*Important notice*

Many practical techniques described in this book involve potentially dangerous applications of electricity and engineering equipment. The authors, editors and publishers cannot take responsibility for any personal, professional or financial risk involved in carrying out these techniques, or any resulting injury, accident or loss. The techniques described in this book should only be implemented by professional and fully qualified electrical engineers using their own professional judgement and due regard to health and safety issues.

## Preface

## Section A – General Principles

### 1 Units, Mathematics and Physical Quantities

International unit system . Mathematics . Physical quantities . Physical properties . Electricity

### 2 Electrotechnology

Nomenclature . Thermal effects . Electrochemical effects . Magnetic field effects . Electric field effects . Electromagnetic field effects . Electrical discharges

### 3 Network Analysis

Introduction . Basic network analysis . Power-system network analysis

## Section B – Materials & Processes

### 4 Fundamental Properties of Materials

Introduction . Mechanical properties . Thermal properties . Electrically conducting materials . Magnetic materials . Dielectric materials . Optical materials . The plasma state

### 5 Conductors and Superconductors

Conducting materials . Superconductors

### 6 Semiconductors, Thick and Thin-Film Microcircuits

Silicon, silicon dioxide, thick- and thin-film technology . Thick- and thin-film microcircuits

### 7 Insulation

Insulating materials . Properties and testing . Gaseous dielectrics . Liquid dielectrics . Semi-fluid and fusible materials . Varnishes, enamels, paints and lacquers . Solid dielectrics . Composite solid/liquid dielectrics . Irradiation effects . Fundamentals of dielectric theory . Polymeric insulation for high voltage outdoor applications

### 8 Magnetic Materials

Ferromagnetics . Electrical steels including silicon steels . Soft irons and relay steels . Ferrites . Nickel–iron alloys . Iron–cobalt alloys . Permanent magnet materials

### 9 Electroheat and Materials Processing

Introduction . Direct resistance heating . Indirect resistance heating . Electric ovens and furnaces . Induction heating . Metal melting . Dielectric heating . Ultraviolet processes . Plasma torches . Semiconductor plasma processing . Lasers

### 10 Welding and Soldering

Arc welding . Resistance welding . Fuses . Contacts . Special alloys . Solders . Rare and precious metals . Temperature-sensitive bimetals . Nuclear-reactor materials . Amorphous materials

## Section C – Control

### 11 Electrical Measurement

Introduction . Terminology . The role of measurement traceability in product quality . National and international measurement standards . Direct-acting analogue measuring instruments . Integrating (energy) metering . Electronic instrumentation . Oscilloscopes . Potentiometers and bridges . Measuring and protection transformers . Magnetic measurements . Transducers . Data recording

### 12 Industrial Instrumentation

Introduction . Temperature . Flow . Pressure . Level transducers . Position transducers . Velocity and acceleration . Strain gauges, loadcells and weighing . Fieldbus systems . Installation notes

### 13 Control Systems

Introduction . Laplace transforms and the transfer function . Block diagrams . Feedback . Generally desirable and acceptable behaviour . Stability . Classification of system and static accuracy . Transient behaviour . Root-locus method . Frequency-response methods . State-space description . Sampled-data systems . Some necessary mathematical preliminaries . Sampler and zero-order hold . Block diagrams . Closed-loop systems . Stability . Example . Dead-beat response . Simulation . Multivariable control . Dealing with non linear elements .

Disturbances . Ratio control . Transit delays . Stability .  
Industrial controllers . Digital control algorithms .  
Auto-tuners . Practical tuning methods

## **14 Digital Control Systems**

Introduction . Logic families . Combinational logic . Storage .  
Timers and monostables . Arithmetic circuits . Counters and  
shift registers . Sequencing and event driven logic . Analog  
interfacing . Practical considerations . Data sheet notations

## **15 Microprocessors**

Introduction . Structured design of programmable logic  
systems . Microprogrammable systems . Programmable  
systems . Processor instruction sets . Program structures .  
Reduced instruction set computers (RISC) . Software  
design . Embedded systems

## **16 Programmable Controllers**

Introduction . The programmable controller . Programming  
methods . Numerics . Distributed systems and fieldbus .  
Graphics . Software engineering . Safety

## **Section D – Power Electronics and Drives**

### **17 Power Semiconductor Devices**

Junction diodes . Bipolar power transistors and  
Darlington's . Thyristors . Schottky barrier diodes .  
MOSFET . The insulated gate bipolar  
transistor (IGBT)

### **18 Electronic Power Conversion**

Electronic power conversion principles . Switch-mode  
power supplies . D.c./a.c. conversion . A.c./d.c. conversion .  
A.c./a.c. conversion . Resonant techniques . Modular  
systems . Further reading

### **19 Electrical Machine Drives**

Introduction . Fundamental control requirements for electrical  
machines . Drive power circuits . Drive control . Applications  
and drive selection . Electromagnetic compatibility

### **20 Motors and Actuators**

Energy conversion . Electromagnetic devices . Industrial  
rotary and linear motors

## **Section E – Environment**

### **21 Lighting**

Light and vision . Quantities and units . Photometric  
concepts . Lighting design technology . Lamps . Lighting  
design . Design techniques . Lighting applications

### **22 Environmental Control**

Introduction . Environmental comfort . Energy  
requirements . Heating and warm-air systems . Control .  
Energy conservation . Interfaces and associated data

## **23 Electromagnetic Compatibility**

Introduction . Common terms . The EMC model . EMC  
requirements . Product design . Device selection . Printed  
circuit boards . Interfaces . Power supplies and power-line  
filters . Signal line filters . Enclosure design . Interface cable  
connections . Golden rules for effective design for EMC .  
System design . Buildings . Conformity assessment . EMC  
testing and measurements . Management plans

## **24 Health and Safety**

The scope of electrical safety considerations . The nature of  
electrical injuries . Failure of electrical equipment

## **25 Hazardous Area Technology**

A brief UK history . General certification requirements .  
Gas group and temperature class . Explosion protection  
concepts . ATEX certification . Global view . Useful  
websites

## **Section F – Power Generation**

### **26 Prime Movers**

Steam generating plant . Steam turbine plant . Gas turbine  
plant . Hydroelectric plant . Diesel-engine plant

### **27 Alternative Energy Sources**

Introduction . Solar . Marine energy . Hydro . Wind .  
Geothermal energy . Biofuels . Direct conversion . Fuel cells .  
Heat pumps

### **28 Alternating Current Generators**

Introduction . Airgap flux and open-circuit e.m.f. .  
Alternating current windings . Coils and insulation .  
Temperature rise . Output equation . Armature reaction .  
Reactances and time constants . Steady-state operation .  
Synchronising . Operating charts . On-load excitation .  
Sudden three phase short circuit . Excitation systems .  
Turbogenerators . Generator–transformer connection .  
Hydrogenerators . Salient-pole generators other than  
hydrogenerators . Synchronous compensators . Induction  
generators . Standards

### **29 Batteries**

Introduction . Cells and batteries . Primary cells .  
Secondary cells and batteries . Battery applications .  
Anodising . Electrodeposition . Hydrogen and oxygen  
electrolysis

## **Section G – Transmission and Distribution**

### **30 Overhead Lines**

General . Conductors and earth wires . Conductor fittings .  
Electrical characteristics . Insulators . Supports . Lightning .  
Loadings

## **31 Cables**

Introduction . Cable components . General wiring cables and flexible cords . Supply distribution cables . Transmission cables . Current-carrying capacity . Jointing and accessories . Cable fault location

## **32 HVDC**

Introduction . Applications of HVDC . Principles of HVDC converters . Transmission arrangements . Converter station design . Insulation co-ordination of HVDC converter stations . HVDC thyristor valves . Design of harmonic filters for HVDC converters . Reactive power considerations . Control of HVDC . A.c. system damping controls . Interaction between a.c. and d.c. systems . Multiterminal HVDC systems . Future trends

## **33 Power Transformers**

Introduction . Magnetic circuit . Windings and insulation . Connections . Three-winding transformers . Quadrature booster transformers . On-load tap changing . Cooling . Fittings . Parallel operation . Auto-transformers . Special types . Testing . Maintenance . Surge protection . Purchasing specifications

## **34 Switchgear**

Circuit-switching devices . Materials . Primary-circuit-protection devices . LV switchgear . HV secondary distribution switchgear . HV primary distribution switchgear . HV transmission switchgear . Generator switchgear . Switching conditions . Switchgear testing . Diagnostic monitoring . Electromagnetic compatibility . Future developments

## **35 Protection**

Overcurrent and earth leakage protection . Application of protective systems . Testing and commissioning . Overvoltage protection

## **36 Electromagnetic Transients**

Introduction . Basic concepts of transient analysis . Protection of system and equipment against transient overvoltage . Power system simulators . Waveforms associated with the electromagnetic transient phenomena

## **37 Optical Fibres in Power Systems**

Introduction . Optical fibre fundamentals . Optical fibre cables . British and International Standards . Optical fibre telemetry on overhead power lines . Power equipment monitoring with optical fibre sensors

## **38 Installation**

Layout . Regulations and specifications . High-voltage supplies . Fault currents . Substations . Wiring systems . Lighting and small power . Floor trunking . Stand-by and emergency supplies . Special buildings . Low-voltage switchgear and protection . Transformers . Power-factor correction . Earthing . Inspection and testing

## **Section H – Power Systems**

### **39 Power System Planning**

The changing electricity supply industry (ESI) . Nature of an electrical power system . Types of generating plant and characteristics . Security and reliability of a power system . Revenue collection . Environmental sustainable planning

### **40 Power System Operation and Control**

Introduction . Objectives and requirements . System description . Data acquisition and telemetering . Decentralised control: excitation systems and control characteristics of synchronous machines . Decentralised control: electronic turbine controllers . Decentralised control: substation automation . Decentralised control: pulse controllers for voltage control with tap-changing transformers . Centralised control . System operation . System control in liberalised electricity markets . Distribution automation and demand side management . Reliability considerations for system control

### **41 Reactive Power Plant and FACTS Controllers**

Introduction . Basic concepts . Variations of voltage with load . The management of vars . The development of FACTS controllers . Shunt compensation . Series compensation . Controllers with shunt and series components . Special aspects of var compensation . Future prospects

### **42 Electricity Economics and Trading**

Introduction . Summary of electricity pricing principles . Electricity markets . Market models . Reactive market

### **43 Power Quality**

Introduction . Definition of power quality terms . Sources of problems . Effects of power quality problems . Measuring power quality . Amelioration of power quality problems . Power quality codes and standards

## **Section I – Sectors of Electricity Use**

### **44 Road Transport**

Electrical equipment of road transport vehicles . Light rail transit . Battery vehicles . Road traffic control and information systems

### **45 Railways**

Railway electrification . Diesel-electric traction . Systems, EMC and standards . Railway signalling and control

### **46 Ships**

Introduction . Regulations . Conditions of service . D.c. installations . A.c. installations . Earthing . Machines

and transformers . Switchgear . Cables . Emergency power .  
Steering gear . Refrigerated cargo spaces . Lighting .  
Heating . Watertight doors . Ventilating fans . Radio  
interference and electromagnetic compatibility . Deck  
auxiliaries . Remote and automatic control systems .  
Tankers . Steam plant . Generators . Diesel engines .  
Electric propulsion

## **47 Aircraft**

Introduction . Engine technology . Wing technology .  
Integrated active controls . Flight-control systems . Systems  
technology . Hydraulic systems . Air-frame mounted  
accessory drives . Electrohydraulic flight controls .  
Electromechanical flight controls . Aircraft electric power .  
Summary of power systems . Environmental control  
system . Digital power/digital load management

## **48 Mining Applications**

General . Power supplies . Winders . Underground  
transport . Coal-face layout . Power loaders . Heading  
machines . Flameproof and intrinsically safe equipment .  
Gate-end boxes . Flameproof motors . Cables, couplers,  
plugs and sockets . Drilling machines . Underground  
lighting . Monitoring and control

## **49 Standards and Certification**

Introduction . Organisations preparing electrical standards .  
The structure and application of standards . Testing,  
certification and approval to standard recommendations .  
Sources of standards information

## **Index**

# Preface

The *Electrical Engineer's Reference Book* was first published in 1945: its original aims, to reflect the state of the art in electrical science and technology, have been kept in view throughout the succeeding decades during which subsequent editions have appeared at regular intervals.

Publication of a new edition gives the opportunity to respond to many of the changes occurring in the practice of electrical engineering, reflecting not only the current commercial and environmental concerns of society, but also industrial practice and experience plus academic insights into fundamentals. For this 16th edition, thirty-nine chapters are either new, have been extensively rewritten, or augmented and updated with new material. As in earlier editions this wide range of material is brought within the scope of a single volume. To maintain the overall length within the possible bounds some of the older material has been deleted to make way for new text.

The organisation of the book has been recast in the following format with the aim of facilitating quick access to information.

**General Principles** (Chapters 1–3) covers basic scientific background material relevant to electrical engineering. It includes chapters on units, mathematics and physical quantities, electrotechnology and network analysis.

**Materials & Processes** (Chapters 4–10) describes the fundamentals and range of materials encountered in electrical engineering in terms of their electromechanical, thermoelectric and electromagnetic properties. Included are chapters on the fundamental properties of materials, conductors and superconductors, semiconductors, insulation, magnetic materials, electroheat and materials processing and welding and soldering.

**Control** (Chapters 11–16) is a largely new section with six chapters on electrical measurement and instruments, industrial instrumentation for process control, classical control systems theory, fundamentals of digital control, microprocessors and programmable controllers.

**Power Electronics and Drives** (Chapters 17–20) reflect the significance of upto 50% of all electrical power passing through semiconductor conversion. The subjects included of greatest importance to industry, particularly those related to the area of electrical variable speed drives, comprise power semiconductor devices, electronic power conversion, electrical machine drives, motors and actuators.

**Environment** (Chapters 21–25) is a new section of particular relevance to current concerns in this area including lighting, environmental control, electromagnetic compatibility, health and safety, and hazardous area technology.

**Power Generation** (Chapters 26–29) sees some rationalisation of contributions to previous editions in the largely mechanical engineering area of prime movers, but with an expanded treatment of the increasingly important topic of alternative energy sources, along with further chapters on alternating current generators and batteries.

**Transmission and Distribution** (Chapters 30–38) is concerned with the methods and equipment involved in the delivery of electric power from the generator to the consumer. It deals with overhead lines, cables, HVDC transmission, power transformers, switchgear, protection, and optical fibres in power systems and aspects of installation with an additional chapter on the nature of electromagnetic transients.

**Power Systems** (Chapters 39–43) gathers together those topics concerned with present day power system planning and power system operation and control, together with aspects of related reactive power plant and FACTS controllers. Chapters are included on electricity economics and trading in the liberalised electricity supply industry now existing in many countries, plus an analysis of the power supply quality necessary for modern industrialised nations.

**Sectors of Electricity Use** (Chapters 44–49) is a concluding section comprising chapters on the special requirements of agriculture and horticulture, roads, railways, ships, aircraft, and mining with a final chapter providing a preliminary guide to Standards and Certification.

Although every effort has been made to cover the scope of electrical engineering, the nature of the subject and the manner in which it is evolving makes it inevitable that improvements and additions are possible and desirable. In order to ensure that the reference information provided remains accurate and relevant, communications from professional engineers are invited and all are given careful consideration in the revision and preparation of new editions of the book.

The expert contributions made by all the authors involved and their patience through the editorial process is gratefully acknowledged.

M. A. Laughton  
D. F. Warne  
2002

Electrical Engineer's Reference Book—online edition

As this book goes to press an online electronic version is also in preparation. The online edition will feature

- the complete text of the book
- access to the latest revisions (a rolling chapter-by-chapter revision will take place between print editions)
- additional material not included in the print version

- 1.1 International unit system 1/3
  - 1.1.1 Base units 1/3
  - 1.1.2 Supplementary units 1/3
  - 1.1.3 Notes 1/3
  - 1.1.4 Derived units 1/3
  - 1.1.5 Auxiliary units 1/4
  - 1.1.6 Conversion factors 1/4
  - 1.1.7 CGS electrostatic and electromagnetic units 1/4
- 1.2 Mathematics 1/4
  - 1.2.1 Trigonometric relations 1/6
  - 1.2.2 Exponential and hyperbolic relations 1/7
  - 1.2.3 Bessel functions 1/9
  - 1.2.4 Series 1/9
  - 1.2.5 Fourier series 1/9
  - 1.2.6 Derivatives and integrals 1/10
  - 1.2.7 Laplace transforms 1/10
  - 1.2.8 Binary numeration 1/10
  - 1.2.9 Power ratio 1/13
  - 1.2.10 Matrices and vectors 1/13
- 1.3 Physical quantities 1/17
  - 1.3.1 Energy 1/17
  - 1.3.2 Structure of matter 1/19
- 1.4 Physical properties 1/26
- 1.5 Electricity 1/26
  - 1.5.1 Charges at rest 1/26
  - 1.5.2 Charges in motion 1/26
  - 1.5.3 Charges in acceleration 1/28

This reference section provides (a) a statement of the International System (SI) of Units, with conversion factors; (b) basic mathematical functions, series and tables; and (c) some physical properties of materials.

