspension, so that filtering may be necessary at the end of the day's work.

### 29.6.3 Workpieces

The pieces to be anodised are wired for connection to the anode rod by aluminium wire if they are small. Larger pieces may be connected by dural rods and clamps. The cross-section of the wires and rods must be adequate for the appropriate current, and that of the connection point to the workpiece must also be sufficient. Multiple connections can be used for this purpose. The action of the bath produces an effervescence of oxygen from the aluminium and dural, and a gas accumulation may exclude workpiece recesses from the anodising process. This can be overcome by tilting the workpiece, or may necessitate two runs with the workpiece in different orientation.

#### 29.6.3.1 Cleaning

Before anodising, workpieces must be cleaned by a process similar to those for the preparation of work for electroplating. Items that have not been heat-treated, welded or riveted are more easily cleaned than fabricated parts or castings. If the workpiece has been previously treated in a salt bath, all trace of the salt must be removed by flushing in running water. Built-up fittings require the joining surfaces to be scratch-brushed or buffed before refitting, and immersed in boiling water immediately prior to anodising. Welded aluminium parts must be kept in contact with boiling water for 30 min to remove flux residues, which lead to pitting. In large anodising shops greasy articles are held in the smoke arising from electrically heated trichloroethylene, which cleans them thoroughly in about 2 min. Before anodising they are dipped in a hot swill to remove traces of the smoke, which would contaminate the anodising bath.

## 29.7 Electrodeposition

Electrodeposition is carried out in electrochemical reactors that use electrical energy to extract metals from their compounds. The processes include electrowinning, electrorefining, electroplating and electroforming.

**Electrowinning** A mineral, or a compound prepared therefrom, is decomposed to a metal and (usually) a gas. The prime process in this class is the refining of aluminium: the Hall-Héroult process involves the electrolytic decomposition of alumina (prepared from bauxite) dissolved in molten cryolite ( $\text{Na}_3\text{AlF}_6$ ) at about  $1000^\circ\text{C}$ . Aluminium is produced as a liquid at the cathode. The primary anode product, oxygen, reacts with the carbon anode to give mainly carbon dioxide,

with a small proportion of carbon monoxide. The process is highly energy intensive.

**Electrorefining** An impure anode (perhaps a cathode from an electrowinning stage) is converted to a pure cathode. Copper is refined in this way. The process is much less energy intensive than electrowinning, mainly because of the lower voltages employed.

**Electroplating** This is the electrodeposition of a thin protective metal coating on another metal. Protection is obtained with the minimum amount of material and with a low expenditure of energy. The process has imperfections: for example, chromium plating has high porosity and poor adherence, particularly in extreme conditions.

**Electroforming** The aim in this extension of electroplating is to build up the plate so that the cheap substrate can be dissolved to leave an article of the plate metal which has mechanical integrity. Nickel electroforms are made in this way, but the process is particularly advantageous for refractory metals (e.g. tantalum, niobium). Thus, an article that would be costly and wasteful when made from bulk metal can be prepared directly.

### 29.7.1 Electroplating

In modern mass production processes automatic plating plants are regularly used for the deposition of nickel, chromium, brass, zinc, silver, copper and cadmium, and, in addition, for depositing composite coats of two metals, such as in nickel and silver plating, brassing and bronzing. In using plants of this kind, the product is extremely consistent, as the plater is relieved from manual duties and left free to devote his attention to the control of essential operations. The plant is usually arranged so that the various vats are placed in line one behind the other in proper sequence. Two conveyors travel slowly over the vats, the articles to be plated being loaded on insulated suspenders which are arranged in two or three rows on cross rods attached to the conveyor chains. The suspended articles pass in succession through cleaning and swilling vats before passing to the vats for deposition, and finally to the swilling and drying-out apparatus after plating is completed.

As each loaded cross rod arrives at a vat or tank it is lifted by an auxiliary fast-moving transfer chain, and lowered into the next vat along the line. After passing through drying apparatus, the suspenders are unloaded from the cross rods, the latter being automatically returned to the loading position for the work to continue. The cycle of operations in the case of automatic nickel-plating plants is usually as follows: hot alkaline electrolytic cleaner used cathodically at about  $300\text{ A/m}^2$ ; cold water swill; anodic etch in sulphuric acid in the case of iron and steel articles; agitated cold water swill; nickel plating; cold water swill; hot water swill; and drying.

#### 29.7.1.1 Barrel plating

The barrel planting method of electroplating is automatic insofar as the actual deposition of metal is concerned, and the method is extremely efficient and economical within the limits of the capacity of the barrel and the size of the articles. Any difficulties experienced are usually traceable to overloading the barrel, which causes the articles to be carried round in a mass as the barrel revolves, or to attempts to plate articles having awkward shapes which shield one another in the mass and prevent regular deposition.

Plating barrels are available for use with all types of solutions, and excellent results can be obtained with such articles as screws, cycle and car fittings, and hooks and eyes. Some of the early machines were extremely clumsy, and offered great resistance to the flow of current, since when many improvements have been made, particularly in the use of rubber lined tanks, stoneware vats and containers of other non-metallic material.

An important advantage of barrel plating is that, as the articles are receiving the deposit of metal, they rub together and become burnished, while the deposit being consolidated by the rubbing is close-grained and durable. As in so many plating processes, the speed at which a plating barrel should revolve is critical and is governed by the class of article being plated and the diameter of the barrel.

Speeds vary between 30 and 45 rev/min, although in the case of large plating barrels the speeds may be as low as 10–15 rev/min. It sometimes happens that articles all of one shape cannot conveniently be plated in a barrel by themselves, and in such cases scrap metal pieces or steel balls of suitable size can also be put into the barrel.

Although barrel plating can be carried out with some solutions at 6 V, it is usually necessary to use voltages of 10–18 V. In the case of nickel a current of about 45–60 A at 10 V can be passed. A higher current is needed for 'brassing'.

Barrel plating was developed specially for handling small articles in quantities, and in many cases this process has a number of advantages over the original suspended anode method. In one of the best-known makes the anode insulated by a vulcanite cover is situated at the base of the barrel. The barrel itself is made of welded steel internally lined with vulcanite, and is mounted on a swivel arrangement, which permits immediate removal of the work by dumping it into a suitable container for transfer to the drier. Electrical contact is made through an insulated rod passing through the centre of the shaft and directly connected to the anode, the current returning to the plating rectifier by way of the barrel and framework of the machines. An important feature of this type of barrel is that it can be relined with vulcanite at very small cost, and it is also easily and quickly rinsed.

### 29.7.1.2 Polishing

The speed of a polishing mop or bob is a factor affecting efficiency and economy, and speeds between 30 and 45 m/s are the rule according to the article to be polished.

Variable-speed machines are necessary, so that when a mop or bob becomes worn, say from 30 to 20 cm in diameter, the peripheral speed may be increased. Too low a speed causes a mop to drag and the articles to become heated, and a burnishing rather than a polishing effect is produced. 'Polishing bobs' is the term used for all solid leather wheels, compress wheels, made up of sections of leather, canvas or felt, and solid felt. These are dressed with emery, and the felt bob is the type in most general use. Polishing mops consist of discs of cotton cloth, varying in size from 5 to 40 cm in diameter and held together at the centre by means of washers of leather or fibre.

## 29.8 Hydrogen and oxygen electrolysis

There are several processes by which oxygen and hydrogen are produced as a main product or by-product. The industrial uses are considerable.

*Oxygen* is used to a very large extent in metal working and metallurgical industries. In conjunction with acetylene or

hydrogen, it is used for welding and cutting; with butane and propane, for tempering steel. Very large (tonnage) quantities are now used in the production of steel, in the gasification of coal and to a lesser extent in the oxidation of olefines. The use for medical purposes and in super-atmospheric aviation is relatively small in quantity but of high importance.

In the chemical industry oxygen or oxygen enriched air is sometimes used in place of air in the oxidation of ammonia to produce nitric acid in highly concentrated form. The electrolysis of water can therefore conveniently be used for the production of hydrogen for the synthesis of ammonia and of oxygen for the subsequent preparation of nitric acid. The nitric acid and ammonia together produce ammonium nitrate, an important fertiliser.

*Hydrogen* is used in a number of industries. In the food industry the production of margarine and cooking fats from liquid oils such as groundnut, cottonseed, whale, etc., is based upon the partial catalytic hydrogenation of these oils, which converts them into solids at normal temperatures. Sorbitol, a sugar used by diabetics and in the production of synthetic resins, is produced from glucose by hydrogenation. Ammonia, a basic chemical for the fertiliser industry, is produced in very large quantities annually by the catalytic combination under high pressure of hydrogen and nitrogen.

Large quantities are used in the fuel industries, mainly in the processing of mineral oils but also in the production of synthetic liquid fuels from coal.

Many other uses exist in the chemical industry, such as in the production of synthetic solvents and the hydrofining of benzole. In the metallurgical industry hydrogen alone or mixed with nitrogen is used to provide inert atmospheres for the annealing of alloy steels, and in the lamp industry it is used for the reduction of tungsten and molybdenum ores to the metals and in the subsequent manufacturing processes for the production of lamps. Large synchronous machines are sometimes cooled by the circulation of hydrogen in a closed system. Meteorological balloons are filled with the gas.