## 1.1 International unit system

The International System of Units (SI) is a metric system giving a fully coherent set of units for science, technology and engineering, involving no conversion factors. The starting point is the selection and definition of a minimum set of independent 'base' units. From these, 'derived' units are obtained by forming products or quotients in various combinations, again without numerical factors. For convenience, certain combinations are given shortened names. A single SI unit of energy (joule = kilogram metre-squared per second-squared) is, for example, applied to energy of any kind, whether it be kinetic, potential, electrical, thermal, chemical . . . , thus unifying usage throughout science and technology.

The SI system has seven *base* units, and two *supplementary* units of angle. Combinations of these are *derived* for all other units. Each physical quantity has a quantity symbol (e.g.  $m$  for mass,  $P$  for power) that represents it in physical equations, and a unit symbol (e.g. kg for kilogram, W for watt) to indicate its SI unit of measure.

### 1.1.1 Base units

Definitions of the seven base units have been laid down in the following terms. The quantity symbol is given in italic, the unit symbol (with its standard abbreviation) in roman type. As measurements become more precise, changes are occasionally made in the definitions.

**Length:**  $l$ , metre (m) The metre was defined in 1983 as the length of the path travelled by light in a vacuum during a time interval of  $1/299\,792\,458$  of a second.

**Mass:**  $m$ , kilogram (kg) The mass of the international prototype (a block of platinum preserved at the International Bureau of Weights and Measures, Sèvres).

**Time:**  $t$ , second (s) The duration of  $9\,192\,631\,770$  periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the caesium-133 atom.

**Electric current:**  $i$ , ampere (A) The current which, maintained in two straight parallel conductors of infinite length, of negligible circular cross-section and 1 m apart in vacuum, produces a force equal to  $2 \times 10^{-7}$  newton per metre of length.

**Thermodynamic temperature:**  $T$ , kelvin (K) The fraction  $1/273.16$  of the thermodynamic (absolute) temperature of the triple point of water.

**Luminous intensity:**  $I$ , candela (cd) The luminous intensity in the perpendicular direction of a surface of  $1/600\,000\text{ m}^2$  of a black body at the temperature of freezing platinum under a pressure of  $101\,325$  newton per square metre.

**Amount of substance:**  $Q$ , mole (mol) The amount of substance of a system which contains as many elementary entities as there are atoms in  $0.012$  kg of carbon-12. The elementary entity must be specified and may be an atom, a molecule, an ion, an electron . . . , or a specified group of such entities.

### 1.1.2 Supplementary units

**Plane angle:**  $\alpha, \beta, \zeta, \dots$ , radian (rad) The plane angle between two radii of a circle which cut off on the circumference of the circle an arc of length equal to the radius.

**Solid angle:**  $\Omega$ , steradian (sr) The solid angle which, having its vertex at the centre of a sphere, cuts off an area of the surface of the sphere equal to a square having sides equal to the radius.

### 1.1.3 Notes

**Temperature** At zero K, bodies possess no thermal energy. Specified points (273.16 and 373.16 K) define the Celsius (centigrade) scale (0 and 100°C). In terms of *intervals*,  $1^\circ\text{C} = 1\text{ K}$ . In terms of *levels*, a scale Celsius temperature  $\theta_{\text{C}}$  corresponds to  $(\theta_{\text{C}} + 273.16)\text{ K}$ .

**Force** The SI unit is the newton (N). A force of 1 N endows a mass of 1 kg with an acceleration of  $1\text{ m/s}^2$ .

**Weight** The weight of a mass depends on gravitational effect. The standard weight of a mass of 1 kg at the surface of the earth is 9.807 N.

### 1.1.4 Derived units

All physical quantities have units derived from the base and supplementary SI units, and some of them have been given names for convenience in use. A tabulation of those of interest in electrical technology is appended to the list in *Table 1.1*.

**Table 1.1** SI base, supplementary and derived units

<i>Quantity</i>	<i>Unit name</i>	<i>Derivation</i>	<i>Unit symbol</i>
Length	metre		m
Mass	kilogram		kg
Time	second		s
Electric current	ampere		A
Thermodynamic temperature	kelvin		K
Luminous intensity	candela		cd
Amount of substance	mole		mol
Plane angle	radian		rad
Solid angle	steradian		sr
Force	newton	$\text{kg m/s}^2$	N
Pressure, stress	pascal	$\text{N/m}^2$	Pa
Energy	joule	$\text{N m}, \text{W s}$	J
Power	watt	$\text{J/s}$	W
Electric charge, flux	coulomb	$\text{A s}$	C
Magnetic flux	weber	$\text{V s}$	Wb
Electric potential	volt	$\text{J/C}$	V
Magnetic flux density	tesla	$\text{Wb/m}^2$	T
Resistance	ohm	$\text{V/A}$	$\Omega$
Inductance	henry	$\text{Wb/A}, \text{V s/A}$	H
Capacitance	farad	$\text{C/V}, \text{A s/V}$	F
Conductance	siemens	$\text{A/V}$	S
Frequency	hertz	$\text{s}^{-1}$	Hz
Luminous flux	lumen	$\text{cd sr}$	lm
Illuminance	lux	$\text{lm/m}^2$	lx
Radiation activity	becquerel	$\text{s}^{-1}$	Bq
Absorbed dose	gray	$\text{J/kg}$	Gy
Mass density	kilogram per cubic metre		$\text{kg/m}^3$
Dynamic viscosity	pascal-second		$\text{Pa s}$
Concentration	mole per cubic metre		$\text{mol/m}^3$
Linear velocity	metre per second		$\text{m/s}$
Linear acceleration	metre per second-squared		$\text{m/s}^2$
Angular velocity	radian per second		$\text{rad/s}$

*cont'd*

Table 1.1 (continued)

Quantity	Unit name	Derivation	Unit symbol
Angular acceleration	radian per second-squared		rad/s <sup>2</sup>
Torque	newton metre		N m
Electric field strength	volt per metre		V/m
Magnetic field strength	ampere per metre		A/m
Current density	ampere per square metre		A/m <sup>2</sup>
Resistivity	ohm metre		Ω m
Conductivity	siemens per metre		S/m
Permeability	henry per metre		H/m
Permittivity	farad per metre		F/m
Thermal capacity	joule per kelvin		J/K
Specific heat capacity	joule per kilogram kelvin		J/(kg K)
Thermal conductivity	watt per metre kelvin		W/(m K)
Luminance	candela per square metre		cd/m <sup>2</sup>

Decimal multiples and submultiples of SI units are indicated by prefix letters as listed in Table 1.2. Thus, kA is the unit symbol for kiloampere, and μF that for microfarad. There is a preference in technology for steps of 10<sup>3</sup>. Prefixes for the kilogram are expressed in terms of the gram: thus, 1000 kg = 1 Mg, not 1 kkg.

Table 1.2 Decimal prefixes

10 <sup>18</sup> exa E	10 <sup>9</sup> giga G	10 <sup>2</sup> hecto h	10 <sup>-3</sup> milli m	10 <sup>-12</sup> pico p
10 <sup>15</sup> peta P	10 <sup>6</sup> mega M	10 <sup>1</sup> deca da	10 <sup>-6</sup> micro μ	10 <sup>-15</sup> femto f
10 <sup>12</sup> tera T	10 <sup>3</sup> kilo k	10 <sup>-1</sup> deci d	10 <sup>-9</sup> nano n	10 <sup>-18</sup> atto a
		10 <sup>-2</sup> centi c		

Table 1.3 Auxiliary units

Quantity	Symbol	SI	Quantity	Symbol	SI
Angle			Mass		
degree	(°)	π/180	tonne	t	1000 kg
minute	(')	—			
second	( <sup>''</sup> )	—	Nucleonics, Radiation		
Area			becquerel	Bq	1.0 s <sup>-1</sup>

Ångstrom	Å	0.1	Volume		
			litre	l or L	1.0 dm <sup>3</sup>

### 1.1.5 Auxiliary units

Some quantities are still used in special fields (such as vacuum physics, irradiation, etc.) having non-SI units. Some of these are given in Table 1.3 with their SI equivalents.

### 1.1.6 Conversion factors

Imperial and other non-SI units still in use are listed in Table 1.4, expressed in the most convenient multiples or submultiples of the basic SI unit [ ] under classified headings.

### 1.1.7 CGS electrostatic and electromagnetic units

Although obsolescent, electrostatic and electromagnetic units (e.s.u., e.m.u.) appear in older works of reference. Neither system is 'rationalised', nor are the two mutually compatible. In e.s.u. the electric space constant is ε<sub>0</sub> = 1, in e.m.u. the magnetic space constant is μ<sub>0</sub> = 1; but the SI units take account of the fact that 1/√(ε<sub>0</sub>μ<sub>0</sub>) is the velocity of electromagnetic wave propagation in free space. Table 1.5 lists SI units with the equivalent number *n* of e.s.u. and e.m.u. Where these lack names, they are expressed as SI unit names with the prefix 'st' ('electrostatic') for e.s.u. and 'ab' ('absolute') for e.m.u. Thus, 1 V corresponds to 10<sup>-2/3</sup> stV and to 10<sup>8</sup> abV, so that 1 stV = 300 V and 1 abV = 10<sup>-8</sup> V.

## 1.2 Mathematics

Mathematical symbolism is set out in Table 1.6. This subsection gives trigonometric and hyperbolic relations, series (including Fourier series for a number of common wave forms), binary enumeration and a list of common derivatives and integrals.

**Table 1.4** Conversion factors

### 1.2.1 Trigonometric relations

The trigonometric functions (sine, cosine, tangent, cosecant, secant, cotangent) of an angle  $\theta$  are based on the circle, given by  $x^2 + y^2 = h^2$ . Let two radii of the circle enclose an angle  $\theta$  and form the sector area  $S_c = (\pi h^2)(\theta/2\pi)$  shown shaded in Figure 1.1 (left); then  $\theta$  can be defined as  $2S_c/h^2$ . The right-angled triangle with sides  $h$  (hypotenuse),  $a$  (adjacent side) and  $p$  (opposite side) give ratios defining the trigonometric functions

$$\begin{aligned}\sin \theta &= p/h & \text{cosec } \theta &= 1/\sin \theta = h/p \\ \cos \theta &= a/h & \sec \theta &= 1/\cos \theta = h/a \\ \tan \theta &= p/a & \text{cotan } \theta &= 1/\tan \theta = a/p\end{aligned}$$

In any triangle (Figure 1.1, right) with angles,  $A$ ,  $B$  and  $C$  at the corners opposite, respectively, to sides  $a$ ,  $b$  and  $c$ , then  $A + B + C = \pi$  rad ( $180^\circ$ ) and the following relations hold:

$$\begin{aligned}a &= b \cos C + c \cos B \\ b &= c \cos A + a \cos C \\ c &= a \cos B + b \cos A \\ a/\sin A &= b/\sin B = c/\sin C \\ a^2 &= b^2 + c^2 + 2bc \cos A \\ (a+b)/(a-b) &= (\sin A + \sin B)/(\sin A - \sin B)\end{aligned}$$

Other useful relationships are:

$$\begin{aligned}\sin(x \pm y) &= \sin x \cdot \cos y \pm \cos x \cdot \sin y \\ \cos(x \pm y) &= \cos x \cdot \cos y \mp \sin x \cdot \sin y\end{aligned}$$

$$\tan(x \pm y) = (\tan x \cdot \tan y)/(1 \mp \tan x \cdot \tan y)$$

$$\sin^2 x = \frac{1}{2}(1 - \cos 2x) \quad \cos^2 x = -\frac{1}{2}(1 + \cos 2x)$$

$$\sin^2 x + \cos^2 x = 1 \quad \sin^3 x = -\frac{1}{4}(3 \sin x - \sin 3x)$$

$$\cos^3 x = \frac{1}{4}(3 \cos x + \cos 3x)$$

$$\sin x \pm \sin y = 2 \left[ \sin \frac{1}{2}(x-y) \cdot \frac{\sin}{\cos} \frac{1}{2}(x+y) \right]$$

$$\cos x \pm \cos y = -2 \left[ \cos \frac{1}{2}(x-y) \cdot \frac{\sin}{\cos} \frac{1}{2}(x+y) \right]$$

$$\tan x \pm \tan y = \sin(x \pm y)/\cos x \cdot \cos y$$

$$\sin^2 x - \sin^2 y = \sin(x+y) \cdot \sin(x-y)$$

$$\cos^2 x - \cos^2 y = -\sin(x+y) \cdot \sin(x-y)$$

$$\cos^2 x - \sin^2 y = \cos(x+y) \cdot \cos(x-y)$$

$$d(\sin x)/dx = \cos x \quad \int \sin x \cdot dx = -\cos x + k$$

$$d(\cos x)/dx = -\sin x \quad \int \cos x \cdot dx = \sin x + k$$

$$d(\tan x)/dx = \sec^2 x \quad \int \tan x \cdot dx = -\ln |\cos x| + k$$

Values of  $\sin \theta$ ,  $\cos \theta$  and  $\tan \theta$  for  $0^\circ \leq \theta < 90^\circ$  (or  $0 < \theta \leq 1.571$  rad) are given in Table 1.7 as a check list, as they can generally be obtained directly from calculators.

## 1.2.2 Exponential and hyperbolic relations

**Exponential functions** For a positive datum ('real') number  $u$ , the exponential functions  $\exp(u)$  and  $\exp(-u)$  are given by the summation to infinity of the series

$$\exp(\pm u) = 1 \pm u + u^2/2! \pm u^3/3! + u^4/4! \pm \dots \Leftarrow$$

with  $\exp(+u)$  increasing and  $\exp(-u)$  decreasing at a rate proportional to  $u$ .

If  $u = 1$ , then

$$\exp(+1) = 1 + 1 + 1/2 + 1/6 + 1/24 + \dots = e = 2.718 \dots \Leftarrow$$

$$\exp(-1) = 1 - 1 + 1/2 - 1/6 + 1/24 - \dots = 1/e = 0.368 \dots \Leftarrow$$

In the electrical technology of transients,  $u$  is most commonly a negative function of time  $t$  given by  $u = -(t/T)$ . It then has the graphical form shown in *Figure 1.2* (left) as a time dependent variable. With an initial value  $k$ , i.e.  $y = k \exp(-t/T)$ , the rate of reduction with time is  $dy/dt = -(k/T) \exp(-t/T)$ . The initial rate at  $t = 0$  is  $-k/T$ . If this rate were maintained,  $y$  would reach zero at  $t = T$ , defining the *time constant*  $T$ . Actually, after time  $T$  the value of  $y$  is  $k \exp(-1) = k \exp(-1) = 0.368k$ . Each successive interval  $T$  decreases  $y$  by the factor 0.368. At a time  $t = 4.6T$  the value of  $y$  is 0.01k, and at  $t = 6.9T$  it is 0.001k.

**Figure 1.1** Trigonometric relations

Figure 1.2 Exponential relations

Figure 1.3 Hyperbolic relations

If  $u$  is a quadrature ('imaginary') number  $\pm jv$ , then

$$\exp(\pm jv) = 1 \pm jv - v^2/2! \mp jv^3/3! + v^4/4! \pm \dots$$

because  $j^2 = -1$ ,  $j^3 = -j$ ,  $j^4 = +1$ , etc. Figure 1.2 (right) shows the summation of the first five terms for  $\exp(j1)$ , i.e.

$$\exp(j1) = 1 + j1 - 1/2 - j1/6 + 1/24$$

a complex expression converging to a point P. The length OP is unity and the angle of OP to the datum axis is, in fact, 1 rad. In general,  $\exp(jv)$  is equivalent to a shift by  $\angle v$  rad. It follows that  $\exp(\pm jv) = \cos v \pm j \sin v$ , and that

$$\exp(jv) + \exp(-jv) = 2 \cos v \quad \exp(jv) - \exp(-jv) = j2 \sin v$$

For a complex number  $(u + jv)$ , then

$$\exp(u + jv) = \exp(u) \cdot \exp(jv) = \exp(u) \cdot \angle v$$

**Hyperbolic functions** A point P on a rectangular hyperbola  $(x/a)^2 - (y/a)^2 = 1$  defines the hyperbolic 'sector' area  $S_h = \frac{1}{2}a^2 \ln[(x/a) - (y/a)]$  shown shaded in Figure 1.3 (left). By analogy with  $\theta \Leftarrow 2S_c/h^2$  for the trigonometrical angle  $\theta$ , the hyperbolic entity (not an angle in the ordinary sense) is  $u = 2S_h/a^2$ , where  $a$  is the major semi-axis. Then the hyperbolic functions of  $u$  for point P are:

$$\begin{aligned} \sinh u &= y/a & \operatorname{cosech} u &= a/y \\ \cosh u &= x/a & \operatorname{sech} u &= a/x \\ \tanh u &= y/x & \operatorname{coth} u &= x/y \end{aligned}$$

The principal relations yield the curves shown in the diagram (right) for values of  $u$  between 0 and 3. For higher values  $\sinh u$  approaches  $\pm \cosh u$ , and  $\tanh u$  becomes asymptotic to  $\pm 1$ . Inspection shows that  $\cosh(-u) = \cosh u$ ,  $\sinh(-u) = -\sinh u$  and  $\cosh^2 u - \sinh^2 u = 1$ .

The hyperbolic functions can also be expressed in the exponential form through the series

$$\cosh u = 1 + u^2/2! + u^4/4! + u^6/6! + \dots \Leftarrow$$

$$\sinh u = u + u^3/3! + u^5/5! + u^7/7! + \dots \Leftarrow$$

so that

$$\cosh u = \frac{1}{2}[\exp(u) + \exp(-u)] \quad \sinh u = \frac{1}{2}[\exp(u) - \exp(-u)]$$

$$\cosh u + \sinh u = \exp(u) \Leftarrow \quad \cosh u - \sinh u = \exp(-u) \Leftarrow$$

Other relations are:

$$\sinh u + \sinh v = 2 \sinh \frac{1}{2}(u + v) \cdot \cosh \frac{1}{2}(u - v)$$

$$\cosh u + \cosh v = 2 \cosh \frac{1}{2}(u + v) \cdot \cosh \frac{1}{2}(u - v)$$

$$\cosh u - \cosh v = 2 \sinh \frac{1}{2}(u + v) \cdot \sinh \frac{1}{2}(u - v)$$

$$\sinh(u \pm v) = \sinh u \cdot \cosh v \pm \cosh u \cdot \sinh v$$

$$\cosh(u \pm v) = \cosh u \cdot \cosh v \pm \sinh u \cdot \sinh v$$

$$\tanh(u \pm v) = (\tanh u \pm \tanh v) / (1 \pm \tanh u \cdot \tanh v) \Leftarrow$$

6.908	1000	0.0010	500		

$$\sinh(u \pm jv) = (\sinh u \cdot \cos v) \pm j(\cosh u \cdot \sin v) \Leftarrow$$

$$\cosh(u \pm jv) = (\cosh u \cdot \cos v) \pm j(\sinh u \cdot \sin v) \Leftarrow$$

$$d(\sinh u)/du = \cosh u \quad \int \sinh u \cdot du = \cosh u$$

$$d(\cosh u)/du = \sinh u \quad \int \cosh u \cdot du = \sinh u$$

Exponential and hyperbolic functions of  $u$  between zero and 6.908 are listed in Table 1.8. Many calculators can give such values directly.

### 1.2.3 Bessel functions

Problems in a wide range of technology (e.g. in eddy currents, frequency modulation, etc.) can be set in the form of the Bessel equation

$$\frac{d^2 y}{dx^2} + \frac{1}{x} \cdot \frac{dy}{dx} + \left[ 1 - \frac{n^2}{x^2} \right] y = 0$$

and its solutions are called Bessel functions of order  $n$ . For  $n = 0$  the solution is

$$J_0(x) = 1 - (x^2/2^2) + (x^4/2^2 \cdot 4^2) - (x^6/2^2 \cdot 4^2 \cdot 6^2) + \dots \Leftarrow$$

and for  $n = 1, 2, 3 \dots$

$$J_n(x) = \frac{x^n}{2^n n!} \left[ 1 - \frac{x^2}{2(2n+2)} + \frac{x^4}{2 \cdot 4(2n+2)(2n+4)} - \dots \right] \Leftarrow$$

Table 1.9 gives values of  $J_n(x)$  for various values of  $n$  and  $x$ .

### 1.2.4 Series

**Factorials** In several of the following the factorial ( $n!$ ) of integral numbers appears. For  $n$  between 2 and 10 these are

$2! = 2$	$1/2! = 0.5$
$3! = 6$	$1/3! = 0.1667$
$4! = 24$	$1/4! = 0.417 \times 10^{-1}$
$5! = 120$	$1/5! = 0.833 \times 10^{-2}$
$6! = 720$	$1/6! = 0.139 \times 10^{-2}$
$7! = 5040$	$1/7! = 0.198 \times 10^{-3}$
$8! = 40320$	$1/8! = 0.248 \times 10^{-4}$
$9! = 362880$	$1/9! = 0.276 \times 10^{-5}$
$10! = 3628800$	$1/10! = 0.276 \times 10^{-6}$

#### Progression

**Arithmetic**  $a + (a + d) + (a + 2d) + \dots + [a + (n - 1)d]$   
 $= \frac{1}{2} n$  (sum of 1st and  $n$ th terms)

**Geometric**  $a + ar + ar^2 + \dots + ar^{n-1} = a(1 - r^n)/(1 - r)$

**Trigonometric** See Section 1.2.1.

**Exponential and hyperbolic** See Section 1.2.2.

#### Binomial

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{2!} x^2 \pm \frac{n(n-1)(n-2)}{3!} x^3 + \dots \Leftarrow$$

$$+ (-1)^r \frac{n!}{r!(n-r)!} x^r + \dots \Leftarrow$$

$$(a \pm x)^n = a^n [1 \pm (x/a)]^n$$

Binomial coefficients  $n!/r!(n-r)!$  are tabulated:

Term $r \Leftarrow 0$	1	2	3	4	5	6	7	8	9	10	
$n=1$	1	1									
2	1	2	1								
3	1	3	3	1							
4	1	4	6	4	1						
5	1	5	10	10	5	1					
6	1	6	15	20	15	6	1				
7	1	7	21	35	35	21	7	1			
8	1	8	28	56	70	56	28	8	1		
9	1	9	36	84	126	126	84	36	9	1	
10	1	10	45	120	210	252	210	120	45	10	1

**Power** If there is a power series for a function  $f(h)$ , it is given by

$$f(h) = f(0) + hf^{(i)}(0) + (h^2/2!)f^{(ii)}(0) + (h^3/3!)f^{(iii)}(0) + \dots \Leftarrow$$

$$+ (h^r/r!)f^{(r)}(0) + \dots \Leftarrow \quad (\text{Maclaurin}) \Leftarrow$$

$$f(x+h) = f(x) + hf^{(i)}(x) + (h^2/2!)f^{(ii)}(x) + \dots \Leftarrow$$

$$+ (h^r/r!)f^{(r)}(x) + \dots \Leftarrow \quad (\text{Taylor}) \Leftarrow$$

**Permutation, combination**

$${}^nP_r = n(n-1)(n-2)(n-3) \dots (n-r+1) = n!/(n-r)!$$

$${}^nC_r = (1/r!)[n(n-1)(n-2)(n-3) \dots (n-r+1)] = n!/r!(n-r)!$$

**Bessel** See Section 1.2.3.

**Fourier** See Section 1.2.5.

## 1.2.5 Fourier series

A univalued periodic wave form  $f(\theta)$  of period  $2\pi$  is represented by a summation in general of sine and cosine waves of fundamental period  $2\pi$  and of integral harmonic orders  $n$  ( $= 2, 3, 4, \dots$ ) as

$$f(\theta) = c_0 + a_1 \cos \theta + a_2 \cos 2\theta + \dots + a_n \cos n\theta + \dots \Leftarrow$$

$$+ b_1 \sin \theta + b_2 \sin 2\theta + \dots + b_n \sin n\theta + \dots \Leftarrow$$

The mean value of  $f(\theta)$  over a full period  $2\pi$  is

$$c_0 = \frac{1}{2\pi} \int_0^{2\pi} f(\theta) \cdot d\theta$$

and the harmonic-component amplitudes  $a$  and  $b$  are

$$a_n = \frac{1}{\pi} \int_0^{2\pi} f(\theta) \cdot \cos n\theta \, d\theta, \quad b_n = \frac{1}{\pi} \int_0^{2\pi} f(\theta) \cdot \sin n\theta \, d\theta$$

Table 1.10 gives for a number of typical wave forms the harmonic series in square brackets, preceded by the mean value  $c_0$  where it is not zero.

Decimal	1	2	3	4	5	6	7	8	9	10	100
Binary	1	10	11	100	101	110	111	1000	1001	1010	1100100

## 1.2.6 Derivatives and integrals

Some basic forms are listed in Table 1.11. Entries in a given column are the integrals of those in the column to its left and the derivatives of those to its right. Constants of integration are omitted.

## 1.2.7 Laplace transforms

Laplace transformation is a method of deriving the response of a system to any stimulus. The system has a basic equation of behaviour, and the stimulus is a pulse, step, sine wave or other variable with time. Such a response involves integration: the Laplace transform method removes integration difficulties, as tables are available for the direct solution of a great variety of problems. The process is analogous to evaluation (for example) of  $y = 2.1^{3.6}$  by transformation into a logarithmic form  $\log y = 3.6 \times \log(2.1)$ , and a subsequent inverse transformation back into arithmetic by use of a table of antilogarithms.

The Laplace transform (L.t.) of a time-varying function  $f(t)$  is

$$L[f(t)] = F(s) = \int_0^{\infty} \exp(-st) \cdot f(t) \cdot dt$$

and the inverse transformation of  $F(s)$  to give  $f(t)$  is

$$L^{-1}[F(s)] = f(t) = \lim_{\epsilon \rightarrow 0} \frac{1}{2\pi} \int_{\epsilon - j\omega\epsilon}^{\epsilon + j\omega\epsilon} \exp(st) \cdot F(s) \cdot ds$$

The process, illustrated by the response of a current  $i(t)$  in an electrical network of impedance  $z$  to a voltage  $v(t)$  applied at  $t=0$ , is to write down the transform equation

$$I(s) = V(s)/Z(s)$$

where  $I(s)$  is the L.t. of the current  $i(t)$ ,  $V(s)$  is the L.t. of the voltage  $v(t)$ , and  $Z(s)$  is the operational impedance.  $Z(s)$  is obtained from the network resistance  $R$ , inductance  $L$  and capacitance  $C$  by leaving  $R$  unchanged but replacing  $L$  by  $Ls$  and  $C$  by  $1/Cs$ . The process is equivalent to writing the network impedance for a steady state frequency  $\omega$  and then replacing  $j\omega$  by  $s$ .  $V(s)$  and  $Z(s)$  are polynomials in  $s$ : the quotient  $V(s)/Z(s)$  is reduced algebraically to a form recognisable in the transform table. The resulting current/time relation  $i(t)$  is read out: it contains the complete solution. However, if at  $t=0$  the network has initial energy (i.e. if currents flow in inductors or charges are stored in capacitors), the equation becomes

$$I(s) = [V(s) + U(s)]/Z(s)$$

where  $U(s)$  contains such terms as  $LI_0$  and  $(1/s)V_0$  for the inductors or capacitors at  $t=0$ .

A number of useful transform pairs is listed in Table 1.12.

## 1.2.8 Binary numeration

A number  $N$  in decimal notation can be represented by an ordered set of binary digits  $a_n, a_{n-2}, \dots, a_2, a_1, a_0$  such that

$$N = 2^n a_n + 2^{n-1} a_{n-1} + \dots + 2a_1 + a_0$$

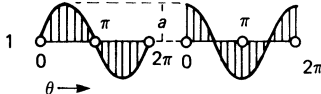

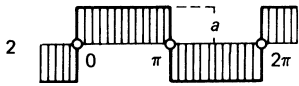

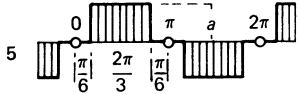

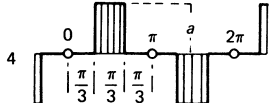

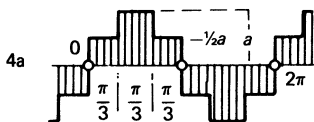

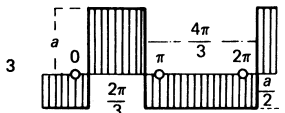

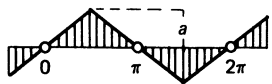

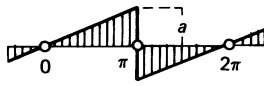

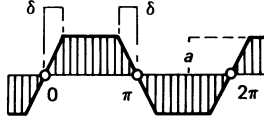

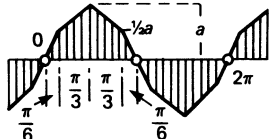

**Table 1.9** Bessel functions  $J_n(x)$

Table 1.10 (continued)

Wave form	Series
	Rectified sine (half-wave): $a \frac{1}{\pi} + a \frac{2}{\pi \zeta} \left[ \frac{\pi \sin \theta \zeta}{4} - \frac{\cos 2\theta \zeta}{1 \cdot 3} + \frac{\cos 4\theta \zeta}{3 \cdot 5} - \frac{\cos 6\theta \zeta}{5 \cdot 7} + \dots \right] \Leftarrow$
	Rectified sine (full-wave): $a \frac{2}{\pi} - a \frac{4}{\pi \zeta} \left[ \frac{\cos 2\theta \zeta}{1 \cdot 3} + \frac{\cos 4\theta \zeta}{3 \cdot 5} + \frac{\cos 6\theta \zeta}{5 \cdot 7} + \frac{\cos 8\theta \zeta}{7 \cdot 9} + \dots \right] \Leftarrow$
	Rectified sine (m-phase): $a \frac{m}{\pi \zeta} \sin \frac{\pi \zeta}{m} + a \frac{2m}{\pi \zeta} \sin \frac{\pi \zeta}{m} \left[ \frac{\cos m\theta \zeta}{m^2 - 1} - \frac{\cos 2m\theta \zeta}{4m^2 - 1} + \frac{\cos 3m\theta \zeta}{9m^2 - 1} - \dots \right] \Leftarrow$
	Rectangular pulse train: $a \frac{\delta \zeta}{\pi} + a \frac{2}{\pi \zeta} \left[ \frac{\sin \delta \zeta \cos \theta \zeta}{1} + \frac{\sin 2\delta \zeta \cos 2\theta \zeta}{2} + \frac{\sin 3\delta \zeta \cos 3\theta \zeta}{3} + \dots \right] \Leftarrow$ $a \frac{\delta \zeta}{\pi} + a \frac{2\delta \zeta}{\pi \zeta} \left[ \frac{\cos \theta \zeta}{1} + \frac{\cos 2\theta \zeta}{2} + \frac{\cos 3\theta \zeta}{3} + \dots \right] \Leftarrow \text{for } \delta \zeta \ll \pi \zeta$
	Triangular pulse train: $a \frac{\delta \zeta}{2\pi \zeta} + a \frac{4}{\pi \delta \zeta} \left[ \frac{\sin^2(\frac{1}{2}\delta \zeta)}{1} \cos \theta + \frac{\sin^2 2(\frac{1}{2}\delta \zeta)}{4} \cos 2\theta + \frac{\sin^2 3(\frac{1}{2}\delta \zeta)}{9} \cos 3\theta + \dots \right] \Leftarrow$ $a \frac{\delta}{2\pi} + a \frac{\delta \zeta}{\pi \zeta} [\cos \theta + \cos 2\theta + \cos 3\theta + \dots] \Leftarrow \text{for } \delta \zeta \ll \pi \zeta$

where the  $a$ s have the values either 1 or 0. Thus, if  $N = 19$ ,  $19 = 16 + 2 + 1 = (2^4)1 + (2^3)0 + (2^2)0 + (2^1)1 + (2^0)1 = 10011$  in binary notation. The rules of addition and multiplication are

$$0 + 0 = 0, 0 + 1 = 1, 1 + 1 = 10; 0 \times 0 = 0, 0 \times 1 = 0, 1 \times 1 = 1$$

### 1.2.9 Power ratio

In communication networks the powers  $P_1$  and  $P_2$  at two specified points may differ widely as the result of amplification or attenuation. The power ratio  $P_1/P_2$  is more convenient in logarithmic terms.

**Neper [Np]** This is the natural logarithm of a voltage or current ratio, given by

$$a = 4.34(V_1/V_2) \Leftarrow \text{or } a = 4.34(I_1/I_2) \text{ Np}$$

If the voltages are applied to, or the currents flow in, identical impedances, then the power ratio is

$$a = 4.34(V_1/V_2)^2 = 8.68 \ln(V_1/V_2) \Leftarrow$$

and similarly for current.

**Decibel [dB]** The power gain is given by the common logarithm  $\lg(P_1/P_2)$  in bel [B], or most commonly by  $A = 10 \lg(P_1/P_2)$  decibel [dB]. With again the proviso

that the powers are developed in identical impedances, the power gain is

$$A = 40 \log(P_1/P_2) = 40 \log(V_1/V_2)^2 = 20 \log(V_1/V_2) \text{ dB}$$

Table 1.13 gives the power ratio corresponding to a gain  $A$  (in dB) and the related identical-impedance voltage (or current) ratios. Approximately, 3 dB corresponds to a power ratio of 2, and 6 dB to a power ratio of 4. The decibel equivalent of 1 Np is 8.69 dB.

### 1.2.10 Matrices and vectors

#### 1.2.10.1 Definitions

If  $a_{11}, a_{12}, a_{13}, a_{14} \dots$  is a set of elements, then the rectangular array

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \dots a_{1n} \\ a_{21} & a_{22} & a_{23} & a_{24} \dots a_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ a_{m1} & a_{m2} & a_{m3} & a_{m4} \dots a_{mn} \end{bmatrix}$$

arranged in  $m$  rows and  $n$  columns is called an  $(m \times n)$  matrix. If  $m = n$  then  $\mathbf{A}$  is  $n$ -square.

**Table 1.11** Derivatives and integrals

An ordered set of elements  $\mathbf{x} = [x_1, x_2, x_3 \dots x_n]$  is called an  $n$ -vector.

An  $(n \times 1)$  matrix is called a *column vector* and a  $(1 \times n)$  matrix a *row vector*.