### 29.8.1 Process

Water dissociation to give small (equal) concentrations of the hydronium ion ( $\text{H}_3\text{O}^+$ ) and the hydroxide ion ( $\text{OH}^-$ ) is in accordance with the equation

Thus, it is possible in principle to decompose water electrolytically in an electrochemical reactor, to give hydrogen at the cathode and oxygen at the anode according to the reactions

Practical reactions are slightly more complex, as the electrolyte added to the water to improve its conductivity plays a role in the reaction.

In simple water electrolysis the hydrogen produced per coulomb is 0.010 45 mg/C. Thus, 1 kA produces 0.42 m<sup>3</sup>/h (at 0°C, 760 mmHg, dry). The corresponding quantity of oxygen is 0.21 m<sup>3</sup>/h. Stray current prevents full attainment of these outputs, but the current efficiency can be as high as 98–99%. The specific energy consumption depends on the voltage. The decomposition voltage of water is 1.23 V, but that to operate a hydrogen/oxygen cell exceeds this value, because of the ohmic resistance of the electrolyte and the overpotentials for the evolution of the gases at the electrodes. Solutions of caustic soda or potash are almost

invariably used to lower the resistivity, using mild steel cathodes and nickel-plated anodes, which are immune to attack by the electrolyte or the gases. Soda and potash solutions are always prepared from the purest material: the caustic must have limited amounts of chlorides, sulphates and carbonates, which raise the resistance, while the former two may cause corrosion of the electrodes. The water feed must be pure (i.e. a very high resistivity). It is produced in a water still or by treating the raw water in an ion exchange plant, followed sometimes by active carbon treatment to remove oil traces, as when the source is a steam condensate.

### 29.8.2 Electrolysers

Water electrolyzers are distinguished by electrode arrangement and gas pressure.

#### 29.8.2.1 Tank type

The tank or unit-cell electrolyser has unipolar electrodes in one tank and connected in parallel. Normally several tanks are connected in series, facilitating extension and enabling a faulty tank to be bypassed.

#### 29.8.2.2 Filter-press type

The filter-press type has bipolar electrodes arranged to act as a positive on one side and a negative on the other, with terminal connections at the end of the battery. *Figure 29.13* shows a section, the construction having some similarity to a filter press. The cell frames (1) are made of an electrically insulating caustic-resistant material and into them are fitted the diaphragms (9) and main electrodes (10). In order to maintain the optimum distance between the active faces of the electrodes, the main electrodes each carry a perforated auxiliary cathode (11) and a similar auxiliary anode (12). The various ports are sealed off from one another, and the whole assembly of a number of cells is made leak proof by means of the joints (2). The action is as follows.

Hydrogen evolved at the cathode (11) rises through the gas port (5), carrying with it some of the electrolyte. The mixture passes along the channel (4) common to the pack of cells, thence to an arrangement of gas washing and cooling drums mounted on the electrolyser, from which the gas passes to process. The electrolyte, after cooling, returns by a pipe system through a filter to the electrolyte channel (7).

**Figure 29.13** Section through a typical 'filter-press' electrolyser. 1, cell frame; 2, joint; 3, oxygen gas channel; 4, hydrogen gas channel; 5, hydrogen gas port; 6, oxygen gas port; 7, electrolyte channel; 8, electrolyte ports; 9, diaphragm; 10, main electrode; 11, auxiliary cathode; 12, auxiliary anode

The ports (8) then ensure an electrolyte feed to each cell to replace that taken out with the gas. A similar circulation occurs with the oxygen from the anodes (12) through the ports (6) and channel (3) returning through (7) and (8). The current connections to the electrolyser are to the electrodes at the ends of the pack, which are extended beyond the bottoms of their respective cells for cable or bus-bar.

It will be seen that, for a given output, a filter press electrolyser is constructed as one unit consisting of a number of cells of an appropriate size, clamped together as a pack, variations in the size and number of electrodes being made to suit the required electrical conditions. A tank type electrolyser, on the other hand, will consist of a number of unit cells connected in series externally, but here again variations in size and number can be made to suit the electrical conditions.

The filter-press electrolyser can produce in a single unit up to 500 m<sup>3</sup>/h of hydrogen: the connections are simple; gases can be delivered at normal gas holder pressures without the need for separate boosters; the electrolyte is in an enclosed system and the constant circulation through a filter ensures thorough mixing and freedom from contamination; and the quantity of electrolyte is small compared with the output.

#### 29.8.2.3 Pressure type

The pressure type electrolyser is a development of the filter-press electrolyser in which electrolysis is carried out under pressure. Lower cell voltages are obtained because of decreased blanketing effect of the smaller gas bubbles. The optimum pressure is about 30 atm, giving a 14% power advantage over that achieved at normal atmospheric pressure. Further, the cost of post-compression of the gases is less. The basic design is similar to that of the filter-press type, but adapted to work under pressure, having cells of circular section. Gas purity is a little less than for the unpurified equipment, but is adequate for most industrial purposes.

### 29.8.3 Gas purity

The makers of atmospheric pressure filter-press electrolyzers guarantee a purity of 99.7% for oxygen and 99.9% for hydrogen. A check is normally kept on the gas purities by drawing off samples into measuring burettes. In the case of oxygen the sample is then passed over copper, which combines with the oxygen and leaves the hydrogen impurity as residue; while in the case of hydrogen, a platinum spiral electrically heated to redness in the gas causes the oxygen impurity to be removed by a combination with twice its volume of hydrogen to form water, leaving the main bulk of hydrogen as residue.

Automatic gas analysers can also be fitted which give a continuous check on gas purities.

### 29.8.4 Plant arrangement

The electrolytic plant will usually comprise a source of direct current, the electrolyser, a tank for the storage and make-up of electrolyte and a transfer pump, a source of purified water, gas holders and compressors for hydrogen and oxygen, and pressure storage tanks. In the case of pressure electrolyzers buffer tanks are provided in place of low-pressure gas holders. The direct connection of electrolyzers working at low pressure to compressors is not recommended.

Depending on the required specification of the gases, dryers are installed before the gases are delivered to process. The capacities of gas holders, compressors and high-pressure storage vessels depend upon the user process and its demand cycle. The compressors are normally started and stopped automatically by pressure switches on the high-pressure storage vessels and capacity switches on the gas holders. Complete automatic control of electrolytic plants including variation of output to suit demand is possible but so far has not been attempted.

Because of the explosion hazard, electrolyzers are housed in rooms isolated from the electrical conversion equipment by a gasproof wall, intercommunication between the two being by outside doors. Lighting of the electrolyser room can be either by pressurised fittings or by lamps placed outside the windows.

The electrical energy consumption for the production of given quantities of hydrogen and oxygen depends on the type of electrolyser and on the output per unit cell, because the cell voltage increases with the current density at the electrodes. For atmospheric types the operating voltage per cell is 1.9–2.1, corresponding to specific d.c. energy

consumptions of 4.5–5.0 kW-h/m<sup>3</sup> of hydrogen. The selection of an electrolyser for a given duty is based on the capital cost of the installation and the cost of energy. Thus, where the energy cost is low, it is economic to work at a high current density (and therefore a high specific energy consumption).

## 30.1 General

The overhead line is the cheapest form of transmission and distribution of electrical energy. Line design and construction involve several engineering disciplines (electrical, civil, mechanical, structural, etc.), and must conform to national and international specifications, regulations and standards. These refer to conductor size and tension, minimum clearance to ground, stresses in supports and foundations, insulation levels, etc. Lines must operate in conditions of large temperature change and in still air and gales, and (in non-tropical climates) may have ice formation on conductors and supports.

The structural design of a d.c. line does not differ essentially from that of an a.c. line, but electrical features related to frequency (such as inductive, capacitive and skin effects) do not apply in the d.c. case under normal operating conditions.

## 30.2 Conductors and earth wires

### 30.2.1 Materials

Many years of operating experience, and the costs as affected by metal market trends, have combined to favour aluminium based conductors<sup>1</sup> (see also Chapter 5, Section 5.1.2). Copper and cadmium-copper are seldom used, even for distribution lines.

The intractability of large solid conductors has led to the almost exclusive use of stranded conductors (in spite of their greater cost), which have a larger diameter than equivalent solid circular conductors. With strands of diameter  $d$ , the outside diameter of uniformly stranded conductors is:

No. of strands	3	7	19	37	61
Overall diameter	$2.15d$	$3d$	$5d$	$7d$	$9d$

Aluminium based conductors in normal use are categorised as

AAC	All-Aluminium Conductors (BS 215, IEC 207)
ACSR	Aluminium Conductors Steel Reinforced (BS 215, IEC 209)
AAAC	All-Aluminium Alloy Conductors (BS 3242, IEC 208)
AACSR	All-Aluminium Alloy Conductors Steel Reinforced (IEC 210)
ACAR	Aluminium Conductors Alloy Reinforced

Figure 30.1(a) illustrates typical strandings of ACSR. The conductor with an outer layer of segmented strands has a smooth surface and a slightly reduced diameter for the same electrical area.

Any of the above types can be used as an earth wire, although generally preference is given to steel. In areas where high short-circuit currents are anticipated, one layer (or more) of aluminium or aluminium alloy strands is added.

For distribution lines, any of the above conductor types can be used, but in addition mention must be made of Aerial Bundled Conductors (ABC), commercially available for systems up to 30 kV with greatly reduced environmental impact.<sup>2</sup> They consist essentially of four PVC covered cables bunched together and strung overhead rather than underground.