### 1.2.10.2 Basic operations

If  $\mathbf{A} = (a_{rs})$ ,  $\mathbf{B} = (b_{rs})$ ,

- Sum**  $\mathbf{C} = \mathbf{A} + \mathbf{B}$  is defined by  $c_{rs} = a_{rs} + b_{rs}$ , for  $r = 1 \dots m$ ;  $s = 1 \dots n$ .
- Product** If  $\mathbf{A}$  is an  $(m \times q)$  matrix and  $\mathbf{B}$  is a  $(q \times n)$  matrix, then the product  $\mathbf{C} = \mathbf{AB}$  is an  $(m \times n)$  matrix defined by  $(c_{rs}) = \sum_p a_{rp} b_{ps}$ ,  $p = 1 \dots q$ ;  $r = 1 \dots m$ ;  $s = 1 \dots n$ . If  $\mathbf{AB} = \mathbf{BA}$  then  $\mathbf{A}$  and  $\mathbf{B}$  are said to *commute*.
- Matrix-vector product** If  $\mathbf{x} = [x_1 \dots x_n]$ , then  $\mathbf{b} = \mathbf{Ax}$  is defined by  $(b_r) = \sum_p a_{rp} x_p$ ,  $p = 1 \dots n$ ;  $r = 1 \dots m$ .
- Multiplication of a matrix by a (scalar) element** If  $k$  is an element then  $\mathbf{C} = k\mathbf{A} = \mathbf{Ak}$  is defined by  $(c_{rs}) = k(a_{rs})$ .
- Equality** If  $\mathbf{A} = \mathbf{B}$ , then  $(a_{ij}) = (b_{ij})$ , for  $i = 1 \dots n$ ;  $j = 1 \dots m$ .

### 1.2.10.3 Rules of operation

- Associativity**  $\mathbf{A} + (\mathbf{B} + \mathbf{C}) = (\mathbf{A} + \mathbf{B}) + \mathbf{C}$ ,  
 $\mathbf{A}(\mathbf{BC}) = (\mathbf{AB})\mathbf{C} = \mathbf{ABC}$ .
- Distributivity**  $\mathbf{A}(\mathbf{B} + \mathbf{C}) = \mathbf{AB} + \mathbf{AC}$ ,  
 $(\mathbf{B} + \mathbf{C})\mathbf{A} = \mathbf{BA} + \mathbf{CA}$ .
- Identity** If  $\mathbf{U}$  is the  $(n \times n)$  matrix  $(\delta_{ij})$ ,  $i, j = 1 \dots n$ , where  $\delta_{ij} = 1$  if  $i = j$  and 0 otherwise, then  $\mathbf{U}$  is the diagonal *unit matrix* and  $\mathbf{AU} = \mathbf{A}$ .
- Inverse** If the product  $\mathbf{U} = \mathbf{AB}$  exists, then  $\mathbf{B} = \mathbf{A}^{-1}$  the inverse matrix of  $\mathbf{A}$ . If both inverses  $\mathbf{A}^{-1}$  and  $\mathbf{B}^{-1}$  exist, then  $(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$ .
- Transposition** The transpose of  $\mathbf{A}$  is written as  $\mathbf{A}^T$  and is the matrix whose rows are the columns of  $\mathbf{A}$ . If the product  $\mathbf{C} = \mathbf{AB}$  exists then  $\mathbf{C}^T = (\mathbf{AB})^T = \mathbf{B}^T\mathbf{A}^T$ .
- Conjugate** For  $\mathbf{A} = (a_{rs})$ , the conjugate of  $\mathbf{A}$  is denoted by  $\mathbf{A}^* = (a_{rs}^*)$ .
- Orthogonality** Matrix  $\mathbf{A}$  is orthogonal if  $\mathbf{AA}^T = \mathbf{U}$ .

#### 1.2.10.4 Determinant and trace

- The *determinant* of a square matrix  $\mathbf{A}$  denoted by  $|\mathbf{A}|$ , also  $\det(\mathbf{A})$ , is defined by the recursive formula  $|\mathbf{A}| = a_{11} M_{11} - a_{12} M_{12} + a_{13} M_{13} - \dots (\leq 1)^n a_{1n} M_{1n}$  where  $M_{11}$  is the determinant of the matrix with row 1 and column 1 missing,  $M_{12}$  is the determinant of the matrix with row 1 and column 2 missing etc.
- The *Trace* of  $\mathbf{A}$  is denoted by  $\text{tr}(\mathbf{A}) = \sum_i a_{ii}$ ,  $i = 1, 2, \dots, n$ .
- Singularity* The square matrix  $\mathbf{A}$  is singular if  $\det(\mathbf{A}) = 0$ .
- The *Characteristic Polynomial*  $P(\lambda) = \det(\mathbf{A} - \lambda \mathbf{U})$ .

#### 1.2.10.5 Eigensystems

- Eigenvalues* The eigenvalues of a matrix  $\lambda(\mathbf{A})$  are the  $n$  complex roots  $\lambda_1(\mathbf{A}), \lambda_2(\mathbf{A}) \dots \lambda_n(\mathbf{A})$  of the characteristic polynomial  $\det(\mathbf{A} - \lambda \mathbf{U}) = 0$ . Normally in most engineering systems there are no equal roots so the eigenvalues are distinct.
- Eigenvectors* For any distinct eigenvalue  $\lambda_i(\mathbf{A})$ , there is an associated non-zero *right eigenvector*  $\mathbf{X}_i$  satisfying the homogeneous equations  $(\mathbf{A} - \lambda_i \mathbf{U}) \mathbf{X}_i = \mathbf{0}$ ,  $i = 1, 2, \dots, n$ . The matrix  $(\mathbf{A} - \lambda_i \mathbf{U})$  is singular, however, because the  $\det(\mathbf{A} - \lambda_i \mathbf{U}) = 0$ ; hence  $\mathbf{X}_i$  is not unique. In each set of equations  $(\mathbf{A} - \lambda_i \mathbf{U}) \mathbf{X}_i = \mathbf{0}$  one equation is redundant and only the relative values of the elements of  $\mathbf{X}_i$  can be determined. Thus the eigenvectors can be scaled arbitrarily, one element being assigned a value and the other elements determined accordingly from the remaining non-homogeneous equations.

The equations can be written also as  $\mathbf{A}\mathbf{X}_i = \lambda_i \mathbf{X}_i$ , or combining all eigenvalues and right eigenvectors,  $\mathbf{A}\mathbf{X} = \mathbf{X}\mathbf{\Lambda}$ , where  $\mathbf{\Lambda}$  is a diagonal matrix of the eigenvalues and  $\mathbf{X}$  is a square matrix containing all the right eigenvectors in corresponding order.

Since the eigenvalues of  $\mathbf{A}$  and  $\mathbf{A}^T$  are identical, for every eigenvalue  $\lambda_i$  associated with an eigenvector  $\mathbf{X}_i$  of  $\mathbf{A}$  there is also an eigenvector  $\mathbf{P}_i$  of  $\mathbf{A}^T$  such that  $\mathbf{A}^T \mathbf{P}_i = \lambda_i \mathbf{P}_i$ . Alternatively the eigenvector  $\mathbf{P}_i$  can be considered to be the *left eigenvector* of  $\mathbf{A}$  by transposing the equation to give  $\mathbf{P}_i^T \mathbf{A} = \lambda_i \mathbf{P}_i^T$ , or combining into one matrix equation,  $\mathbf{P}^T \mathbf{A} = \mathbf{P}^T \mathbf{\Lambda}$ .

*Reciprocal eigenvectors* Post-multiplying this last equation by the right eigenvector matrix  $\mathbf{X}$  gives  $\mathbf{P}^T \mathbf{A} \mathbf{X} = \mathbf{P}^T \mathbf{\Lambda} \mathbf{X}$ , which summarises the  $n$  sets of equations  $\mathbf{P}_i^T \mathbf{A} \mathbf{X}_i = \mathbf{P}_i^T \lambda_i \mathbf{X}_i = \lambda_i \mathbf{P}_i^T \mathbf{X}_i = k_i \lambda_i$ , where  $k_i$  is a scalar formed from the  $(1 \times n)$  by  $(n \times 1)$  vector product  $\mathbf{P}_i^T \mathbf{X}_i$ . With both  $\mathbf{P}_i$  and  $\mathbf{X}_i$  being scaled arbitrarily, re-scaling the left eigenvectors such that  $\mathbf{W}_i = (1/k_i) \mathbf{P}_i$ , gives  $\mathbf{W}_i^T \mathbf{X}_j = \delta_{ij} = 1$ , if  $i = j$ , and  $= 0$  otherwise. In matrix form  $\mathbf{W}^T \mathbf{X} = \mathbf{U}$ , the unit matrix. The re-scaled left eigenvectors  $\mathbf{W}_i^T$  are said to be the reciprocal eigenvectors corresponding to the right eigenvectors  $\mathbf{X}_i$ .

- Eigenvalue sensitivity analysis* The change in the numerical value of  $\lambda_i$  with a change in any matrix  $\mathbf{A}$  element  $\delta a_{rs}$  is to a first approximation given by  $\delta \lambda_i = (w_r)_i (x_s)_i \delta a_{rs}$  where  $(w_r)_i$  is the  $r$ -th element of the reciprocal eigenvector  $\mathbf{W}_i$  corresponding to  $\lambda_i$  and  $(x_s)_i$  is the  $s$ -th element of the associated right eigenvector  $\mathbf{X}_i$ . In more compact form the sensitivity coefficients  $\delta \lambda_i / \delta a_{rs}$  or condition numbers of all  $n$  eigenvalues with respect to all elements of matrix  $\mathbf{A}$  are expressible by the 1-term dyads  $\mathbf{S}_i = \mathbf{W}_i \mathbf{X}_i^T$ ,  $i = 1 \dots n$ .

$$\mathbf{S}_i = \begin{bmatrix} \delta \lambda_i / \delta a_{11} & \delta \lambda_i / \delta a_{12} & \dots & \delta \lambda_i / \delta a_{1n} \\ \delta \lambda_i / \delta a_{21} & \delta \lambda_i / \delta a_{22} & \dots & \delta \lambda_i / \delta a_{2n} \\ \dots & \dots & \dots & \dots \\ \delta \lambda_i / \delta a_{n1} & \delta \lambda_i / \delta a_{n2} & \dots & \delta \lambda_i / \delta a_{nn} \end{bmatrix}$$

The matrix  $\mathbf{S}_i$  is known as *i*-th *eigenvalue sensitivity matrix*.

- Matrix functions* Transposed eigenvalue sensitivity matrices appear also in the dyadic expansion of a matrix and in matrix functions, thus  $\mathbf{A} = \sum_i \lambda_i \mathbf{X}_i \mathbf{W}_i^T = \sum_i \lambda_i \mathbf{S}_i^T$ ,  $i = 1 \dots n$ . Likewise  $[\mathbf{A}]^2 > [\sum_i \lambda_i \mathbf{S}_i^T]^2 = \sum_i \lambda_i^2 \mathbf{S}_i^T$  or in general  $[\mathbf{A}]^p = \sum_i \lambda_i^p \mathbf{S}_i^T$ ; thus, for example,  $[\mathbf{A}]^{-1} = \sum_i \lambda_i^{-1} \mathbf{S}_i^T$ .

#### 1.2.10.6 Norms

- Vector norms* A scalar measure of the magnitude of a vector  $\mathbf{X}$  with elements  $x_1, x_2 \dots x_n$ , is provided by a *norm*, the general family of norms being defined by  $\|\mathbf{X}\| = [\sum_i |x_i|^p]^{1/p}$ . The usual norms are found from the values of  $p$ . If  $p = 1$ ,  $\|\mathbf{X}\|$  is the sum of the magnitudes of the elements,  $p = 2$ ,  $\|\mathbf{X}\|$  is *Euclidean norm* or square root of the sum of the squares of the magnitudes of the elements,  $p = \text{infinity}$ ,  $\|\mathbf{X}\|$  is the *infinity norm* or magnitude of the largest element.
- Matrix norms* Several norms for matrices have also been defined, for matrix  $\mathbf{A}$  two being the *Euclidean norm*,  $\|\mathbf{A}\|_E = [\sum_r \sum_s |a_{rs}|^2]^{1/2}$ ,  $r = 1, 2 \dots m$ ;  $s = 1, 2 \dots n$ , and the *absolute norm*,  $\|\mathbf{A}\| = \max_{r,s} |a_{rs}|$ .

### 1.3 Physical quantities

Engineering processes involve energy associated with physical materials to convert, transport or radiate energy. As energy has several natural forms, and as materials differ profoundly in their physical characteristics, separate technologies have been devised around specific processes; and materials may have to be considered macroscopically in bulk, or in microstructure (molecular, atomic and subatomic) in accordance with the applications or processes concerned.

#### 1.3.1 Energy

Like 'force' and 'time', energy is a unifying concept invented to systematise physical phenomena. It almost defies precise

definition, but may be described, as an aid to an intuitive appreciation.

*Energy* is the capacity for 'action' or *work*.

*Work* is the measure of the change in energy *state*.

*State* is the measure of the energy condition of a *system*.

*System* is the ordered arrangement of related physical entities or processes, represented by a *model*.

*Mode* is a description or mathematical formulation of the system to determine its *behaviour*.

*Behaviour* describes (verbally or mathematically) the energy processes involved in changes of state. Energy *storage* occurs if the work done on a system is recoverable in its original form. Energy *conversion* takes place when related changes of state concern energy in a different form, the process sometimes being reversible. Energy *dissipation* is an irreversible conversion into heat. Energy *transmission* and *radiation* are forms of energy transport in which there is a finite propagation time.

In a physical system there is an identifiable energy input  $W_i$  and output  $W_o$ . The system itself may store energy  $W_s$  and dissipate energy  $W$ . The energy conservation principle states that

$$W_i = W_s + W + W_o$$

Comparable statements can be made for energy changes  $\Delta w$  and for energy rates (i.e. powers), giving

$$\Delta w_i = \Delta w_s + \Delta w + \Delta w_o \text{ and } p_i = p_s + p + p_o$$

### 1.3.1.1 Analogues

In some cases the *mathematical* formulation of a system model resembles that of a model in a completely different physical system: the two systems are then analogues. Consider linear and rotary displacements in a simple mechanical system with the conditions in an electric circuit, with the following nomenclature:

$f$	force [N]	$M$	torque [Nm]	$v$	voltage [V]
$m$	mass [kg]	$J$	inertia [ $\text{kg m}^2$ ]	$L$	inductance [H]
$r$	friction [Ns/m]	$r$	friction [Nm s/rad]	$R$	resistance [ $\Omega$ ]
$k$	compliance [m/N]	$k$	compliance [rad/Nm]	$C$	capacitance [F]
$l$	displacement [m]	$\theta$	displacement [rad]	$q$	charge [C]
$u$	velocity [m/s]	$\omega$	angular velocity [rad/s]	$i$	current [A]

The force necessary to maintain a uniform linear velocity  $u$  against a viscous frictional resistance  $r$  is  $f = ur$ ; the power is  $p = fu = u^2 r$ , and the energy expended over a distance  $l$  is  $W = fut = u^2 rt$ , since  $l = ut$ . These are, respectively, the analogues of  $v = iR$ ,  $p = vi = i^2 R$  and  $W = vit = i^2 Rt$  for the corresponding electrical system. For a constant angular velocity in a rotary mechanical system,  $M = \omega r$ ,  $p = M\omega = \omega^2 r$  and  $W = \omega^2 rt$ , since  $\theta = \omega t$ .

If a mass is given an acceleration  $du/dt$ , the force required is  $f = m(du/dt)$  and the stored kinetic energy at velocity  $u_1$  is  $W = \frac{1}{2}mu_1^2$ . For rotary acceleration,  $M = J(d\omega/dt)$  and  $W = \frac{1}{2}J\omega_1^2$ . Analogously the application of a voltage  $v$  to a pure inductor  $L$  produces an increase of current at the rate  $di/dt$  such that  $v = L(di/dt)$  and the magnetic energy stored at current  $i_1$  is  $W = \frac{1}{2}Li_1^2$ .

A mechanical element (such as a spring) of compliance  $k$  (which describes the displacement per unit force and is the inverse of the stiffness) has a displacement  $l = kf$  when a force  $f$  is applied. At a final force  $f_1$  the potential energy stored is  $W = \frac{1}{2}kf_1^2$ . For the rotary case,  $\theta = kM$  and  $W = \frac{1}{2}kM^2$ . In the electric circuit with a pure capacitance  $C$ , to which a p.d.  $v$  is applied, the charge is  $q = Cv$  and the electric energy stored at  $v_1$  is  $W = \frac{1}{2}Cv_1^2$ .

Use is made of these correspondences in mechanical problems (e.g. of vibration) when the parameters can be considered to be 'lumped'. An ideal transformer, in which the primary m.m.f. in ampere-turns  $i_1N_1$  is equal to the secondary m.m.f.  $i_2N_2$  has as analogue the simple lever, in which a force  $f_1$  at a point distant  $l_1$  from the fulcrum corresponds to  $f_2$  at  $l_2$  such that  $f_1l_1 = f_2l_2$ .

A simple series circuit is described by the equation  $v = L(di/dt) + Ri + q/C$  or, with  $i$  written as  $dq/dt$ ,

$$v = L(d^2q/dt^2) + R(dq/dt) + (1/C)q$$

A corresponding mechanical system of mass, compliance and viscous friction (proportional to velocity) in which for a displacement  $l$  the inertial force is  $m(du/dt)$ , the compliance force is  $l/k$  and the friction force is  $ru$ , has a total force

$$f = m(d^2l/dt^2) + r(dl/dt) + (1/k)l$$

Thus the two systems are expressed in identical mathematical form.

### 1.3.1.2 Fields

Several physical problems are concerned with 'fields' having stream-line properties. The eddyless flow of a liquid, the current in a conducting medium, the flow of heat from a high- to a low-temperature region, are fields in which representative lines can be drawn to indicate at any point the direction of

the flow there. Other lines, orthogonal to the flow lines, connect points in the field having equal potential. Along these equipotential lines there is no tendency for flow to take place.