Recently, there has been an increased tendency to favour earth wires with incorporated optical fibres (Figure 30.1(b)) which can be used for communication purposes. These are often referred to as optical ground wires (OPGW) (Chapter 27, Section 27.5.2). Also, developed for telecommunication purposes, all-dielectric self-supporting (ADSS) aerial optic cables with a high strength non-metallic component as support are occasionally installed. These can in fact be added at a later date (subject to a check on the mechanical strength of the structures). In such cases, a knowledge of the electric field conditions along the overhead line is required to locate the ADSS cable in a zone of minimum field strength.

### 30.2.2 Nomenclature

There is as yet no international agreement on nomenclature. In the UK conductors were referred to the approximate area in (inches)<sup>2</sup> of a copper conductor having the same conductance. Nowadays, aluminium based conductors are referred to their nominal aluminium area. Thus, ACSR with 54 aluminium strands surrounding seven steel strands, all strands of diameter  $d = 3.18$  mm (designated: 54/7/3.18; alu. area = 428.9 mm<sup>2</sup>, steel area = 55.6 mm<sup>2</sup>) is described as 400 mm<sup>2</sup> nominal aluminium area. In France the total area (485 mm<sup>2</sup>) is quoted; in Germany the aluminium and steel areas are quoted (429/56); whereas in Canada and the USA the area is stated in thousands of circular mils (1000 circular mils = 0.507 mm<sup>2</sup>).

Code names using animal, bird or flower names, etc., are also used. Thus, the 400 mm<sup>2</sup> nominal aluminium area ACSR is known as 'Zebra'.

### 30.2.3 Mechanical characteristics

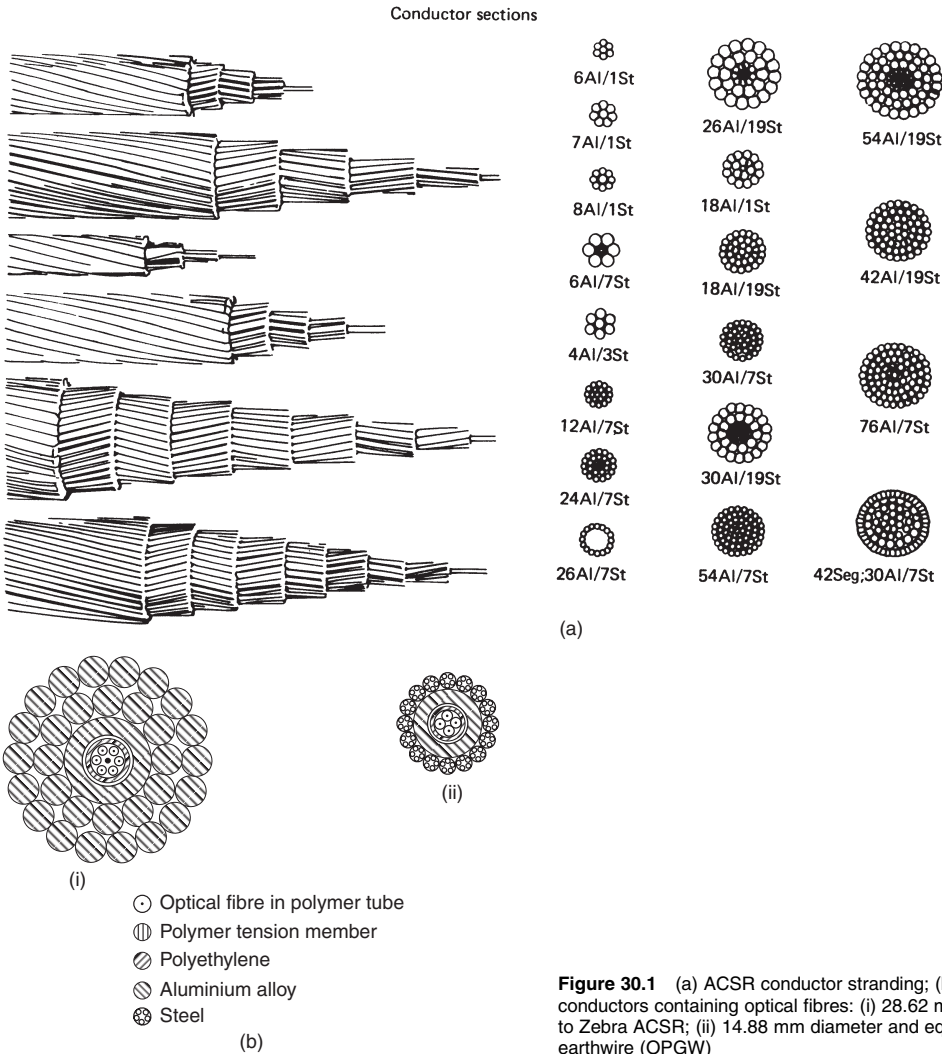

The choice of a conductor from the mechanical viewpoint depends on external loading conditions (such as wind speed, ice loading and ambient temperature), and on internal characteristics (such as stranding, modulus of elasticity, thermal expansion and creep). For lines of 33 kV and over, hard-drawn AAC is not likely to be adopted; economics and creep behaviour lead to the choice of ACSR or AAAC. As can be seen from Figure 30.1(a), a wide range of breaking strength/weight ratio can be achieved by modifying the aluminium and steel content, and by using aluminium alloy strands where conditions demand. Table 30.1 gives typical properties of ACSR conductors.

As a result of many investigations into the economics of the complete overhead line (system economics) and the improved ability of manufacturers to produce alloy at competitive prices, the tendency to use AAAC on the British grid has increased. The overhead line engineer should now familiarise him/herself with names such as Totara, Rubus, Araucaria for AAAC and Collybia for ACAR.<sup>3</sup> These are certainly favoured for refurbishment work, since they quite often permit increased transmission capacity for the same wayleaves. Probabilistic techniques applied to existing lines are one of the many factors enabling relevant decisions to be taken.

**Modulus of elasticity** For a complete ACSR the modulus of elasticity can be estimated from

$$E = [(70r + 200)/(r + 4)] \times 40^3 \text{ (MN/m}^2\text{)} \leftarrow$$

where  $r$  is the ratio aluminium area/steel area.

**Figure 30.1** (a) ACSR conductor stranding; (b) typical cross-section of conductors containing optical fibres: (i) 28.62 mm diameter and equivalent to Zebra ACSR; (ii) 14.88 mm diameter and equivalent to half-inch-steel earthwire (OPGW)

**Linear expansion** The coefficient of linear expansion of an ACSR conductor per degree Celsius is given by

$$\alpha_s = 40^{-6} [(23r + 32.6)/(r + 2.83)] \leftarrow$$

Some useful reference data are given in *Table 30.2*.

**Oscillation phenomena** Exposed to wind and ice loading, overhead line conductors are subject to oscillations that affect the design and application of the conductor fittings.

**Aeolian vibrations** These are typically in the range 8–40 Hz, occasionally higher, and are generated by wind speeds of 2–40 km/h. As a laminar air flow is involved, certain regions of terrain are prone to develop the aeolian phenomenon. The consequent vibration causes strand breakdown by fatigue.

As a result of international enquiries covering thousands of kilometres-years of lines, the concept of EDS (everyday stress defined as the general order of stress which exists over the larger proportion of the life of a conductor, and therefore,

**Table 30.1** Typical properties of ACSR conductors

Code name	Stranding	Aluminium area (mm <sup>2</sup> )	Steel area (mm <sup>2</sup> )	Diameter (mm)	Mass (kg/km)	Breaking load (kN)	Resistance at 25 °C (Ω/km)

at or around mean temperature with little or no superimposed load) was introduced as a means of ensuring a longer conductor life before strand damage. Typical values as proportion of breaking loads are: for ACSR: 18 to 24%; for Aluminium: 17% for Aluminium alloy: 18%. The subject is now well documented and much more sophisticated techniques can be used<sup>4,5,6</sup> to refine these values. The concept of EDS should not be underestimated as it constitutes one of the bases for 'sag and tension' calculations.

**Subspan oscillations** These affect only bundled conductors (Section 30.4.1). They occur at a frequency of 0.5–5 Hz,<sup>7</sup> and wind speeds of 15–65 km/h. Their intensity is considerably reduced if the ratio between subconductor spacing and conductor diameter exceeds 16.

**Galloping** This involves complete spans in a fundamental mode. Amplitudes reaching the value of the sag have been recorded. Bundled conductors may be more prone to galloping than single conductors, but the latter have been known to gallop.<sup>8</sup> It is now generally accepted that near-freezing temperatures are required for galloping to occur with conductor diameters up to 35 mm. Large conductors can gallop under specific conditions due to aerodynamic instability, even in the absence of ice.

**Creep** Aluminium based conductors are subject to a permanent non-elastic elongation ('creep'), which must be predicted with adequate precision in order that ground clearance regulations may be satisfied. Creep changes the conductor length, tension and sag, and this in turn affects the creep, as does the conductor temperature.<sup>9,10</sup>

### 30.2.4 Sag and tension

Almost all the elements of an overhead line are based on the mechanical loading of the conductors. The loading includes the effect of stringing tension, wind pressure, temperature and ice formation.

The configuration of a conductor between supports approximates a catenary curve, but for most purposes it may be taken as a parabola. The catenary has a constant mass per unit length *along the conductor*; the parabolic curve assumes a constant mass along the *straight horizontal line* between the points of support. The following nomenclature is employed.

Quantity	Symbol	Unit	
		SI	Imperial
Span length	$L$	m	ft
Half span length	$l$	m	ft
Conductor diameter	$d$	m	ft
Conductor section	$a$	$\text{m}^2$	$\text{ft}^2$
Thickness of ice	$t$	m	ft
Tension			
Total	$T$	N	lb-f
Horizontal	$T_h$	N	lb-f
Stress	$f$	$\text{N}/\text{m}^2$	$\text{lb-f}/\text{ft}^2$
Maximum sag (at midspan)	$s$	m	ft
Weight			
Conductor	$w_c$	N/m	lb-f/ft
Ice	$w_i$	N/m	lb-f/ft
Wind pressure	$p$	$\text{N}/\text{m}^2$	$\text{lb-f}/\text{ft}^2$
Wind loading	$w_w$	N/m	lb-f/ft
Total loading	$w$	N/m	lb-f/ft

lb-f = pound force.

The stress is  $f = T/a$ , the wind loading is  $w_w = p_2(d + 2t)$  and the 'total' loading is  $w = \sqrt{(w_c + w_i)^2 + w_w^2}$  as the conductor and ice loadings are directed vertically downward, whereas the wind loading is directed horizontally and acts on the projected area of the conductor and its ice loading (if applicable).

The catenary equation for a conductor between supports at the same height is expressed in terms of the distance  $x$  from the centre of the span (point of maximum sag) and of  $y$  the conductor height above this point (*Figure 30.2(a)*). Then

$$y = (T_h/w)[\cosh(wx/T_h) - 1] \Leftarrow$$

is the catenary equation. Putting  $x = L/2$  gives  $y$  at either support and, therefore, the sag  $s$ . The hyperbolic cosine term can be expanded into a series. For typical low-sag cases all terms but the first are negligible. Furthermore, with the assumption of a uniform conductor tension throughout, the equation reduces to  $y = wx^2/2T_h$ , representing a parabola. Therefore, for a span  $L$  the sag is

$$s = wL^2/8T_h$$

Figure 30.2 Sag and tension

and the length of conductor in a half-span is

$$l_c = l + w^2 l^3 / 6T_h^2 = l + 2s^2 / 3l$$

For supports at different heights (Figure 30.2(b)) that differ by  $h$ , the distances of the supports from the point of maximum sag are

$$l_1, l_2 = \frac{1}{2} [L \pm 2hT/wL]$$

with the parabolic assumption. For large values of  $h$  the value of  $l_2$  may be negative, indicating that the lowest point of the conductor is outside the span, on the left of the lowest support. Such a case would involve an upward component of pull on the lower support, not admissible with suspension insulators.<sup>38</sup>

#### 30.2.4.1 Change of state

If after erection the conductor temperature rises (because of  $I^2 R$  loss or of a rise in ambient temperature), the conductor expands, increasing the sag; but at the same time reduction of the tension allows the conductor to contract elastically. Furthermore, if the loading increases (owing, for example, to wind pressure and/or ice), the tension rises and the conductor stretches. Analysis of these opposing tendencies

leads to a cubic equation relating tension, temperature, loading and elasticity. For two sets of conditions (subscripts 1 and 2)

$$\frac{w_2^2 L^3}{24f_2^2 a^2} = \frac{w_1^2 L^3}{24f_1^2 a^2} + \frac{f_2 - f_1}{E} - (\theta_1 - \theta_2)\alpha\zeta$$

Here  $E$  is the modulus of elasticity,  $\theta$  is the temperature ( $^{\circ}\text{C}$ ) and  $\alpha\zeta$  is the coefficient of linear thermal expansion per degree Celsius. The above equation illustrates the relationships between the various factors affecting the conductor behaviour under 'change of state' conditions. With the availability and extensive use of computers, much more complex and more accurate catenary equations (hyperbolic functions) can be used. Surprisingly programming is easier with those equations.

The maximum permissible stress  $f_2$  (or tension  $f_2 a$ ) that will occur under the most onerous conditions and at a low temperature  $\theta_2$  is usually accepted and known. However in tropical countries the EDS could be a starting point for the calculations. The stress  $f_1$  at which the line must be strung can then be calculated. 'Stringing charts' for a range of spans and temperatures can then be prepared for use by linemen in the field. Such charts are readily prepared by computers. For convenience, for spans up to 300 m the parabolic assumption can still be used, but for longer spans, the catenary equations should be preferred.

#### 30.2.4.2 Equivalent span

As an actual overhead line comprises a series of spans of not necessarily equal length, supported by suspension insulator sets and with tension insulators at the ends of a section, it is generally assumed that the behaviour of a section is that given by a series of equal equivalent spans, each given by

$$L_{eq} = \sqrt{[\sum L_i^3 / \sum L_i]}$$

where  $L_i$  is an individual span length. It is possible to improve on this estimate by use of a complex computer program.

#### 30.2.4.3 Creep

As a result of international discussions, two distinct methods of evaluation have been adopted. The first one<sup>9,10</sup> is based on results of laboratory tests on complete conductors and the empirical expression

$$\epsilon\zeta = K \cdot f^{\beta\zeta} \cdot \exp(\phi\theta) \cdot t^{\gamma\delta\zeta}$$

for the creep extension  $\epsilon\zeta$  (in mm/km) in terms of conductor stress  $f$  (in kg/mm<sup>2</sup>) and temperature  $\theta$  (in  $^{\circ}\text{C}$ ), time  $t$  (in h), a constant  $K$  and creep indices  $\beta$ ,  $\phi$ ,  $\gamma$  and  $\delta$ . Typical values of  $K$  and the creep indices are given in Table 30.3 for ACSR conductors. Evaluation of the expression for the range of operating conditions requires a sophisticated computer program. Figure 30.3 shows a predicted creep-time curve, a series of measured values and a 'best fit' for them, in the case of a Zebra 54/7/3.18 conductor.

The second method<sup>10</sup> calls for laboratory tests on single wires destranded from the conductors, or even on the wires which will be used to form the conductors. In this case, the mathematical model must allow separately for the metallurgical creep and for the geometric settlement, both contributing to the inelastic elongation.

**Table 30.3** Creep coefficients for ACSR conductors

No. of strands		Aluminium/steel area ratio	Process*	Coefficients				
Al	Steel			$\kappa\varsigma$	$\phi\varsigma$	$\beta\varsigma$	$\gamma\varsigma$	$\delta\varsigma$

\* Industrial processing of aluminium rod: HR, hot-rolled; EP, extruded or Properzi.

**Figure 30.3** Typical creep/time relations

Comparison of results for a particular conductor has shown acceptable agreement.

**30.3 Conductor fittings**

*Suspension clamp* Figure 30.4 illustrates a typical UK design, light and suitably profiled to limit the effects of combined static tension, compression and bending, and stresses due to dynamic bending. Positioning the axis of rotation on the axis of the conductor is considered desirable.

*Tension and mid-span joints* A bolted clamp or a cone-type grip is usually adequate for monometallic conductors of small size. For composite conductors (especially when greased) compression clamps must be used for joints and conductor ends.

*Vibration dampers* These absorb vibration energy. The Stockbridge damper (Figure 30.5) is well known. Other

**Figure 30.4** Suspension clamp

**Figure 30.5** Stockbridge vibration damper

Figure 30.6 Schematised spacer-damper

types, such as 'bretelles', festoons, Elgra, etc., have also proved successful.

**Spacers and spacer-dampers** These maintain bundled conductors in proper configuration. Experience has shown the desirability of incorporating a damping element in the fitting which then becomes a spacer-damper. Figure 30.6 illustrates such a device for a quad bundle. The specifications for such a fitting are quite complex since the damping element should desirably be efficient to damp aeolian vibrations and subsnap oscillations.

**Anti-galloping devices** When fitted to bundled conductors, significant reduction in gallop amplitude is achieved, reducing outages due to interphase flashover.

### 30.4 Electrical characteristics

Electrical characteristics are concerned with voltage regulation and current carrying capability. The electric field strength (or voltage gradient) at the conductor surfaces affects corona and radio interference phenomena.

**Voltage regulation** This must be maintained within specified limits (normally 5–12%). The voltage drop depends on the electrical line parameters of resistance, inductance and capacitance, the two latter being influenced by the geometry of the support structures and the frequency of the system. For power lines of length up to about 80 km the capacitance is usually ignored in electrical calculations.

**Current rating** Aluminium is subject to annealing at temperatures exceeding 75°C. Hence 75°C is usually accepted as an upper limit for normal conditions. Higher temperatures can only be tolerated for short periods.

For design purposes, current rating is assessed from a heat balance equation: i.e.  $I^2 R$  loss + heat absorbed from solar radiation = heat loss by radiation + heat loss by convection. As the current rating (which has no unique value) depends on local meteorological conditions, knowledge of these conditions is paramount. Recently, probabilistic techniques<sup>11</sup> have been introduced for the definition of current ratings, recognising that wind speeds, temperatures and solar radiation could be described by random functions. During a period of testing which preceded the calibration of the mathematical models, in the UK it was interesting to discover that the heat gained from solar absorption contributed little (if at all) to the heat input simply because higher ambient temperatures led to increased air convection currents which cancelled the effect of the heat absorption. On this basis, system operators in several countries are introducing special techniques to adapt the thermal rating of the conductors to the changing ambient conditions.