Static electric fields between charged conductors (having equipotential surfaces) are of interest in problems of insulation stressing. Magnetic fields, which in air-gaps may be assumed to cross between high-permeability ferromagnetic surfaces that are substantially equipotentials, may be studied in the course of investigations into flux distribution in machines. All the fields mentioned above satisfy Laplacian equations of the form

$$(\partial^2 V/\partial x^2) + (\partial^2 V/\partial y^2) + (\partial^2 V/\partial z^2) = 0$$

The solution for a physical field of given geometry will apply to other Laplacian fields of similar geometry, e.g.

System	Potential	Flux	Medium
current flow	voltage $V$	current $I$	conductivity $\sigma$
heat flow	temperature $\theta$	heat $q$	thermal conductivity $\lambda$
electric field	voltage $V$	electric flux $Q$	permittivity $\epsilon$
magnetic field	m.m.f. $F$	magnetic flux $\phi$	permeability $\mu$

The ratio  $I/V$  for the first system would give the effective conductance  $G$ ; correspondingly for the other systems,  $q/\theta\varsigma$  gives the thermal conductance,  $Q/V$  gives the capacitance and  $\Phi/F$  gives the permeance, so that if measurements are made in one system the results are applicable to all the others.

It is usual to treat problems as two-dimensional where possible. Several field-mapping techniques have been devised, generally electrical because of the greater convenience and precision of electrical measurements. For two-dimensional problems, conductive methods include high-resistivity paper sheers, square-mesh 'nets' of resistors and electrolytic tanks. The tank is especially adaptable to three-dimensional cases of axial symmetry.

In the electrolytic *tank* a weak electrolyte, such as ordinary tap-water, provides the conducting medium. A scale model of the electrode system is set into the liquid. A low-voltage supply at some frequency between 50 Hz and 1 kHz is connected to the electrodes so that current flows through the electrolyte between them. A probe, adjustable in the horizontal plane and with its tip dipping vertically into the electrolyte, enables the potential field to be plotted. Electrode models are constructed from some suitable insulant (wood, paraffin wax, Bakelite, etc.), the electrode outlines being defined by a highly conductive material such as brass or copper. The metal is silver-plated to improve conductivity and reduce polarisation. Three-dimensional cases with axial symmetry are simulated by tilting the tank and using the surface of the electrolyte as a radial plane of the system.

The conducting-sheet analogue substitutes a sheet of resistive material (usually 'teledeltos' paper with silver-painted electrodes) for the electrolyte. The method is not readily adaptable to three-dimensional plots, but is quick and inexpensive in time and material.

The *mesh* or resistor-net analogue replaces a conductive continuum by a square mesh of equal resistors, the potential measurements being made at the nodes. Where the boundaries are simple, and where the 'grain size' is sufficiently small, good results are obtained. As there are no polarisation troubles, direct voltage supply can be used. If the resistors are made adjustable, the net can be adapted to cases of inhomogeneity, as when plotting a magnetic field in which permeability is dependent on flux density. Three-dimensional plots are made by arranging plane meshes in layers; the nodes are now the junctions of six instead of four resistors.

A stretched elastic membrane, depressed or elevated in appropriate regions, will accommodate itself smoothly to the differences in level: the height of the membrane everywhere can be shown to be in conformity with a two-dimensional Laplace equation. Using a rubber sheet as a membrane, the path of electrons in an electric field between electrodes in a vacuum can be investigated by the analogous paths of rolling bearing-balls. Many other useful analogues have been devised, some for the rapid solution of mathematical processes.

Recently considerable development has been made in point-by-point computer solutions for the more complicated field patterns in three-dimensional space.

### 1.3.2 Structure of matter

Material substances, whether solid, liquid or gaseous, are conceived as composed of very large numbers of *molecules*. A molecule is the smallest portion of any substance which cannot be further subdivided without losing its characteristic material properties. In all states of matter molecules are in a state of rapid continuous motion. In a *solid* the molecules are relatively closely 'packed' and the molecules, although rapidly moving, maintain a fixed mean position. Attractive

forces between molecules account for the tendency of the solid to retain its shape. In a *liquid* the molecules are less closely packed and there is a weaker cohesion between them, so that they can wander about with some freedom within the liquid, which consequently takes up the shape of the vessel in which it is contained. The molecules in a *gas* are still more mobile, and are relatively far apart. The cohesive force is very small, and the gas is enabled freely to contract and expand. The usual effect of heat is to increase the intensity and speed of molecular activity so that 'collisions' between molecules occur more often; the average spaces between the molecules increase, so that the substance attempts to expand, producing internal pressure if the expansion is resisted.

Molecules are capable of further subdivision, but the resulting particles, called *atoms*, no longer have the same properties as the molecules from which they came. An atom is the smallest portion of matter than can enter into chemical combination or be chemically separated, but it cannot generally maintain a separate existence except in the few special cases where a single atom forms a molecule. A molecule may consist of one, two or more (sometimes many more) atoms of various kinds. A substance whose molecules are composed entirely of atoms of the same kind is called an *element*. Where atoms of two or more kinds are present, the molecule is that of a chemical *compound*. At present over 100 elements are recognised (*Table 1.14*: the atomic mass number  $A$  is relative to 1/12 of the mass of an element of carbon-12).

If the element symbols are arranged in a table in ascending order of atomic number, and in columns ('groups') and rows ('periods') with due regard to associated similarities, *Table 1.15* is obtained. Metallic elements are found on the left, non-metals on the right. Some of the correspondences that emerge are:

#### Group 1a: Alkali metals

(Li 3, Na 11, K 19, Rb 37, Cs 55, Fr 87)

#### 2a: Alkaline earths

(Be 4, Mg 12, Ca 20, Sr 38, Ba 56, Ra 88)

#### 1b: Copper group (Cu 29, Ag 47, Au 79)

#### 6b: Chromium group (Cr 24, Mo 42, W 74)

#### 7a: Halogens (F 9, Cl 17, Br 35, I 53, At 85)

#### 0: Rare gases

(He 2, Ne 10, Ar 18, Kr 36, Xe 54, Rn 86)

#### 3a–6a: Semiconductors

(B 5, Si 16, Ge 32, As 33, Sb 51, Te 52)

In some cases a horizontal relation obtains as in the transition series (Sc 21...Ni 28) and the heavy-atom rare earth and actinide series. The explanation lies in the structure of the atom.

#### 1.3.2.1 Atomic structure

The original Bohr model of the hydrogen atom was a central nucleus containing almost the whole mass of the atom, and a single *electron* orbiting around it. Electrons, as small particles of negative electric charge, were discovered at the end of the nineteenth century, bringing to light the complex structure of atoms. The hydrogen nucleus is a *proton*, a mass having a charge equal to that of an electron, but positive. Extended to all elements, each has a nucleus comprising mass particles, some (*protons*) with a positive charge, others (*neutrons*) with no charge. The atomic *mass number*  $A$  is the total number of protons and neutrons in the nucleus; the *atomic number*  $Z$  is the number of positive charges, and the normal number of orbital electrons. The nuclear structure is not known, and the forces that bind the protons against their mutual attraction are conjectural.

The hydrogen atom (*Figure 1.4*) has one proton ( $Z=1$ ) and one electron in an orbit formerly called the K shell. Helium ( $Z=2$ ) has two protons, the two electrons occupying the K shell which, by the Pauli exclusion principle, cannot have more than two. The next element in order is lithium ( $Z=3$ ), the third electron in an outer L shell. With elements of increasing atomic number, the electrons are added to the L shell until it holds a maximum of 8, the surplus then occupying the M shell to a maximum of 18. The number of 'valence' electrons (those in the outermost shell) determines the physical and chemical properties of the element. Those with completed outer shells are 'stable'.

**Isotopes** An element is often found to be a mixture of atoms with the same chemical property but different atomic masses: these are isotopes. The isotopes of an element must have the same number of electrons and protons, but differ in the number of neutrons, accounting for the non-integral average mass numbers. For example, neon comprises 90.4% of mass number 20, with 0.6% of 21 and 9.0% of mass number 22, giving a resultant mass number of 20.18.

**Energy states** Atoms may be in various energy states. Thus, the filament of an incandescent lamp may emit light when excited by an electric current but not when the current is switched off. Heat energy is the kinetic energy of the atoms of a heated body. The more vigorous impact of atoms may not always shift the atom as a whole, but may shift an electron from one orbit to another of higher energy level within the atom. This position is not normally stable, and the electron gives up its momentarily acquired potential energy by falling back to its original level, releasing the energy as a light quantum or photon.

**Ionisation** Among the electrons of an atom, those of the outermost shell are unique in that, on account of all the electron charges on the shells between them and the nucleus, they are the most loosely bound and most easily *removable*. In a variety of ways it is possible so to excite an atom that one of the outer electrons is torn away, leaving the atom *ionised* or converted for the time into an *ion* with an effective positive charge due to the unbalanced electrical state it has acquired. Ionisation may occur due to impact by other fast-moving particles, by irradiation with rays of suitable wavelength and by the application of intense electric fields.

### 1.3.2.2 Wave mechanics

The fundamental laws of optics can be explained without regard to the nature of light as an electromagnetic wave phenomenon, and photoelectricity emphasises its nature as a stream or ray of corpuscles. The phenomena of diffraction or interference can only be explained on the wave concept. *Wave mechanics* correlates the two apparently conflicting ideas into a wider concept of 'waves of matter'. Electrons, atoms and even molecules participate in this duality, in that their effects appear sometimes as corpuscular, sometimes as of a wave nature. Streams of electrons behave in a corpuscular fashion in photoemission, but in certain circumstances show the diffraction effects familiar in wave action. Considerations of particle mechanics led de Broglie to write several theoretic papers (1922–1926) on the parallelism between the dynamics of a particle and geometrical optics, and suggested that it was necessary to admit that classical dynamics could not interpret phenomena involving energy quanta. Wave mechanics was established by Schrödinger in 1926 on de Broglie's conceptions.

When electrons interact with matter, they exhibit wave properties: in the free state they act like particles. Light has a similar duality, as already noted. The hypothesis of de Broglie is that a particle of mass  $m$  and velocity  $u$  has wave

properties with a wavelength  $\lambda = h/mv$ , where  $h$  is the Planck constant,  $h = 6.626 \times 10^{-34}$  J s. The mass  $m$  is relativistically affected by the velocity.

When electron waves are associated with an atom, only certain fixed-energy states are possible. The electron can be raised from one state to another if it is provided, by some external stimulus such as a photon, with the necessary energy difference  $\Delta w$  in the form of an electromagnetic wave of wavelength  $\lambda = hc/\Delta w$ , where  $c$  is the velocity of free space radiation ( $3 \times 10^8$  m/s). Similarly, if an electron

falls from a state of higher to one of lower energy, it emits energy  $\Delta w$  as radiation. When electrons are raised in energy level, the atom is *excited*, but not ionised.

### 1.3.2.3 Electrons in atoms

Consider the hydrogen atom. Its single electron is not located at a fixed point, but can be anywhere in a region near the nucleus with some probability. The particular region is a kind of shell or cloud, of radius depending on the electron's energy state.

With a nucleus of atomic number  $Z$ , the  $Z$  electrons can have several possible configurations. There is a certain radial pattern of electron probability cloud distribution (or shell pattern). Each electron state gives rise to a cloud pattern, characterised by a definite energy level, and described by the series of quantum numbers  $n$ ,  $l$ ,  $m_l$  and  $m_s$ . The number  $n (= 1, 2, 3, \dots)$  is a measure of the energy level;  $l (= 0, 1, 2, \dots)$  is concerned with angular momentum;  $m_l$  is a measure of the component of angular momentum in the direction of an applied magnetic field; and  $m_s$  arises from the electron spin. It is customary to condense the nomenclature so that electron states corresponding to  $l = 0, 1, 2$  and  $3$  are described by the letters  $s$ ,  $p$ ,  $d$  and  $f$  and a numerical prefix gives the value of  $n$ . Thus boron has 2 electrons at level 1 with  $l = 0$ ; two at level 2 with  $l = 0$ ; and one at level 3 with  $l = 1$ ; this information is conveyed by the description  $(1s)^2(2s)^2(2p)^1$ .

The energy of an atom as a whole can vary according to the electron arrangement. The most stable state is that of minimum energy, and states of higher energy content are *excited*. By Pauli's *exclusion principle* the maximum possible number of electrons in states  $1, 2, 3, 4, \dots, n$  are  $2, 8, 18, 32, \dots, 2n^2$ , respectively. Thus, only 2 electrons can occupy the  $1s$  state (or K shell) and the remainder must, even for the normal minimum-energy condition, occupy other states. Hydrogen and helium, the first two elements, have, respectively, 1 and 2 electrons in the 1-quantum (K) shell; the next, lithium, has its third electron in the 2-quantum (L) shell. The passage from lithium to neon results in the filling up of this shell to its full complement of 8 electrons. During the process, the electrons first enter the  $2s$  subgroup, then fill the  $2p$  subgroup until it has 6 electrons, the maximum allowable by the exclusion principle (see Table 1.14).

Very briefly, the effect of the electron-shell filling is as follows. Elements in the same chemical family have the same number of electrons in the subshell that is incompletely filled. The rare gases (He, Ne, Ar, Kr, Xe) have no uncompleted shells. Alkali metals (e.g. Na) have shells containing a single electron. The alkaline earths have two electrons in uncompleted shells. The good conductors (Ag, Cu, Au) have a single electron in the uppermost quantum state. An irregularity in the ordered sequence of filling (which holds consistently from H to Ar) begins at potassium (K) and continues to Ni, becoming again regular with Cu, and beginning a new irregularity with Rb.

The electron of a hydrogen atom, normally at level 1, can be raised to level 2 by endowing it with a particular quantity of energy most readily expressed as 10.2 eV. (1 eV = 1.6  $\times 10^{-19}$  J is the energy acquired by a free electron falling through a potential difference of 1 V, which accelerates it and gives it kinetic energy.) The 10.2 V is the *first excitation potential* for the hydrogen atom. If the electron is given an energy of 13.6 eV, it is freed from the atom, and 13.6 V is the *ionisation potential*. Other atoms have different potentials in accordance with their atomic arrangement.

**Figure 1.4** Atomic structure

### 1.3.2.4 Electrons in metals

An approximation to the behaviour of metals assumes that the atoms lose their valency electrons, which are free to wander in the ionic lattice of the material to form what is called an electron gas. The sharp energy levels of the free atom are broadened into wide bands by the proximity of others. The potential within the metal is assumed to be smoothed out, and there is a sharp rise of potential at the surface which prevents the electrons from escaping: there is a potential-energy step at the surface which the electrons cannot normally overcome: it is of the order of 10 eV. If this is called  $W$ , then the energy of an electron wandering within the metals is  $-W + \frac{1}{2}mu^2$ .

The electrons are regarded as undergoing continual collisions on account of the thermal vibrations of the lattice, and on Fermi-Dirac statistical theory it is justifiable to treat the energy states (which are in accordance with Pauli's principle) as forming an energy continuum. At very low temperatures the ordinary classical theory would suggest that electron energies spread over an almost zero range, but the exclusion principle makes this impossible and even at absolute zero of temperature the energies form a continuum, and physical properties will depend on how the electrons are distributed over the upper levels of this energy range.

**Conductivity** The interaction of free electrons with the thermal vibrations of the ionic lattice (called 'collisions' for brevity) causes them to 'rebound' with a velocity of random direction but small compared with their average velocities as particles of an electron gas. Just as a difference of electric potential causes a drift in the general motion, so a difference of temperature between two parts of a metal carries energy from the hot region to the cold, accounting for thermal conduction and for its association with electrical conductivity. The free electron theory, however, is inadequate to explain the dependence of conductivity on crystal axes in the metal.

At absolute zero of temperature (zero K = -273°C) the atoms cease to vibrate, and free electrons can pass through the lattice with little hindrance. At temperatures over the range 0.3–10 K (and usually round about 5 K) the resistance of certain metals, e.g. Zn, Al, Sn, Hg and Cu, becomes substantially zero. This phenomenon, known as *superconductivity*, has not been satisfactorily explained.

Superconductivity is destroyed by moderate magnetic fields. It can also be destroyed if the current is large enough to produce at the surface the same critical value of magnetic field. It follows that during the superconductivity phase the current must be almost purely superficial, with a depth of penetration of the order of 10  $\mu$ m.

**Electron emission** A metal may be regarded as a potential ‘well’ of depth  $-V$  relative to its surface, so that an electron in the lowest energy state has (at absolute zero temperature) the energy  $W = \phi$  (of the order 10 eV); other electrons occupy levels up to a height  $\varepsilon^*$  (5–8 eV) from the bottom of the ‘well’. Before an electron can escape from the surface it must be endowed with an energy not less than  $\phi = W - \varepsilon^*$ , called the *work function*.

Emission occurs by *surface irradiation* (e.g. with light) of frequency  $\nu$  if the energy quantum  $h\nu$  of the radiation is at least equal to  $\phi$ . The threshold of photoelectric emission is therefore with radiation at a frequency not less than  $\nu = \phi/h$ .