**Radio interference** Considerations of amenity require the radio noise from overhead lines to be kept within acceptable limits of signal/noise ratio in the vicinity of the line.

#### 30.4.1 Bundled conductors

At operating frequency the inductive reactance of an overhead line with an equivalent spacing  $s'$  and a conductor system of geometric mean radius  $r'$  has the form  $X = \omega L \ln(s'/r')$ . An increase of  $r'$  reduces the inductance (and therefore increases the capacitance) of the line; it also lowers the voltage gradient for a given working voltage. High-voltage lines can utilise bundles of two or more spaced subconductors to give an effective increase in  $r'$ . For a bundle of  $n$  subconductors each of radius  $r$ , arranged symmetrically around the circumference of a circle of radius  $R$ , the geometric mean radius of the assembly is

$$r_i = \sqrt[n]{r R^{n-1}}$$

Bundled conductors have the following advantages:

- (1) reduced inductance and increased capacitance, improving 'surge impedance loading', i.e. raising the power transmission capability of a long line;
- (2) greater thermal rating because of the greater cooling surface area compared with that of a single conductor with the same total cross-sectional area; and
- (3) lower surface voltage gradient, so reducing corona loss and radio interference.

The main disadvantage is the sometimes unsatisfactory aerodynamic performance: interbundle oscillations can occur between subconductor spacers. The effect can be controlled by judicious arrangement of spacers and spacer-dampers.<sup>7</sup>

#### 30.4.2 Electrical parameters

**Resistance** Because of the lay in strands, the current flow in a conductor is helical, developing an axial magnetic field. If the conductor has a steel core, the magnetic loss therein may increase the effective resistance by 4–5%. The proximity effect is usually negligible, but the skin effect may produce a small increase in the effective resistance.

**Inductance** For a three-phase line with asymmetrical phase spacing and transposition, each phase comprising (a) a single conductor of radius  $r$  and geometric mean radius  $r' \approx 0.78r$ , or (b) a bundle of geometric mean radius  $r' = \sqrt[n]{r R^{n-1}}$  the line-to-neutral inductance is

$$L = [0.20 \ln(s'/r') + K] \text{ (mH/km)}$$

where  $s' = \sqrt[3]{s_{ab} \cdot s_{bc} \cdot s_{ca}}$  is the geometric mean spacing between phases ab, bc and ca.  $K$  is a correction factor for the steel core and is equal to zero when there is no steel.<sup>12</sup>

**Capacitance** An isolated three-phase asymmetric transposed line with single conductors per phase of overall radius  $r$  has a line-to-neutral capacitance

$$C = 4/[18 \ln(s'/r)] \text{ (}\mu\text{F/km)}$$

As the earth is a conductor, it influences the line capacitance. An adjusted value of  $C$  is obtained by modifying the

logarithmic term to  $[\ln (s'/r) \leftarrow \ln (s'/s_i)]$ , where  $s_i = (s_{aa}' \cdot s_{bb}' \cdot s_{cc}')^{1/3}$  is the geometric mean of the respective distances between conductors  $abc$  and their images  $a'b'c'$  across the earth plane. A similar (but much more complex) expression is required for a bundle-conductor assembly.<sup>13</sup>

### 30.4.3 Voltage-gradient effects

For a single conductor of radius  $r$  (in centimetres) operating at a phase voltage  $V_{ph}$  (in kilovolts), the surface electric field strength is

$$E = 1.8V_{ph}C/r(\text{kV/cm}) \leftarrow$$

where  $C$  is the capacitance of the conductor (in pF/cm). In a bundle conductor the voltage gradient is not the same at all points on a subconductor surface.<sup>13</sup> For  $n$  subconductors each of radius  $r$  (in centimetres) spaced a distance  $a$  apart, the maximum voltage gradient (in r.m.s. kV/cm) is given by

$$E = \frac{1.8V_{ph}C}{nr} \left[ 1 + \frac{2(n-1)\sin(\pi/n)}{a/r} \right] \leftarrow$$

**Corona** The corona onset voltage gradient<sup>12</sup> can be estimated from the Peek formula

$$E_c = 32\delta \left[ 1 + 0.308/\sqrt{(\delta r)} \right] (\text{kV/cm}) \leftarrow$$

where  $\delta$  is the relative air density  $3.92b/(\theta + 273)$ ,  $b$  is the barometric pressure (in cmHg),  $\theta$  is the temperature (in degrees Celsius) and  $r$  is the conductor radius (in centimetres). The number 32 is an average value of the peak breakdown electric strength of air, corresponding to about 22 r.m.s. kV/cm. Thus, a surface voltage gradient of 18–19 kV/cm r.m.s. represents an acceptable upper limit.

**Radio noise** Electromagnetic fields, including interference fields, are generally expressed either in microvolts per metre ( $\mu\text{V/m}$ ), in millivolts per metre ( $\text{mV/m}$ ) or in decibels, as follows:

Field in decibels =  $20 \log$  (field in  $\mu\text{V/m}$ )

Thus, an interference level expressed as 46 dB corresponds to an electric field of 200  $\mu\text{V/m}$  (i.e.  $46 = 20 \log (200/1)$ ). Consequently, the radio noise from overhead lines is expressed in decibels above one microvolt per metre (dB/1  $\mu\text{V/m}$ ). The main source of radio interference (RI) is conductor corona which depends on voltage gradient. Other factors come into play. There are many methods for calculating RI, both analytical and empirical,<sup>39</sup> but the following empirical formula is often accepted in which RI is the radio noise to be calculated (in dB/1  $\mu\text{V/m}$ ),  $E_a$  is the average surface gradient,  $r$  is the radius of the subconductor,  $n$  is the number of subconductors in the bundle,  $h$  is the altitude of the line,  $D$  is the distance of the line at which the noise is measured (typically 15–30 m) and  $f$  is the frequency at which noise is calculated (typically 0.5 or 1.0 MHz in the medium-wave band).

$$\begin{aligned} \text{RI} = (\text{RI})_0 + 3.8(E_a - E_0) + 40 \log \frac{r}{r_0} + 10 \log \frac{n}{n_0} \\ + 30 \log \frac{D_0}{D} + 20 \log \frac{1 + f_0^2}{1 + f^2} + \frac{h - h_0}{300} \end{aligned}$$

The suffix '0' refers to the same parameters as obtained from a known line with fairly close characteristics.<sup>14</sup>

For example, a 500 kV line is designed so that  $E_a = 16 \text{ kV/cm}$ ,  $r = 1.6 \text{ cm}$ ,  $n = 4$ ,  $D = 30 \text{ m}$ ,  $f = 1.0 \text{ MHz}$ , and  $h = 600 \text{ m}$ .

Analysis of data for a comparable construction yields  $(\text{RI})_0 = 57$ ,  $E_0 = 17 \text{ kV/cm}$ ,  $r_0 = 2.14$ ,  $n_0 = 2$ ,  $D_0 = 15$ ,  $f_0 = 0.5 \text{ MHz}$ , and  $h_0 = 300 \text{ m}$ .

Thus,

$$\begin{aligned} \text{RI} &= 57 + 3.8(16 - 17) + 40 \log \frac{1.6}{2.14} + 10 \log \frac{4}{2} \\ &+ 30 \log \frac{15}{30} + 20 \log \frac{1 + 0.5^2}{1 + 1^2} + \frac{600 - 300}{300} \\ &= 57 - 3.8 - 5.05 + 3 - 9.03 - 4.1 + 1 \\ &= 39.02 \text{ dB above } 1 \mu\text{V/m}. \end{aligned}$$

Before the design of the line is accepted, it is necessary to obtain the strength of the radio signal received at the position of the line. The decision will be governed by the desired quality of reception, on the basis of the following table:

Class of reception	Quality of reception	Approximate signal/noise ratio
A	Background undetectable	32
B	Background detectable	27
C	Background evident	22
D	Background evident but speech still understood	16

If, for example, a class of reception B is desired, in the case of the line mentioned above, the signal strength received at 30 m from the axis of the line should be  $39.02 + 27 = 66.02 \text{ dB/1 } \mu\text{V/m}$  under fair weather conditions. If this is not the case, another look at the design or at the route of the line would be justified.

Under foul weather conditions, the radio noise from the line would be some 10 dB/1  $\mu\text{V/m}$  greater.

### 30.4.4 Distribution lines

**Voltage regulation** For distribution lines of short length, the capacitance is usually ignored and the voltage drop is given by:

$$\Delta V = I \cdot l \cdot (R \cos \phi + X \sin \phi) \leftarrow$$

and the regulation is

$$(\Delta V/V)100\%$$

where  $I$  is the current in the line,  $l$  is the length of the line,  $R$  is the resistance per unit length,  $X$  is the inductive reactance per unit length and  $V$  is the nominal voltage. Unfortunately, for conductors greater than approximately 100 mm<sup>2</sup> the reductions in resistance and reactance as a function of increased conductor sizes are small.<sup>2</sup> Table 30.4 and Figure 30.7 illustrate this point. Hence, using conductors with a cross-section above  $2 \times 10^2 \text{ mm}^2$  is unlikely to have a serious impact on regulation.

**Table 30.4** The inductive reactances ( $\Omega/\text{km}$ ) all-aluminium alloy conductors (AAAC)

	Equivalent aluminium area ( $\text{mm}^2$ )					
	25	75	100	150	200	250
Stranding (No./mm)	7/2.34	7/4.04	7/4.65	19/3.48	37/2.87	37/3.23
Resistance at 20 °C	1.093	0.3669	0.2769	0.1831	0.1385	0.1093
Resistance at 75 °C	1.295	0.4347	0.3280	0.2169	0.1641	0.1295
0.3 m ES (415 V)	0.300	0.265	0.256	0.240	0.230	0.223
1.4 m ES (11 kV)	0.396	0.362	0.353	0.337	0.327	0.319
3.0 m ES (66 kV)	0.444	0.410	0.401	0.385	0.375	0.367
4.9 m ES (132 kV)	0.475	0.441	0.432	0.415	0.406	0.398

ES, equivalent spacing.

**Figure 30.7** Plots of (1) the resistance, (2) the reactance and (3)  $R \cos \phi + X \sin \phi$  for the data given in Table 30.4. Drawn for 11 kV line and  $\cos \phi = 0.8$  (typical only)

**Quick method of design** When the voltage regulation is likely to be the controlling factor in the selection of conductors, then the technique of  $\text{kVA} \cdot \text{km}$  is useful.<sup>2</sup> It can be shown that, for 10% voltage drop:

$$\text{kVA} \times \text{km} = 400V^2 / (R \cos \phi + X \sin \phi)$$

i.e. if the regulation is not to exceed 10%, then the  $\text{kVA} \cdot \text{km}$  loading of the line multiplied by its length ( $\text{kVA} \cdot \text{km}$ ) must

be equal to the right-hand side of the above equation. Table 30.5 illustrates some answers.

30.5 Insulators

Air is ubiquitous and is an excellent insulator. The performance of air gaps is well known as regards breakdown as a function of electrode geometry, so that clearances between phase conductors and from conductors to ground can be determined. However, at line supports it is necessary to provide man-made insulators to maintain adequate air gaps and to provide mechanical support.

The electric stresses applied to an overhead line are: (1) internal stresses resulting from (a) normal power frequency voltage, (b) power frequency overvoltage caused by faults or abnormal conditions, and (c) impulse overvoltage (switching); and (2) externally applied stresses due to lightning. Insulation requirements strongly affect the support tower geometry.

The insulation of an overhead line cannot be determined in isolation. It has to be co-ordinated with the system of which it is a part<sup>15,16</sup> and meet specific requirements.<sup>17,18</sup> (See also Chapter 7, Section 7.2.3.)

30.5.1 Types

The most common materials are porcelain (ceramic) and glass. Porcelain insulators are surface glazed, usually in brown but occasionally in other colours (e.g. blue) for reasons of amenity. With glass, the toughening process develops two zones, an outer layer in compression, an inner layer in tension. Damage to the outer skin usually results in an ‘explosion’ of the unit. This feature is sometimes

**Table 30.5** The  $\text{kVA} \cdot \text{km}$  product for a 10% voltage drop and  $\cos \phi = 0.9$  for all-aluminium alloy conductors (AAAC)

	Equivalent aluminium area ( $\text{mm}^2$ )				
	25	75	100	200	250
Current (A)					
Temperate	158	311	370	573	664
Tropical	131	253	299	453	521
415 V	13.3	34.0	42.3	69.5	80.6
11 kV	9042	22 038	26 935	41 706	47 310
66 kV	320 515	764 321	926 600	1 400 638	1 574 662
132 kV	—*	—*	3 603 404	5 370 515	6 006 871

\*Voltage gradient exceeds 18 kV/Cm. Conductor not recommended for this voltage.

regarded as a maintenance advantage, as a damaged unit is readily observed by foot or helicopter patrols.

Although the above materials have been considered suitable for insulation purposes as from the early days of overhead line engineering, designers, laboratories, manufacturers, etc. have been investigating not only new shapes, but also new materials to improve the electrical and mechanical performances of insulators. Thus, in the last few decades, composite insulators, consisting of a high mechanical strength core of parallel glass fibres, within a body of synthetic rubber or cycloaliphatic resin, with improved insulating properties, have been actively investigated with a high degree of success. In fact the combination of such materials offers the possibility of almost endless permutations of strength with a large degree of freedom in the shapes.<sup>42</sup>

Composite insulators have also the added advantage of being more resistant to vandalism than the classical types. They are now used at all voltages from distribution to EHV. It is not always appreciated that on an angle tower at 745 kV the weight of classical insulators could reach 30 tonnes, whereas a single man could carry each tension set if it consists of composite insulators.

Figure 30.8 shows some types of insulator units and sets:

- (a) Shackle: for low-voltage distribution lines.
- (b) Pin: used for voltages up to 33 kV (occasionally 66 kV).
- (c) Post: used up to 66 kV, mainly for the support of air insulated bus-bars.
- (d) Cap and pin: as elements in insulator strings.

**Figure 30.8** Typical insulator units and insulator sets. (a) Shackle insulator; (b) pin insulator; (c) post insulator; (d) normal cap and pin unit; (e) anti-fog cap and pin unit; (f) aerodynamic cap and pin unit; (g) insulator set (single string); (h) 500 kV vee insulator set; (i) composite pin insulator on 11 kV line (courtesy of EA Technology Ltd, Capenhurst)

- (e) Anti-fog cap and pin: for regions of high pollution level, especially if humid.
- (f) Aerodynamic cap and pin: for desert regions.
- (g) Insulator set.
- (h) Vee insulator set.
- (i) Composite insulator on 11 kV line (by courtesy of EA Technology Ltd, Capenhurst)

The elements (d), (e) and (f) can be assembled into one, two or more strings in parallel. Vee types (h) are often favoured for extra high voltage (EHV) lines, as they show economic advantage.

### 30.5.2 Selection

As insulators must meet specified criteria, the choice of type, configuration, etc., is complex. Units are characterised by lightning impulse voltage; power frequency voltage when wet; electromechanical failing load, mechanical load and puncture voltage (when applicable); and dimensions, of which creepage path is the most important parameter for selection.

In addition, strings or sets are characterised by: lightning withstand voltage (dry); switching impulse withstand voltage (wet); and power frequency voltage (wet). The wave shapes for switching surge and lightning impulse tests have been standardised in terms of time to crest and time to half-value on the tail. These, in microseconds, are:

Switching surge:  $(250 \pm 400)/(2500 \pm 400)$

Lightning impulse: 1.2/50

The performance of an air gap depends on the electrode shapes and on the applied voltage wave shape. *Figure 30.9*

**Figure 30.9** Insulation strength of rod/plane air gaps. A, 200/3000  $\mu$ s, negative, switching surge; B, 200/3000  $\mu$ s, positive, switching surge; C, 1.2/50  $\mu$ s, negative, impulse; D, 1.2/50  $\mu$ s, positive, impulse; E, 50 Hz, power frequency

shows typical values for a rod/plane gap. Comparable information (or correction factors) is needed for other configurations.<sup>19</sup> The types of gaps are as follows:

*Rod/plane*: live ends of insulators and fittings to structure and ground.

*Conductor/structure*: inside or outside a tower window, outer phases to any part of the tower.

*Conductor/plane*: clearance at mid-span to ground, or conductor jumper to cross-arm.

*Conductor/conductor*: flashover between phases or between conductor and earth wire.

For insulation co-ordination, the electric strength of the air gaps must be about 10% greater than that of the insulators.<sup>20</sup>

Up to about 400 kV, line insulation is governed by the requirements of creepage distance. For higher voltages, switching-surge considerations predominate.

### 30.5.3 Pollution

A first approximation to the number of units in a string is by an assessment of the intensity of pollution in the area, adopting a creepage distance of 18 mm/kV of line voltage for clean air and up to 30 mm/kV or more for severe pollution.<sup>3,21</sup>

Insulator surfaces may be contaminated by dust and dirt, whose composition varies according to the area where the line is built. If frequent rains occur, these layers may be washed, but occasionally insoluble layers are formed in the presence of mist or dew; and in the absence of heavy down-pours, they reduce the insulation resistance of the insulators. Under certain conditions, flashover can occur which ionises a path in air, providing a channel for follow-currents at power frequency.

To assess the insulation performance of insulators under pollution, two series of tests have been devised.<sup>22</sup>

- (1) *Salt-fog method*: generally representative of coastal areas or of zones where rain can wash the insulators. In this test, insulators are submitted to electrical stresses in an artificial fog of variable salinity.
- (2) *Solid-layer method*: generally representative of industrial zones or desert areas where a solid crust of insoluble deposits can be formed. In this test, the insulators are covered with a special mixture attempting to reproduce natural pollution.

If measurements are made of leakage currents under natural pollution (e.g. at an open-air station), these can be reproduced in the laboratory by varying either the degree of salinity or the composition of the solid layer. Thus, a correlation can be found and a rational assessment can be made as to the ultimate behaviour of the insulators.

Work has been done on palliative measures such as coatings of hydrocarbon or silicon grease, or live-line working. These measures are normally restricted to specific areas.