Emission takes place at *high temperatures* if, put simply, the kinetic energy of electrons normal to the surface is great enough to jump the potential step  $W$ . This leads to an expression for the emission current  $i$  in terms of temperature  $T$ , a constant  $A$  and the thermionic work function  $\phi$ :

$$i = AT^2 \exp(-\phi/kT)$$

Electron emission is also the result of the application of a *high electric field intensity* (of the order 1–10 GV/m) to a

metal surface; also when the surface is bombarded with electrons or ions of sufficient kinetic energy, giving the effect of *secondary emission*.

**Crystals** When atoms are brought together to form a crystal, their individual sharp and well-defined energy levels merge into energy *bands*. These bands may overlap, or there may be gaps in the energy levels available, depending on the lattice spacing and interatomic bonding. Conduction can take place only by electron migration into an empty or partly filled band; filled bands are not available. If an electron acquires a small amount of energy from the externally applied electric field, and can move into an available empty level, it can then contribute to the conduction process.

### 1.3.2.5 Insulators

In this case the ‘distance’ (or energy increase  $\Delta W$  in electron-volts) is too large for moderate electric applied fields to endow electrons with sufficient energy, so the material remains an insulator. High temperatures, however, may

result in sufficient thermal agitation to permit electrons to ‘jump the gap’.

### 1.3.2.6 Semiconductors

*Intrinsic* semiconductors (i.e. materials between the good conductors and the good insulators) have a small spacing of about 1 eV between their permitted bands, which affords a low conductivity, strongly dependent on temperature and of the order of one-millionth that of a conductor.

*Impurity* semiconductors have their low conductivity raised by the presence of minute quantities of foreign atoms (e.g. 1 in  $10^8$ ) or by deformations in the crystal structure. The impurities ‘donate’ electrons of energy level that can be raised into a conduction band (n-type); or they can

attract an electron from a filled band to leave a ‘hole’, or electron deficiency, the movement of which corresponds to the movement of a positive charge (p-type).

### 1.3.2.7 Magnetism

Modern magnetic theory is very complex, with ramifications in several branches of physics. Magnetic phenomena are associated with moving charges. Electrons, considered as particles, are assumed to possess an axial spin, which gives them the effect of a minute current turn or of a small permanent magnet, called a *Bohr magneton*. The gyroscopic effect of electron spin develops a precession when a magnetic field is applied. If the precession effect exceeds the spin effect, the external applied magnetic field produces less

\*At pressure of 5 atm.

magnetisation than it would in free space, and the material of which the electron is a constituent part is *diamagnetic*. If the spin effect exceeds that due to precession, the material is *paramagnetic*. The spin effect may, in certain cases, be very large, and high magnetisations are produced by an external field: such materials are *ferromagnetic*.

An iron atom has, in the  $n=4$  shell (N), electrons that give it conductive properties. The K, L and N shells have equal numbers of electrons possessing opposite spin directions, so cancelling. But shell M contains 9 electrons spinning in one direction and 5 in the other, leaving 4 net magnetons. Cobalt has 3, and nickel 2. In a solid metal further cancellation occurs and the average number of unbalanced magnetons is: Fe, 2.2; Co, 1.7; Ni, 0.6.

In an iron crystal the magnetic axes of the atoms are aligned, unless upset by excessive thermal agitation. (At 770°C for Fe, the Curie point, the directions become random and ferromagnetism is lost.) A single Fe crystal magnetises most easily along a cube edge of the structure. It does not exhibit spontaneous magnetisation like a permanent magnet, however, because a crystal is divided into a large number of *domains* in which the various magnetic directions of the atoms form closed paths. But if a crystal is exposed to an external applied magnetic field, (a) the electron spin axes remain initially unchanged, but those domains having axes in the favourable direction grow at the expense of the others (domain wall displacement); and (b) for higher field intensities the spin axes orientate into the direction of the applied field.

If wall movement makes a domain acquire more internal energy, then the movement will relax again when the external field is removed. But if wall movement results in loss of energy, the movement is non-reversible—i.e. it needs

**Table 1.20** Characteristic temperatures

Temperature  $T$  [kelvin] corresponds to  $\theta_c = T - 273.15$  [degree Celsius] and to  $\theta_f = (9/5)T - 32$  [degree Fahrenheit].

Condition	$T$	$\theta_c$	$\theta_f$

external force to reverse it. This accounts for hysteresis and remanence phenomena.

The closed-circuit self-magnetisation of a domain gives it a mechanical strain. When the magnetisation directions of individual domains are changed by an external field, the strain directions alter too, so that an assembly of domains will tend to lengthen or shorten. Thus, readjustments in the crystal lattice occur, with deformations (e.g. 20 parts in 10<sup>6</sup>) in one direction. This is the phenomenon of *magnetostriction*.

The practical art of magnetics consists in control of magnetic properties by alloying, heat treatment and mechanical working to produce variants of crystal structure and consequent magnetic characteristics.

## 1.4 Physical properties

The nature, characteristics and properties of materials arise from their atomic and molecular structure. Tables of approximate values for the physical properties of metals, non-metals, liquids and gases are appended, together with some characteristic temperatures and the numerical values of general physical constants.

## 1.5 Electricity

In the following paragraphs electrical phenomena are described in terms of the effects of electric charge, at a level adequate for the purpose of simple explanation.

In general, charges may be at rest, or in motion, or in acceleration. *At rest*, charges have around them an electric (or *electrostatic*) field of force. *In motion* they constitute a current, which is associated with a magnetic (or *electrodynamic*) field of force additional to the electric field. *In acceleration*, a third field component is developed which results in energy propagation by *electromagnetic waves*.

### 1.5.1 Charges at rest

Figure 1.5 shows two bodies in air, charged by applying between them a potential difference, or (having been in close contact) by forcibly separating them. Work must have been done in a physical sense to produce on one an excess and on the other a deficiency of electrons, so that

the system is a repository of potential energy. (The work done in separating charges is measured by the product of the charges separated and the difference of electrical potential that results.) Observation of the system shows certain effects of interest: (1) there is a difference of electric potential between the bodies depending on the amount of charge and the geometry of the system; (2) there is a mechanical force of attraction between the bodies. These effects are deemed to be manifestations of the *electric field* between the bodies, described as a special state of space and depicted by *lines of force* which express in a pictorial way the strength and direction of the force effects. The lines stretch between positive and negative elements of charge through the medium (in this case, air) which separates the two charged bodies. The electric field is only a concept—for the lines have no real existence—used to calculate various effects produced when charges are separated by any method which results in excess and deficiency states of atoms by electron transfer. Electrons and protons, or electrons and positively ionised atoms, attract each other, and the stability of the atom may be considered due to the balance of these attractions and dynamic forces such as electron spin. Electrons are repelled by electrons and protons by protons, these forces being summarised in the rules, formulated experimentally long before our present knowledge of atomic structure, that ‘like charges repel and unlike charges attract one another’.

### 1.5.2 Charges in motion

In substances called *conductors*, the outer shell electrons can be more or less freely interchanged between atoms.

Figure 1.5 Charged conductors and their electric field

In copper, for example, the molecules are held together comparatively rigidly in the form of a 'lattice'—which gives the piece of copper its permanent shape—through the interstices of which outer electrons from the atoms can be interchanged within the confines of the surface of the piece, producing a random movement of free electrons called an 'electron atmosphere'. Such electrons are responsible for the phenomenon of electrical conductivity.

In other substances called *insulators*, all the electrons are more or less firmly bound to their parent atoms, so that little or no relative interchange of electron charges is possible. There is no marked line of demarcation between conductors and insulators, but the copper group metals, in the order silver, copper, gold, are outstanding in the series of conductors.

#### 1.5.2.1 Conduction

Conduction is the name given to the movement of electrons, or ions, or both, giving rise to the phenomena described by the term *electric current*. The effects of a current include a redistribution of charges, heating of conductors, chemical changes in liquid solutions, magnetic effects, and many subsidiary phenomena.

If at a specified point on a conductor (Figure 1.6)  $n_1$  carriers of electric charge (they can be water-drops, ions, dust particles, etc.) each with a positive charge  $e_1$  arrive per second, and  $n_2$  carriers (such as electrons) each with a negative charge  $e_2$  arrive in the opposite direction per second, the total rate of passing of charge is  $n_1e_1 + n_2e_2$ , which is the charge per second or *current*. A study of conduction concerns the kind of carriers and their behaviour under given conditions. Since an electric field exerts mechanical forces on charges, the application of an electric field (i.e. a potential difference) between two points on a conductor will cause the movement of charges to occur, i.e. a current to flow, so long as the electric field is maintained.

The discontinuous particle nature of current flow is an observable factor. The current carried by a number of electricity carriers will vary slightly from instant to instant with the number of carriers passing a given point in a conductor. Since the electron charge is  $1.6 \times 10^{-19}$  C, and the passage of one coulomb per second (a rate of flow of *one ampere*) corresponds to  $10^{19}/1.6 = 6.3 \times 10^{18}$  electron charges per second, it follows that the discontinuity will be observed

Figure 1.6 Conduction by charge carriers

Figure 1.7 Electronic conduction in metals

only when the flow comprises the very rapid movement of a few electrons. This may happen in gaseous conductors, but in metallic conductors the flow is the very slow drift (measurable in mm/s) of an immense number of electrons.

A current may be the result of a two-way movement of positive and negative particles. Conventionally the direction of current flow is taken as the same as that of the positive charges and against that of the negative ones.

#### 1.5.2.2 Metals

Reference has been made above to the 'electron atmosphere' of electrons in random motion within a lattice of comparatively rigid molecular structure in the case of copper, which is typical of the class of good metallic conductors. The random electronic motion, which intensifies with rise in temperature, merges into an average shift of charge of almost (but not quite) zero continuously (Figure 1.7). When an electric field is applied along the length of a conductor (as by maintaining a potential difference across its ends), the electrons have a *drift* towards the positive end superimposed upon their random digressions. The drift is slow, but such great numbers of electrons may be involved that very large currents, entirely due to electron drift, can be produced by this means. In their passage the electrons are impeded by the molecular lattice, the collisions producing heat and the opposition called *resistance*. The conventional direction of current flow is actually opposite to that of the drift of charge, which is exclusively electronic.

#### 1.5.2.3 Liquids

Liquids are classified according to whether they are *non-electrolytes* (non-conducting) or *electrolytes* (conducting). In the former the substances in solution break up into electrically balanced groups, whereas in the latter the substances form ions, each a part of a single molecule with either a positive or a negative charge. Thus, common salt, NaCl, in a weak aqueous solution breaks up into sodium and chlorine ions. The sodium ion  $\text{Na}^{+}$  is a sodium atom less one electron; the chlorine ion  $\text{Cl}^{-}$  is a chlorine atom with one electron more than normal. The ions attach themselves to groups of water molecules. When an electric field is applied, the sets of ions move in opposite directions, and since they are much more massive than electrons, the conductivity produced is markedly inferior to that in metals. Chemical actions take place in the liquid and at the electrodes when current passes. Faraday's Electrolysis Law states that the mass of an ion deposited at an electrode by electrolytic action is proportional to the quantity of electricity which passes and to the *chemical equivalent* of the ion.

#### 1.5.2.4 Gases

Gaseous conduction is strongly affected by the pressure of the gas. At pressures corresponding to a few centimetres of mercury gauge, conduction takes place by the movement of positive and negative ions. Some degree of ionisation is

**Figure 1.8** Conduction in low-pressure gas

always present due to stray radiations (light, etc.). The electrons produced attach themselves to gas atoms and the sets of positive and negative ions drift in opposite directions. At very low gas pressures the electrons produced by ionisation have a much longer free path before they collide with a molecule, and so have scope to attain high velocities. Their motional energy may be enough to *shockionise* neutral atoms, resulting in a great enrichment of the electron stream and an increased current flow. The current may build up to high values if the effect becomes cumulative, and eventually conduction may be effected through a *spark* or *arc*.

In a *vacuum* conduction can be considered as purely electronic, in that any electrons present (there can be no *molecular* matter present in a perfect vacuum) are moved in accordance with the force exerted on them by an applied electric field. The number of electrons is small, and although high speeds may be reached, the conduction is generally measurable only in milli- or microamperes.

Some of the effects are illustrated in *Figure 1.8*, representing part of a vessel containing a gas or vapour at low pressure. At the bottom is an electrode, the *cathode*, from the surface of which electrons are emitted, generally by heating the cathode material. At the top is a second electrode, the *anode*, and an electric field is established between the electrodes. The field causes electrons emitted from the cathode to move upward. In their passage to the anode these electrons will encounter gas molecules. If conditions are suitable, the gas atoms are ionised, becoming in effect positive charges associated with the nuclear mass. Thereafter the current is increased by the detached electrons moving upwards and by the positive ions moving more slowly downwards. In certain devices (such as the mercury arc rectifier) the impact of ions on the cathode surface maintains its emission. The impact of electrons on the anode may be energetic enough to cause the *secondary emission* of electrons from the anode surface. If the gas molecules are excluded and a vacuum is established, the conduction becomes purely electronic.

### 1.5.2.5 Insulators

If an electric field is applied to a perfect insulator, whether solid, liquid or gaseous, the electric field affects the atoms by producing a kind of 'stretching' or 'rotation' which displaces the electrical centres of negative and positive in opposite directions. This polarisation of the dielectric insulating material may be considered as taking place in the manner indicated in *Figure 1.9*. Before the electric field is

**Figure 1.9** Polarisation and breakdown in insulator

applied, the atoms of the insulator are neutral and unstrained; as the potential difference is raised the electric field exerts opposite mechanical forces on the negative and positive charges and the atoms become more and more highly strained (*Figure 1.9(a)*). On the left face the atoms will all present their negative charges at the surface: on the right face, their positive charges. These surface polarisations are such as to account for the effect known as *permittivity*. The small displacement of the atomic electric charges constitutes a *polarisation current*. *Figure 1.9(b)* shows that, for excessive electric field strength, conduction can take place, resulting in insulation breakdown.

The electrical properties of metallic conductors and of insulating materials are listed in *Tables 1.22* and *1.23*.

### 1.5.2.6 Convection current

Charges can be moved mechanically, on belts, water-drops, dust and mist particles, and by beams of high-speed electrons (as in a cathode ray oscilloscope). Such movement, independent of an electric field, is termed a *convection current*.

## 1.5.3 Charges in acceleration

Reference has been made to the emission of energy (photons) when an electron falls from an energy level to a lower one. Radiation has both a particle and a wave nature, the latter associated with energy propagation through empty space and through transparent media.

### 1.5.3.1 Maxwell equations

Faraday postulated the concept of the field to account for 'action at a distance' between charges and between magnets. Maxwell (1873) systematised this concept in the form of electromagnetic field equations. These refer to media *in bulk*. They naturally have no direct relation to the electronic nature of conduction, but deal with the fluxes of electric, magnetic and conduction fields, their flux densities, and the bulk material properties (permittivity  $\epsilon$ , permeability  $\mu$  and conductivity  $\sigma$ ) of the media in which the fields exist. To the work of Faraday, Ampère and Gauss, Maxwell added the concept of displacement current.

**Displacement current** Around an electric field that changes with time there is evidence of a magnetic field. By analogy with the magnetic field around a conduction current, the rate of change of an electric field may be represented by the presence of a *displacement current*. The concept is applicable to an electric circuit containing a capacitor: there is a conduction current  $i_c$  in the external circuit but not between the electrodes of the capacitor. The capacitor, however, must be acquiring or losing charge and its electric field must be changing. If the rate of change is represented by a displacement current  $i_d = \epsilon \frac{dE}{dt}$ , not only is the magnetic field accounted for, but also there now exists a 'continuity' of current around the circuit.

Displacement current is present in any material medium, conducting or insulating, whenever there is present an

electric field that changes with time. There is a displacement current along a copper conductor carrying an alternating current, but the conduction current is vastly greater even at very high frequencies. In poor conductors and in insulating materials the displacement current is comparable to (or greater than) the conduction current if the frequency is high enough. In free space and in a perfect insulator only displacement current is concerned.

**Equations** The following symbols are used, the SI unit of each appended. The permeability and permittivity are absolute values ( $\mu = \mu_0$ ,  $\epsilon = \epsilon_0$ ). Potentials and fluxes are scalar quantities; field strength and flux density, also surface and path-length elements, are vectorial.

Field	Electric	Magnetic	Conduction
Potential	$V$ [V]	$F$ [A]	$V$ [V]
Field strength	$E$ [V/m]	$H$ [A/m]	$E$ [V/m]
Flux	$Q$ [C]	$\phi$ [Wb]	$I$ [A]
Flux density	$D$ [C/m <sup>2</sup> ]	$B$ [T]	$J$ [A/m <sup>2</sup> ]
Material property	$\epsilon$ [F/m]	$\mu$ [H/m]	$\sigma$ [S/m]

The total electric flux emerging from a charge  $+Q$  or entering a charge  $-Q$  is equal to  $Q$ . The integral of the electric flux density  $D$  over a closed surface  $s$  enveloping the charge is

$$\oint_s D \cdot d\mathbf{s} = Q \quad (1.1)$$

If the surface has no enclosed charge, the integral is zero. This is the Gauss law.

The magnetomotive force  $F$ , or the line integral of the magnetic field strength  $H$  around a closed path  $l$ , is equal to the current enclosed, i.e.

$$\oint_l H \cdot d\mathbf{l} = I \quad (1.2)$$

This is the Ampère law with the addition of displacement current.

The Faraday law states that, around any closed path  $l$  encircling a magnetic flux  $\phi$  that changes with time, there is an electric field, and the line integral of the electric field strength  $E$  around the path is

$$\oint_l E \cdot d\mathbf{l} = -(\mathrm{d}\phi/\mathrm{d}t) \quad (1.3)$$

Magnetic flux is a solenoidal quantity, i.e. it comprises a structure of closed loops; over any closed surface  $s$  in a magnetic field as much flux leaves the surface as enters it. The surface integral of the flux density  $B$  is therefore always zero, i.e.

$$\oint_s B \cdot d\mathbf{s} = 0 \quad (1.4)$$

To these four laws are added the *constitutive equations*, which relate the flux densities to the properties of the media in which the fields are established. The first two are, respectively, electric and magnetic field relations; the third relates conduction current density to the voltage gradient in a conducting medium; the fourth is a statement of the displacement current density resulting from a time rate of change of the electric flux density. The relations are

$$D = \epsilon E; \quad B = \mu H; \quad J_c = \sigma E; \quad J_d = \partial D / \partial t$$

In electrotechnology concerned with direct or low-frequency currents, the Maxwell equations are rarely used in the form given above. Equation (1.2), for example, appears as the number of amperes (or ampere-turns) required to produce in an area  $a$  the specified magnetic flux  $\phi \Leftarrow Ba = \mu Ha$ . Equation (1.3) in the form  $e = -(d\phi/dt)$

gives the e.m.f. in a transformer primary or secondary turn. The concept of the 'magnetic circuit' embodies Equation (1.4). But when dealing with such field phenomena as the eddy currents in massive conductors, radio propagation or the transfer of energy along a transmission line, the Maxwell equations are the basis of analysis.

Figure 1.10 Electromagnetic wave propagation

### 1.5.3.2 Electromagnetic wave

The local 'induction' field of a charge at rest surrounds it in a predictable pattern. Let the position of the charge be suddenly displaced. The field pattern also moves, but because of the finite rate of propagation there will be a region in which the original field has not yet been supplanted by the new. At the instantaneous boundary the electric field pattern may be pictured as 'kinked', giving a transverse electric field component that travels away from the charge. Energy

is propagated, because the transverse electric field is accompanied by an associated transverse magnetic field in accordance with the Ampère law.

Consider a unit cube of *free space* (Figure 1.10) approached by a transverse electric field of strength  $E$  at a velocity  $u$  in the specified direction. As  $E$  enters the cube, it produces therein an electric flux, of density  $D = \epsilon_0 E$  increasing at the rate  $Du$ . This is a displacement current which produces a magnetic field of strength  $H$  and flux density  $B = \mu_0 H$  increasing at the rate  $Bu$ . Then the  $E$  and  $H$  waves are mutually dependent:

$$Du = \epsilon_0 Eu = H \quad (1.5) \Leftarrow$$

$$Bu = \mu_0 Hu = E \quad (1.6) \Leftarrow$$

Multiplication and division of (1.5) and (1.6) give

$$u = 1/\sqrt{(\epsilon_0 \mu_0)} = c \simeq 3 \times 10^8 \text{ m/s}$$

$$E/H = \sqrt{(\mu_0/\epsilon_0)} = Z_0 \simeq 377 \Omega$$

The velocity of propagation in free space is thus fixed; the ratio  $E/H$  is also fixed, and is called the intrinsic impedance. Further,  $\frac{1}{2} \epsilon_0 E^2 = \frac{1}{2} \mu_0 H^2$  [J/m<sup>3</sup>], showing that the electric and magnetic energy densities are equal.

Propagation is normally maintained by charge acceleration which results from a high-frequency alternating current (e.g. in an aerial), so that waves of  $E$  and  $H$  of sinusoidal distribution are propagated with a wavelength dependent on the frequency (Figure 1.11). There is a fixed relation between the directions of  $E$ ,  $H$  and the energy flow. The rate at which energy passes a fixed point is  $EH$  [W/m<sup>2</sup>], and the direction of  $E$  is taken as that of the wave polarisation.

Plane wave transmission in a perfect homogeneous loss-free insulator takes place as in free space, except that  $\epsilon_0$  is replaced by  $\epsilon = \epsilon_r \epsilon_0$ , where  $\epsilon_r$  is the relative permittivity of the medium: the result is that both the propagation velocity and the intrinsic impedance are reduced.

When a plane wave from free space enters a material with conducting properties, it is subject to attenuation by reason of the  $I^2 R$  loss. In the limit, a perfect conductor presents to the incident wave a complete barrier, reflecting the wave as a perfect mirror. A wave incident upon a general medium is partly reflected, and partly transmitted with attenuation and phase-change.

Table 1.24 gives the wavelength and frequency of free space electromagnetic waves with an indication of their technological range and of the physical origin concerned.

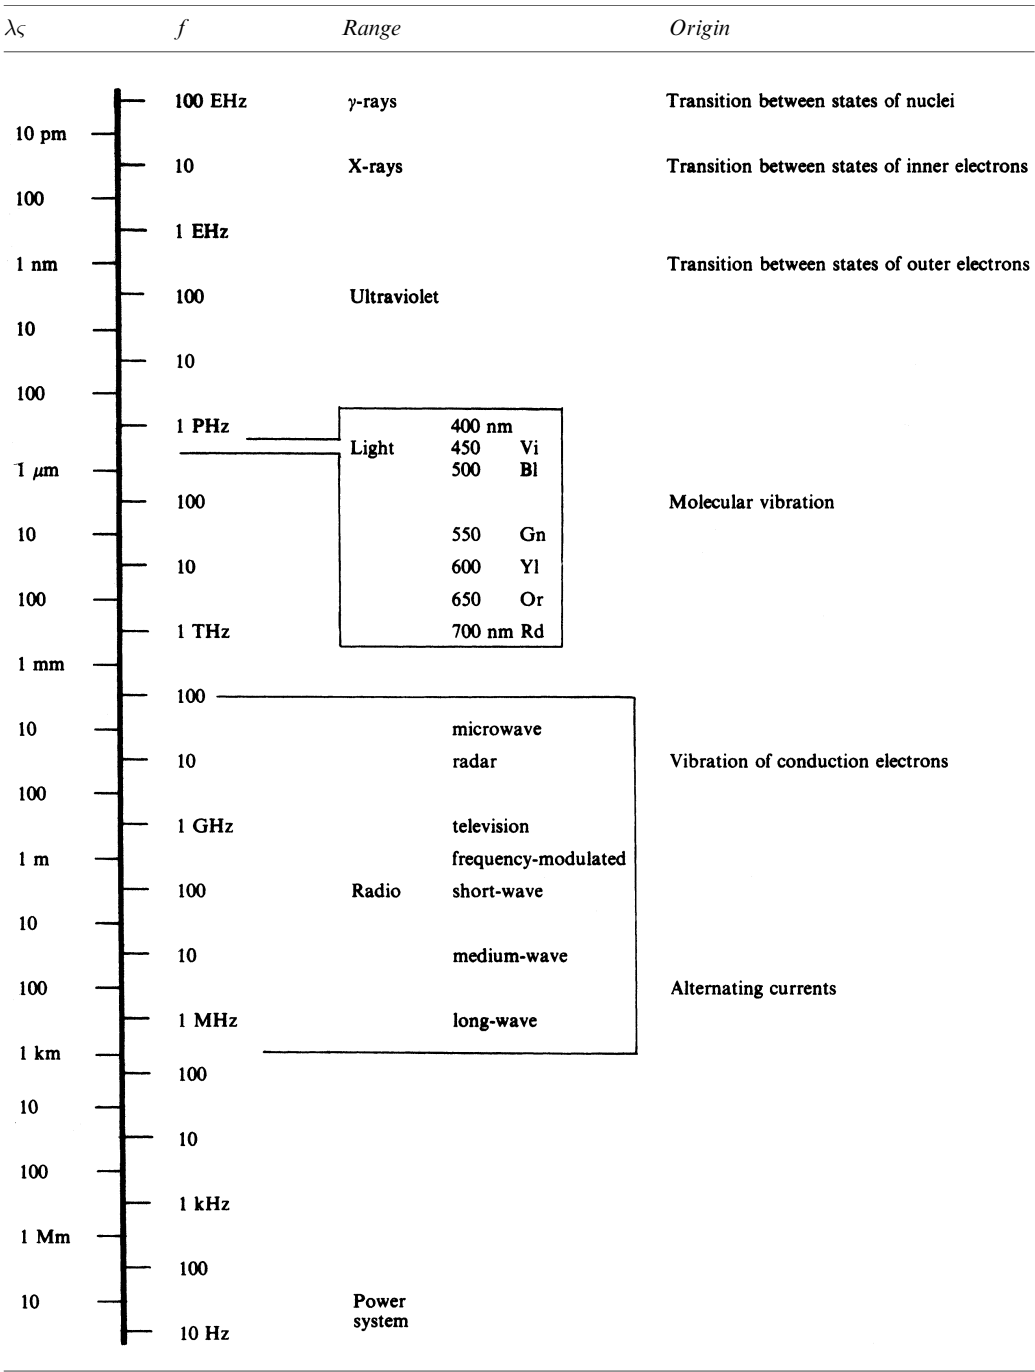

Figure 1.11 Electromagnetic wave

**Table 1.24** Electromagnetic wave spectrum

Free space properties:

Electric constant	$\epsilon_0=8.854\times 10^{-12}$	F/m	Intrinsic impedance	$Z_0=376.8$	$\Omega$
Magnetic constant	$\mu_0=4\pi\times 10^{-7}$	H/m	Velocity	$c=2.9979\times 10^8$	m/s

The product of wavelength  $\lambda$ [m] and frequency  $f$ [Hz] is  $f\lambda=c\simeq 3\times 10^8$  [m/s].

Electrotechnology concerns the electrophysical and allied principles applied to practical electrical engineering. A completely general approach is not feasible, and many separate *ad hoc* technologies have been developed using simplified and delimited areas adequate for particular applications.

In establishing a technology it is necessary to consider whether the relevant applications can be dealt with (a) in *macroscopic* terms of physical qualities of materials in bulk (as with metallic conduction or static magnetic fields); or (b) in *microscopic* terms involving the microstructure of materials as an essential feature (as in domain theory); or (c) in molecular, atomic or *subatomic* terms (as in nuclear reaction and semi-conduction). There is no rigid line of demarcation, and certain technologies must cope with two or more such subdivisions at once. Electrotechnology thus tends to become an assembly of more or less discrete (and sometimes apparently unrelated) areas in which methods of treatment differ widely.

To a considerable extent (but not completely), the items of plant with which technical electrical engineering deals—generators, motors, feeders, capacitors, etc.—can be represented by *equivalent circuits* or *networks* energised by an electrical source.

For the great majority of cases within the purview of 'heavy electrical engineering' (that is, generation, transmission and utilisation for power purposes, as distinct from telecommunications), a *source* of electrical energy is considered to produce a *current* in a conducting *circuit* by reason of an *electromotive force* acting against a property of the circuit called *impedance*. The behaviour of the circuit is described in terms of the energy fed into the circuit by the source, and the nature of the conversion, dissipation or storage of this energy in the several circuit components.

Electrical phenomena, however, are only in part associated with conducting circuits. The generalised basis is one of magnetic and electrical fields in free space or in material media. The fundamental starting point is the conception contained in Maxwell's electromagnetic equations (Section 1.5.3), and in this respect the voltage and currents in a circuit are only representative of the fundamental field phenomena within a restricted range. Fortunately, this range embraces very nearly the whole of 'heavy' electrical engineering practice. The necessity for a more comprehensive viewpoint makes itself apparent in connection with problems of long-line transmission; and when the technique of ultra-high-frequency work is reached, it is necessary to give up the familiar circuit ideas in favour of a whole-hearted application of field principles.

## 2.1 Nomenclature

### 2.1.1 Circuit phenomena

Figure 2.1 shows in a simplified form a hypothetical circuit with a variety of electrical energy sources and a representative selection of devices in which the energy received from the source is converted into other forms, or stored, or both. The forms of variation of the current or voltage are shown in Figure 2.2. In an actual circuit the current may change in a quite arbitrary fashion as indicated at (a); it may rise or fall, or reverse its direction, depending on chance or control. Such random variation is inconveniently difficult to deal with, and engineers prefer to simplify the conditions as much as possible. For example (Figure 2.2(b)), the current may be assumed to be rigidly constant, in which case it is termed a *direct current*. If the current be deemed to reverse cyclically according to a sine function, it becomes a *sinusoidal alternating current* (c). Less simple waveforms, such as (d), may be dealt with by

Figure 2.1 Typical circuit devices. G, source generator; R, resistor; A, arc; B, battery; P, plating bath; M, motor; L, inductor; C, capacitor; I, insulator

Figure 2.2 Modes of current (or voltage) variation

application of Fourier's theorem, thus making it possible to calculate a great range of practical cases—such as those involving rectifiers—in which the sinusoidal waveform assumption is inapplicable. The cases shown in (b), (c) and (d) are known as *steady states*, the current (or voltage) being assumed established for a considerable time before the circuit is investigated. But since the electric circuit is capable of storing energy, a change in the circuit may alter the conditions so as to cause a redistribution of circuit energy. This occurs with a circulation of *transient* current. An example of a simple oscillatory transient is shown in Figure 2.2(e).

The calculation of circuits in which direct currents flow is comparatively straightforward. For sine wave alternating current circuits an algebra has been developed by means of which problems can be reduced to a technique very similar to that of d.c. circuits. Where non-sinusoidal waveforms are concerned, the treatment is based on the analysis of the current and voltage waves into fundamental and harmonic sine waves, the standard sine wave method being applied to the fundamental and to each of the harmonics. In the case of transients, a more searching investigation may be necessary, but there are a number of common modes in which transients usually occur, and (so long as the circuit is relatively simple) it may be possible to select the appropriate mode by inspection.

Circuit *parameters*—resistance, inductance and capacitance—may or may not be constant. If they are not, approximation, linearising or step-by-step computation is necessary.

#### 2.1.1.1 Electromotive-force sources

Any device that develops an electromotive force (e.m.f.) capable of sustaining a current in an electric circuit must be associated with some mode of energy conversion into the electrical from some different form. The modes are (1) mechanical/electromagnetic, (2) mechanical/electrostatic, (3) chemical, (4) thermal, and (5) photoelectric.

### 2.1.2 Electrotechnical terms

The following list includes the chief terms in common use. The symbols and units employed are given in *Table 2.1*.

*Admittance:* The ratio between current and voltage in r.m.s. terms for sinusoidally varying quantities.

*Admittance operator:* The ratio between current and voltage in operational terms.

**Table 2.1** Electrotechnical symbols and units

<i>Quantity</i>	<i>Quantity symbol</i>	<i>Unit name</i>	<i>Unit symbol</i>
Admittance	$Y$	siemens	S
Ampere-turn	—	ampere-turn	A-t
Angular frequency	$\omega = 2\pi f$	radian/second	rad/s
Capacitance	$C$	farad	F
Charge	$Q$	coulomb	C
Conductance	$G$	siemens	S
Conductivity	$\gamma, \sigma$	siemens/metre	S/m

*Ampere-turns:* The product of the number of turns of a circuit and the current flowing in them.

*Angular frequency:* The number of periods per second of a periodically varying quantity multiplied by  $2\pi$ .

*Capacitance:* The property of a conducting body by virtue of which an electric charge has to be imparted to it to produce a difference of electrical potential between it and the surrounding bodies. The ratio between the charge on a conductor and its potential when all neighbouring conductors are at zero (earth) potential. The ratio between the charge on each electrode of a capacitor and the potential difference between them.

*Capacitor:* A device having capacitance as a chief property.

*Charge:* The excess of positive or negative electricity on a body or in space.

*Coercive force:* The demagnetising force required to reduce to zero the remanent flux density in a magnetic body.

*Coercivity:* The value of the coercive force when the initial magnetisation has the saturation value.

*Complexor:* A non-vectorial quantity expressible in terms of a complex number.

*Conductance:* For steady direct currents, the reciprocal of the resistance. For sinusoidal alternating currents, the resistance divided by the square of the impedance.

*Conductivity:* The reciprocal of resistivity.

*Core loss (iron loss):* The loss in a magnetic body subject to changing magnetisation, resulting from hysteresis and eddy current effects.

*Current:* The flow or transport of electric charges along a path or around a circuit.

*Current density:* The current per unit area of a conductor, or per unit width of an extended conductor.

*Diamagnetic:* Having a permittivity less than that of free space.

*Dielectric loss:* The loss in an insulating body, resulting from hysteresis, conduction and absorption.

*Displacement current:* The current equivalent of the rate of change of electric flux with time.

*Eddy current:* The current electromagnetically induced in a conductor lying in a changing magnetic field.

*Electric field:* The energetic state of the space between two oppositely charged conductors.

*Electric field strength:* The mechanical force per unit charge on a very small charge placed in an electric field. The negative voltage gradient.

*Electric flux:* The electric field, equal to the charge, between oppositely charged conductors.

*Electric flux density:* The electric flux per unit area.

*Electric space constant:* The permittivity of free space.

*Electric strength:* The property of an insulating material which enables it to withstand electric stress; or the stress that it can withstand without breakdown.

*Electric stress:* The electric field intensity, which tends to break down the insulating property of an insulating material.

*Electromagnetic field:* A travelling field having electric field and magnetic field components and a speed of propagation depending on the electrical properties of the ambient medium.

*Electromagnetic induction:* The production of an electromotive force in a circuit by a change of magnetic linkage through the circuit. The e.m.f. so produced is an *induced e.m.f.*, and any current that may result therefrom is an *induced current*.