### 30.5.4 Voltage distribution over insulator strings

When assessing radio noise from an insulator string, it is desirable to know how the voltage along the string is distributed. This can be found by test: (1) a small spark-gap of known flashover voltage is connected across the cap and pin of one insulator element; and (2) the voltage across the string is raised until flashover at the spark gap, giving the voltage across the element as a fraction of the test voltage. *Table 30.6* gives the results of such a test for a string of

**Table 30.6** Voltage distribution over insulator strings without grading fitting

No. of units	Unit number from live end	Voltage across unit (%)
4	1, 2, 3, 4	32, 24, 21, 23
6	1, 2, 3, 4, 5, 6	25, 18, 14, 13, 14, 16
8	1, 2, 3, 4, 5, 6, 7, 8	24, 15, 13, 11, 9, 8, 9, 11
12	1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12	23, 13, 10, 8, 7, 6, 5.5, 5, 5, 5.5, 6, 7
16	1, 2, 3, 4, 5...	20, 13, 9, 7.5, 5.5...

porcelain elements of diameter 254 mm, the string having no protective devices. It will be noted that, for strings with eight or more units, the live-end unit carries 0.20–0.24 of the string voltage, and the second 0.13–0.15.

The application of grading rings and horn fittings modifies the voltage distribution by introducing capacitance in shunt with the line-end units to reduce the voltage across them.

## 30.6 Supports

The supports of an overhead line have the greatest impact on visual amenity. They cannot be hidden, but their appearance may be made less objectionable.

### 30.6.1 Materials

Common structural materials are wood, concrete, tubular or rolled-section steel and aluminium alloys. Choice is governed by economics, availability, resistance to deterioration (e.g. by termites in wood, and corrosion in steel), and sometimes by problems of transportation and erection. When helicopters are used in regions of difficult access, aluminium alloy structures may show a lower cost of installation that counterbalances their greater prime cost.<sup>3</sup>

*Wood poles* are usually preferred for low voltage distribution lines; they have been used for 345 kV lines in the USA and 132 kV in the UK, but normally wood poles are unlikely for voltages over 66 kV.

*Concrete* (reinforced, prestressed or spun) has for poles the drawbacks of weight and fragility during transport. Concrete poles have been employed for lines up to about 220 kV. The material is unlikely to be competitive unless local production facilities are available or there are constraints on imported material.

*Steel*, the material most preferred, can be fabricated in convenient lengths for transport after rolling into angles, beams and rounds. Parts are readily bolted together, facilitating unit-type construction. Steel for overhead lines is normally galvanised by the hot-dip process (BS 729) as a protection against corrosion. In clean air, galvanising can ensure 30–50 years of trouble-free life. Where the atmosphere is potentially corrosive, it may be necessary to paint steel structures after 10 years or less. Two grades of steel are commonly applied to line towers, viz. grade 43A and grade 50B (high tensile) to BS 4360, the latter grade showing advantage in weight reduction.

*Aluminium alloy* is advantageous in special cases (sites difficulty of access or with corrosive atmospheres). A structure of this material is 0.6–0.75 of the weight of an equivalent steel tower, but its cost may be three times as much.

### 30.6.2 Configurations

There is a considerable variety in configuration: the more usual forms are shown diagrammatically in *Figure 30.10* for wood poles and *Figure 30.11* for steel towers.

*Wood poles* These are more economical than lattice-steel supports for lines having spans less than about 200 m and are widely used for distribution in rural areas at voltages up to and including 33 kV. Where ample supplies of wood are available, e.g. in Sweden and parts of America, they have been used for lines up to 220 kV; at these high voltages the portal type of construction is essential to keep the length of pole to a minimum. For lower voltage lines the single pole is generally used, although its transverse strength can be increased three or four times by using two poles arranged in A or H formation. The cross-arms in both the single and the portal types may be of wood or steel, the latter being more usual. A zinc or aluminium cap covers the top of the poles to protect the end grain. The life of a red fir pole, if properly creosoted, is 25–30 years, although British fir or larch has a shorter life.

**Figure 30.10** Typical wood pole constructions for 415 V to 132 kV: (a) low voltage single member pole; (b) 11 kV single member pole; (c) 132 kV support with composite (polymeric) insulators; (d) 132 kV portal (H) structure with standard insulator sets

Figure 30.11 Typical steel towers

Wood is an insulator, so that the pole adds to the insulation strength between the conductors and earth and renders flashover due to lightning less likely. On the other hand, if a pole is struck, it may be shattered, causing complete failure of the line. The probability of shattering can be reduced by earthing all metal supports for the insulators either individually at each pole or by connection to a continuous earth wire.

**Tubular steel poles** These are being increasingly used in the UK, because of the reduction in timber supplies. They are usually formed from three tapered, hollow sections, which rest inside one another during transportation and storage, and which are assembled on the site by means of a special winch, or are driven together by a sledgehammer or wooden maul.

**Steel towers** These are employed where long spans and high supports are needed. Normal spans of 200–500 m are usual, with special cases (such as river crossings) requiring

spans up to 2 km. Lines of 66 kV and over usually have lattice steel supports, especially if they are double-circuit lines.

The lattice-steel support may be of the *broad base* (Figure 30.11(b)) or rigid type, in which each leg of the support has a separate foundation, or of the *narrow base* or flexible type, with only a single foundation (a). The latter is, of course, cheaper, but is less resistant to the twisting moment caused by a broken conductor; on the other hand, it gives some flexibility in the direction of the line which tends to relieve the forces to some extent. The narrow base may also simplify wayleave problems in cultivated areas on account of the smaller area occupied.

Double-circuit lines (c) are more economical than two single-circuit lines, although for a given voltage the tower height is greater. There is the possibility of both circuits being affected simultaneously by lightning, but wayleave problems are eased.

The cat's head horizontal configuration (g) minimises height and reduces the possibility of conductor clashing, but line erection is complicated by having to thread one phase through the steelwork.

The tower (f) for a single-circuit d.c. line is simpler, smaller and 20–30% cheaper than a three-phase single-circuit tower to carry the same electrical load.

The 400 kV double-circuit tower (d), widely used in Britain, is 50 m high and may interfere with amenity. To avoid this the lower type (e) may be used but is 10–15% more expensive.

**Compacted lines** Overhead Line Engineers have always been conscious of the fact that their structures could be an eyesore on the countryside, and one way to deal with this aspect would be to reduce their visual impact.

There is no internationally agreed definition of 'compact lines'. Essentially, it is a subjective assessment of the visual impact of the lines on the countryside. It may be that some countries (e.g. Germany, Japan, etc.) would consider as compact lines those that carry an increased number of circuits, thereby avoiding the need to negotiate new wayleaves, but at the expense of wider existing wayleaves for the 'compacted lines'. Other countries would just re-arrange the positions of the circuits on the supports to reduce height at the expense of increased width.

An illustration of the latter concept is given by Figure 30.11(d) and (e) for towers in the UK drawn to the same scale and designed to transmit exactly the same electrical power where (e) illustrates the compacted design.

When the phase conductors are supported by vertical suspension insulators (e.g. Figure 30.11(d)), considerations of electrical clearances can lead to fairly high structures (see next paragraphs on tower top geometries). Almost invariably, because of the presence of earthed steelwork, the horizontal separations are greater than would be justified by straightforward electrical or dynamic (wind induced motions) considerations.

Cap and pin insulators (Figure 30.8(f), (d), (e)) can only be used in tension and cannot accept compression loads. However, if an insulator set is made up of long rods, or composite insulators, some degree of compression can be accepted, a feature which can be used to achieve an assembly which could control the horizontal swing of insulators at the towers. A reasonable horizontal spacing can also be achieved by using 'V' sets, provided that the inside angle of the 'V' is properly selected as function of the horizontal wind loads and of the vertical conductor weight span loads. Such a solution is shown on Figure 30.11(e) where the phase spacing between the two outer phases is much smaller than on the adjacent tower with vertical sets.

**Figure 30.12** Possible tower top geometries for 'compact lines', with no steelwork between conductors

Clearly then the choice of the insulators has a profound impact on the aesthetics of towers. The structure on *Figure 30.10(c)* can be considered as an element of a compact line.

*Figure 30.12* illustrates some possible tower top geometries with no steelwork between the conductors. The horizontal spacings are only governed by electrical and dynamic considerations. It is thus possible to reduce the visual impact due to height, but at the expense of an increased volume impact of a conglomeration of insulator sets. Slim composite insulators would clearly reduce such an impact. Unfortunately installation costs may be increased as conductor stringing may prove more complex.

### 30.6.3 Tower geometry

Considerations of system design will decide whether a line should carry a single or a double circuit. The choice is influenced by the problem of wayleave. In the UK most grid lines carry a double circuit; elsewhere a multiple-circuit construction to accommodate circuits of different voltages is sometimes used.

The geometry of the tower top is controlled essentially by electrical considerations.

- (1) *Height to bottom cross-arm*: the sum of the clearance to ground, the sag and the insulator-set length.
- (2) *Vertical spacing*: the sum of the electrical clearance plus the insulator length.
- (3) *Horizontal spacing*: (a) in still air, a clearance at least equal to the impulse strength of the insulation; (b) in wind conditions (on the assumption that a fault is unlikely to occur during maximum wind speed), a clearance corresponding at least to the power frequency withstand voltage of the air gap; the deflected position of the insulator string determines the cross-arm length.

It is generally found that horizontally placed conductors have sufficient clearance when they are separated by earthed steelwork. For exceptionally long spans, or when two conductors at the same level are on the same side of the structure, their minimum separation should be

$$D = K_1 \sqrt{(s + l)} + K_2 V$$

where  $s$  is the maximum sag of the conductor in the span,  $l$  is the length of a suspension-insulator set,  $V$  is the line voltage (kV),  $K_1 = 0.6 \times K_3$  (usually  $0.7 < K_1 < 0.9$ ),  $K_3 = [\sqrt{(W^2 + p^2)}]/W$  where  $W$  is unit weight of conductor

(kgf/m) and  $p$  is 50% of wind design pressure (kgf/m) per unit length; and  $K_2 = 0.0025 \times \sqrt{3}$ . The expression is empirically based on the performance of long spans.

The phase geometry of single-circuit lines is either triangular or horizontal. Double-circuit lines are more likely to have a vertical formation. From the system viewpoint, a triangular arrangement results in minor imbalance of the phase impedances (see also Section 30.7).

### 30.6.4 Foundations

Foundations<sup>3</sup> must be adapted to the loadings that they have to withstand and the properties of the soil, i.e. cohesion  $C$ , angle of internal friction  $\phi$ , and density  $\gamma$ .

For single poles and narrow-based towers, the foundations are designed on overturning; for broad-based towers, on uplift/compression. Compression effects are well documented, but uplift has been the subject of lengthy investigation.<sup>23</sup>

*Overturning (monobloc) foundations* Resistance to overturning is of the form  $M = kbd^3$  for a width  $b$  and a depth  $d$ . The coefficient  $k$  depends on the shape of the bloc and the properties of the soil.

*Uplift foundations* In the UK, where 'pad and chimney' foundations are favoured, it is customary to assume that the resistance to uplift is due to (a) the dead weight of the foundation and (b) the weight of the earth contained in a volume of a frustum defined by the base of the foundation and an angle to the horizontal reflecting the soil properties. In addition, the 'chimney' is designed in bending. A general expression for the uplift resistance<sup>24</sup> is

$$F_i = A[Ck_1 + d\gamma(k_2 + k_3) + qk_4] + p_c + p_s$$

where  $A$  is the lateral area rising from the base of the foundation to the surface of the soil,  $d$  is the depth,  $p_c$  is the weight of concrete and  $p_s$  is the weight of soil above the foundation, and  $q$  is the overburden pressure for foundations set below the critical depth. The critical depth is a function of the geometry of the foundation and of the soil parameters. The constants  $k$  depend on the type of soil. In a pad and chimney foundation the pad can be shaped by formers or cast on site into an excavated hole. When access is difficult and concrete expensive (because of lack of available

water or aggregates), grillage pads may be considered, as individual bars can be transported to site. In bad soils pile or raft foundations may be used; in good rock the foundation may employ rock anchors.

## 30.7 Lightning

Lightning results from a phenomenon in which the clouds in the ambient atmosphere acquire substantial electric charges, with corresponding potentials which may be several megavolts. When the limit breakdown value of the air is reached, a lightning discharge takes place between clouds, or between clouds and earth. Because of their height, overhead transmission lines 'attract' lightning discharge. Data are available for the percentage of days when thunder is heard<sup>20</sup> and the number of flashes to earth per annum per unit area. The 'keraunic level' is the number of days thunder is heard in a year.

### 30.7.1 Mechanisms of insulation flashover

#### 30.7.1.1 Induced voltage

A lightning stroke to ground near a line discharges the energy in the cloud very rapidly, initiating by travelling wave action an induced voltage rise across the insulators. The problem arises only at line voltages of 66 kV and less, for which lines it would be uneconomic to provide a complete guard against this hazard.

#### 30.7.1.2 Shielding failure

Shielding failure occurs when the leader stroke of the lightning discharge bypasses the earth wire (which is usually at ground potential) and strikes a conductor. Some protection against this hazard is provided by positioning the earth wire(s) above the conductors. Analytical models<sup>25</sup> have been evolved for the calculation of the appropriate position(s). A shielding angle of  $30^\circ$  is generally adequate: the angle is that between the vertical through the earth wire and the line joining the earth wire and the protected conductor. However, in areas of high lightning intensity, zero (or even negative) angles have been used.

#### 30.7.1.3 Back-flashover

Figure 30.13 shows that about 10% of lightning strikes involve a current  $i$  exceeding 50 kA of very steep wavefront. When lightning strikes (a) a tower or (b) an earth wire, their potential may be raised to a value well in excess of the insulation level, possibly high enough to cause flashover to the line conductors.

**Tower** If the tower resistance (mainly that of the footing) is  $R$  and the inductance as a vertical circuit element is  $L$ , then the potential of the tower top will be raised from zero to  $v = Ri + L(di/dt)$ . This simple approach illustrates the effect of the basic parameters: a more critical study would be required to take account of capacitive and inductive couplings between conductors, the effects of multiple reflections, etc.

**Earth wire** Given that the surge impedance of the earth wire is  $Z_0$ , a lightning strike raises the earth wire potential from zero to  $v = \frac{1}{2}Z_0i$ . Two travelling waves are propagated in opposite directions from the point of strike, until each reaches a tower top and is partially discharged through the tower to ground, as in A in Figure 30.13.

**Figure 30.13** Lightning strike magnitude probability curves. Abscissa: lightning strike peak current (kA). Ordinate (left side): percentage of strokes exceeding abscissa. A, Ordinate (right side): percentage of strokes exceeding abscissa. B, for lightning currents exceeding 50 kA

### 30.7.2 Lightning performance

Various methods (ERA,<sup>20</sup> IEEE<sup>26</sup> and EPRI<sup>27</sup>) have been evolved, and refined in the light of experience, for the estimation of the lightning performance of overhead lines. The basic step is the calculation of the potential rise of the tower top or earth wire as a function of the lightning current discharged to ground. It is then necessary to develop an analytical model to include the statistical distribution of current wave shapes, grounding parameters, leader approach angles, ground flash density, back-flashover and shielding failure.<sup>28,29</sup> The ERA method employs a step-by-step procedure clearly demonstrating the factors affecting line performance; the IEEE method, easier to apply, is based on generalised graphs. The EPRI method is very explicit.

In overhead-line design, some parameters will depend on lightning as they affect the number and positioning of earth wires, the length of insulator strings and tower-footing resistance. Further considerations relate to tower height, phase configurations and span lengths. It is now accepted that an earth wire with 10% smaller sag than that of the associated conductor minimises the likelihood of mid-span flashover between them. The main purpose of an earth wire is to shield phase conductors from direct strokes, which would almost always result in insulator flashover.

Increased tower height attracts more lightning strokes. Thus, the lightning performance of a line is improved by shorter towers (and consequently shorter spans). Short towers with wide bodies have lower surge impedance. But in many cases it is economic considerations that settle the final choice.

## 30.8 Loadings

The mechanical loadings on an overhead line are due to conductor tension, wind, icing and temperature variations. The design regulations or codes of practice in most countries were based on the concepts of external working loads multiplied by different factors (often termed factors of safety, overload factors, etc.) to evaluate ultimate (or limit) loads which were compared with the strength of

components. In the UK, the earlier Regulations<sup>30</sup> gave some loadings which were to be compared with a proportion of the strength of components. For the first time, the expression 'factor of safety' was avoided, but the concept is still used in many international regulations. In the UK, the utilities (e.g. National Grid Corporation) in fact use higher loads than those specified in these Regulations. In many cases, the origins of the loads and the factors used are never very clear.

Actually, in 1988, a new set of Regulations was published in the UK<sup>31</sup> which concentrates mainly on electrical safety, but is exceedingly concise regarding the loadings to be applied to an overhead line. In fact, they only state that the '...works shall be sufficient for the purposes for, and the circumstances in, which they are used...'. The onus for the adequate performance lies with the operator and the designer. As a result of international discussions a probabilistic approach is now gaining acceptance.<sup>40,41</sup>

Accepting (Figure 30.14) that the load effects on an overhead line are random<sup>32,33</sup> and can be expressed by a probability density function of extreme values (Gumbel type 1)  $f_Q(X)$ , that the strength of the components can be expressed by a normal probability density function (Gaussian)  $f_R(X)$ , new probabilistic approaches have been evolved<sup>34</sup> which are likely to be used by specification writers.<sup>3</sup> (In Figure 30.14 the strength function is shown as a cumulative distribution,  $F_R(X)$ .) These two functions lend themselves to mathematical treatment and are defined when a mean value and a standard deviation can be evaluated from measurement data. The area under the two overlapping curves is a measure of the risk (in this zone there is a probability that the load is greater than the strength), and they can be located with respect to each other in such a way that a small value of risk can be obtained. The smaller the risk (probability of failure) the greater the reliability. It will be seen that mathematically 100% reliability cannot be achieved. This feature is not due to the approach, it is a hard real fact, except that in the conventional deterministic treatment there is no way to quantify the reliability of a construction.

Some documents<sup>34</sup> have been revised and incorporate comments<sup>35</sup> which have already been made. Several application examples have also been published.<sup>36,37</sup>

Three important concepts have been introduced:

- (1) *Reliability* (structural) is the probability that a system performs a given task under a set of conditions during a specified time. Reliability is thus a measure of the success of a system in accomplishing its task. Reliability, being a probabilistic concept, should always be quantified.
- (2) *Security* (structural) is the ability of a system to be protected from a major collapse (cascading effect) if a failure is triggered in a given component. Security is a deterministic concept.