*Electromotive force (e.m.f.):* That quality which tends to cause a movement of charges around a circuit. The direction is that of the movement of positive charges. E.m.f. is measured by the amount of energy developed by transfer of unit positive charge. The term is applied to sources that convert electrical

energy to or from some other kind (chemical, mechanical, thermal, etc.).

*Ferromagnetic:* Having a permeability much greater than that of free space, and varying with the magnetic flux density.

*Force:* The cause of the mechanical displacement, motion, acceleration and deformation of massive bodies.

*Frequency:* The number of repetitions of a cyclically time-varying quantity in unit time.

*Hysteresis:* The phenomenon by which an effect in a body depends not only on the present cause, but also on the previous state of the body. In *magnetisation* a flux density produced by a given magnetic field intensity depends on the previous magnetisation history. A comparable effect occurs in the *electrification* of insulating materials. In cyclic changes hysteresis is the cause of energy loss.

*Immittance:* A circuit property that can be either impedance or admittance.

*Impedance:* The ratio between voltage and current in r.m.s. terms for sinusoidally varying quantities.

*Impedance operator:* The ratio between voltage and current in operational terms.

*Inductance:* The property of a circuit by virtue of which the passage of a current sets up magnetic linkage and stores magnetic energy. If the linkage of a circuit arises from the current in another circuit, the property is called *mutual inductance*.

*Inductor:* A device having inductance as a chief property.

*Insulation resistance:* The resistance under prescribed conditions between two conductors or conducting systems normally separated by an insulating medium.

*$I^2R$  loss (copper loss):* The loss (converted into heat) due to the passage of a current through the resistance of a conductor.

*Line of flux (line of force):* A line drawn in a field to represent the direction of the flux at any point.

*Linkage:* The summation of the products of elements of magnetic flux and the number of turns of the circuit they embrace in a given direction.

*Loss angle:* The phase angle by which the current in a reactor fails to lead (or lag) the voltage by  $\frac{1}{2}\pi$  rad under sinusoidal conditions. The tangent of this angle is called the *loss tangent*.

*Magnetic circuit:* The closed path followed by a magnetic flux.

*Magnetic field:* The energetic state of the space surrounding an electric current.

*Magnetic field strength:* The cause at any point of a magnetic circuit of the magnetic flux density there.

*Magnetic flux:* The magnetic field, equal to the summation of flux density and area, around a current. A phenomenon in the neighbourhood of currents or magnets. The magnetic flux through any area is the surface integral of the magnetic flux density through the surface. Unit magnetic flux is that flux, the removal of which from a circuit of unit resistance causes unit charge to flow in the circuit; or in an open turn produces a voltage-time integral of unity.

*Magnetic flux density:* The magnetic flux per unit area at a point in a magnetic field, the area being oriented to give a maximum value to the flux. The normal to the area is the direction of the flux at the point. The direction of the current produced in the electric circuit on removal of the flux, and the positive direction of the flux, have the relation of a right-handed screw.

*Magnetic leakage:* That part of a magnetic flux which follows such a path as to make it ineffective for the purpose desired.

*Magnetic potential difference:* A difference between the magnetic states existing at two points which produces a magnetic field between them. It is equal to the line integral of

the magnetic field intensity between the points, except in the presence of electric currents.

**Magnetic space constant:** The permeability of free space.

**Magnetising force:** The same as magnetic field strength.

**Magnetomotive force:** Along any path, the line integral of the magnetic field strength along that path. If the path is closed, the line integral is equal to the total magnetising current in ampere-turns.

**Paramagnetic:** Having a permeability greater than that of free space.

**Period:** The time taken by one complete cycle of a waveform.

**Permeability:** The ratio of the magnetic flux density in a medium or material at a point to the magnetic field strength at the point. The *absolute permeability* is the product of the *relative permeability* and the *permeability of free space* (magnetic space constant).

**Permeance:** The ratio between the magnetic flux in a magnetic circuit and the magnetomotive force. The reciprocal of reluctance.

**Permittivity:** The ratio between the electric flux density in a medium or material at a point and the electric field strength at the point. The *absolute permittivity* is the product of the *relative permittivity* and the *permittivity of free space* (electric space constant).

**Phase angle:** The angle between the phasors that represent two alternating quantities of sinusoidal waveform and the same frequency.

**Phasor:** A sinusoidally varying quantity represented in the form of a complex number.

**Polarisation:** The change of the electrical state of an insulating material under the influence of an electric field, such that each small element becomes an electric dipole or doublet.

**Potential:** The electrical state at a point with respect to potential zero (normally taken as that of the earth). It is measured by the work done in transferring unit charge from potential zero to the point.

**Potential difference:** A difference between the electrical states existing at two points tending to cause a movement of positive charges from one point to the other. It is measured by the work done in transferring unit charge from one point to the other.

**Potential gradient:** The potential difference per unit length in the direction in which it is a maximum.

**Power:** The rate of transfer, storage, conversion or dissipation of energy. In sinusoidal alternating current circuits the *active power* is the mean rate of energy conversion; the *reactive power* is the peak rate of circulation of stored energy; the *apparent power* is the product of r.m.s. values of voltage and current.

**Power factor:** The ratio between active power and apparent power. In sinusoidal alternating current circuits the power factor is  $\cos \phi$ , where  $\phi$  is the phase angle between voltage and current waveforms.

**Quantity:** The product of the current and the time during which it flows.

**Reactance:** In sinusoidal alternating current circuits, the quantity  $\omega L$  or  $1/\omega C$ , where  $L$  is the inductance,  $C$  is the capacitance and  $\omega$  is the angular frequency.

**Reactor:** A device having reactance as a chief property; it may be an inductor or a capacitor. A *nuclear reactor* is a device in which energy is generated by a process of nuclear fission.

**Reluctance:** The ratio between the magnetomotive force acting around a magnetic circuit and the resulting magnetic flux. The reciprocal of permeance.

**Remanence:** The remanent flux density obtained when the initial magnetisation reaches the saturation value for the material.

**Remanent flux density:** The magnetic flux density remaining in a material when, after initial magnetisation, the magnetising force is reduced to zero.

**Residual magnetism:** The magnetism remaining in a material after the magnetising force has been removed.

**Resistance:** That property of a material by virtue of which it resists the flow of charge through it, causing a dissipation of energy as heat. It is equal to the constant potential difference divided by the current produced thereby when the material has no e.m.f. acting within it.

**Resistivity:** The resistance between opposite faces of a unit cube of a given material.

**Resistor:** A device having resistance as a chief property.

**Susceptance:** The reciprocal of reactance.

**Time constant:** The characteristic time describing the duration of a transient phenomenon.

**Voltage:** The same as potential difference.

**Voltage gradient:** The same as potential gradient.

**Waveform:** The graph of successive instantaneous values of a time-varying physical quantity.

## 2.2 Thermal effects

### 2.2.1 Resistance

That property of an electric circuit which determines for a given current the rate at which electrical energy is converted into heat is termed *resistance*. A device whose chief property is resistance is a *resistor*, or, if variable, a *rheostat*. A current  $I$  flowing in a resistance  $R$  develops heat at the rate

$$P = I^2 R \text{ joule/second or watts}$$

a relation expressing *Joule's law*.

#### 2.2.1.1 Voltage applied to a resistor

In the absence of any energy storage effects (a physically unrealisable condition), the current in a resistor of value  $R$  is  $I$  when the voltage across it is  $V$ , in accordance with the relation  $I = V/R$ . If a steady p.d.  $V$  be suddenly applied to a resistor  $R$ , the current instantaneously assumes the value given, and energy is expended at the rate  $P = I^2 R$  watts, continuously. No transient occurs. If a constant frequency, constant amplitude *sine wave* voltage  $v$  is applied, the current  $i$  is at every instant given by  $i = v/R$ , and in consequence the current has also a sine waveform, provided that the resistance is linear. The instantaneous rate of energy dissipation depends on the instantaneous current: it is  $p = i^2 R = v^2/R$ . Should the applied voltage be non-sinusoidal, the current has (under the restriction mentioned) an exactly similar waveform. The three cases are illustrated in Figure 2.3.

Figure 2.3 Voltage applied to a pure resistor

In the case of alternating waveform, the average rate of energy dissipation is given by  $P = I^2 R$ , where  $I$  is the *root-mean-square* current value.

### 2.2.1.2 Voltage-current characteristics

For a given resistor  $R$  carrying a constant current  $I$ , the p.d. is  $V = IR$ . The ratio  $R = V/I$  may or may not be invariable. In some cases it is sufficient to assume a degree of constancy, and calculation is generally made on this assumption. Where the variations of resistance are too great to make the assumption reasonably valid, it is necessary to resort to less simple analysis or to graphical methods.

A constant resistance is manifested by a constant ratio between the voltage across it and the current through it, and by a straight-line graphical relation between  $I$  and  $V$  (Figure 2.4(a)), where  $R = V/I = \cot \theta$ . This case is typical of metallic resistance wires at constant temperature.

Certain circuits exhibit *non-linear* current-voltage relations (Figure 2.4(b)). The non-linearity may be *symmetrical* or *asymmetrical*, in accordance with whether the conduction characteristics are the same or different for the two current-flow directions. Rectifiers are an important class of non-linear, asymmetrical resistors.

A hypothetical device having the current-voltage characteristic shown in Figure 2.4(c) has, at an operating condition represented by the point P, a current  $I_d$  and a p.d.  $V_d$ . The ratio  $R_d = V_d/I_d$  is its *d.c. resistance* for the given condition. If a small alternating voltage  $\Delta v_a$  be applied under the same condition (i.e. superimposed on the p.d.  $V_d$ ), the current will fluctuate by  $\Delta i_a$  and the ratio  $r_a = \Delta v_a / \Delta i_a$  is the *a.c. or incremental resistance* at P. The d.c. resistance is also obtainable from  $R_d = \cot \theta$ , and the a.c. resistance from  $r_a = \cot \alpha$ . In the region of which  $Q$  is a representative point, the a.c. resistance is *negative*, indicating that the device is capable of giving a small output of a.c. power, derived from its greater d.c. input. It remains in sum an energy dissipator, but some of the energy is returnable under suitable conditions of operation.

### 2.2.1.3 D.c. or ohmic resistance: linear resistors

The d.c. or ohmic resistance of linear resistors (a category confined principally to metallic conductors) is a function of the dimensions of the conducting path and of the *resistivity* of the material from which the conductor is made. A wire of length  $l$ , cross-section  $a$  and resistivity  $\rho$  has, at constant given temperature, a resistance

$$R = \rho l / a \text{ ohms}$$

where  $\rho$ ,  $l$  and  $a$  are in a consistent system of dimensions (e.g.  $l$  in metres,  $a$  in square metres,  $\rho$  in ohms per 1 m length and 1 m<sup>2</sup> cross-section—generally contracted to ohm-metres). The expression above, though widely applicable, is true only on the assumption that the current is uniformly distributed over

the cross-section of the conductor and flows in paths parallel to the boundary walls. If this assumption is inadmissible, it is necessary to resort to integration or the use of current-flow lines. Figure 2.5 summarises the expressions for the resistance of certain arrangements and shapes of conductors.

**Resistivity** The resistivity of conductors depends on their composition, physical condition (e.g. dampness in the case of non-metals), alloying, manufacturing and heat treatment, chemical purity, mechanical working and ageing. The *resistance-temperature coefficient* describes the rate of change of resistivity with temperature. It is practically 0.004  $\Omega/^{\circ}\text{C}$  at 20 $^{\circ}\text{C}$  for copper. Most pure metals have a resistivity that rises with temperature. Some alloys have a very small coefficient. Carbon is notable in that its resistivity decreases markedly with temperature rise, while uranium dioxide has a resistivity which falls in the ratio 50:1 over a range of a few hundred degrees. Table 2.2 lists the resistivity  $\rho$  and the resistance-temperature coefficient  $\alpha$  for a number of representative materials. The effect of temperature is assessed in accordance with the expressions

$$R_1 = R_0(1 + \alpha\theta_1); \quad R_2/R_1 = (1 + \alpha\theta_2)/(1 + \alpha\theta_1);$$

or

$$R_2 = R_1[1 + \alpha(\theta_2 - \theta_1)] \leftarrow$$

where  $R_0$ ,  $R_1$  and  $R_2$  are the resistances at temperatures 0,  $\theta_1$  and  $\theta_2$ , and  $\alpha$  is the resistance-temperature coefficient at 0 $^{\circ}\text{C}$ .

### 2.2.1.4 Liquid conductors

The variations of resistance of a given aqueous solution of an electrolyte with temperature follow the approximate rule:

$$R_{\theta_2} = R_0 / (1 + 0.03\theta) \leftarrow$$

where  $\theta$  is the temperature in degrees Celsius. The conductivity (or reciprocal of resistivity) varies widely with the percentage strength of the solution. For low concentrations the variation is that given in Table 2.2.

### 2.2.1.5 Frequency effects

The resistance of a given conductor is affected by the frequency of the current carried by it. The simplest example is that of an isolated wire of circular cross-section. The inductance of the central parts of the conductor is greater than that of the outside skin because of the additional flux linkages due to the internal magnetic flux lines. The impedance of the central parts is consequently greater, and the current flows mainly at and near the surface of the conductor, where the impedance is least. The useful cross-section of the conductor is less than the actual area, and the effective resistance is consequently higher. This is called the *skin effect*. An analogous phenomenon, the *proximity effect*, is due to mutual inductance between conductors arranged closely parallel to one another.

Figure 2.4 Current-voltage characteristics

Figure 2.5 Resistance in particular cases

**Table 2.2** Conductivity of aqueous solutions\* (mS/cm)

Concentration (%)	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>	<i>f</i>	<i>g</i>	<i>h, j</i>	<i>k</i>	<i>l, m</i>
1	40	18	12	10	10	8	6	4	3	3
2	72	35	23	20	20	16	12	8	6	6
3	102	51	34	30	30	24	18	12	9	8
4	130	65	44	39	39	32	23	16	11	10
5		79	55	48	47	39	28	20	13	11
7.5		110	79	69	67	54	39	29	18	16
10			99	90	85	69		31	22	20

\*(a) NaOH, caustic soda; (b) NH<sub>4</sub>Cl, sal ammoniac; (c) NaCl, common salt; (d) NaNO<sub>3</sub>, Chilean saltpetre; (e) CaCl<sub>2</sub>, calcium chloride; (f) ZnCl<sub>2</sub>, zinc chloride; (g) NaHCO<sub>3</sub>, baking soda; (h) Na<sub>2</sub>CO<sub>3</sub>, soda ash; (j) Na<sub>2</sub>SO<sub>4</sub>, Glauber's salt; (k) Al<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>K<sub>2</sub>SO<sub>4</sub>, alum; (l) CuSO<sub>4</sub>, blue vitriol; (m) ZnSO<sub>4</sub>, white vitriol.

The effects depend on conductor size, frequency  $f$  of the current, resistivity  $\rho$  and permeability  $\mu$  of the material. For a circular conductor of diameter  $d$  the increase of effective resistance is proportional to  $d^2 f \mu / \rho$ . At power frequencies and for small conductors the effect is negligible. It may, however, be necessary to investigate the skin and proximity effects in the case of large conductors such as bus-bars.

#### 2.2.1.6 Non-linear resistors

Prominent among non-linear resistors are electric arcs; also silicon carbide and similar materials.

**ArCs** An electric arc constitutes a conductor of somewhat vague dimensions utilising electronic and ionic conduction in a gas. It is strongly affected by physical conditions of temperature, gas pressure and cooling. In air at normal pressure a d.c. arc between copper electrodes has the voltage-current relation given approximately by  $V = 30 + 10/I + I[1 + 3/I]10^3$  for a current  $I$  in an arc length  $l$  metres. The expression is roughly equivalent to 10 V/cm for large currents and high voltages. The current density varies between 1 and 1000 A/mm<sup>2</sup>, being greater for large currents because of the *pinch* effect. See also Section 2.7.

**Silicon carbide** Conducting pieces of this material have a current-voltage relation expressed approximately by  $I = KV^x$ , where  $x$  is usually between 3 and 5. For rising voltage the current increases very rapidly, making silicon carbide devices suitable for circuit protection and the discharge of excess transmission-line surge energy.

### 2.2.2 Heating and cooling

The *heating* of any body such as a resistor or a conducting circuit having inherent resistance is a function of the losses within it that are developed as heat. (This includes core and dielectric as well as ohmic  $I^2 R$  losses, but the effective value of  $R$  may be extended to cover such additional losses.) The *cooling* is a function of the facilities for heat dissipation to outside media such as air, oil or solids, by radiation, conduction and convection.

#### 2.2.2.1 Rapid heating

If the time of heating is short, the cooling may be ignored, the temperature reached being dependent only on the rate of development of heat and the thermal capacity. If  $p$  is the heat development per second in joules (i.e. the power in watts),  $G$  the mass of the heated body in kilograms and  $c$  its specific heat in joules per kilogram per kelvin, then

$$Gc \cdot d\theta = p \cdot dt, \psi \text{ giving } \theta = (1/Gc) \int p \cdot dt$$

For steady heating, the temperature rise is  $p/Gc$  in Kelvin per second.

Standard annealed copper is frequently used for the windings and connections of electrical equipment. Its density is  $G = 8900 \text{ kg/m}^3$  and its resistivity at 20°C is  $0.017 \mu\Omega\text{-m}$ ; at 75°C it is  $0.021 \mu\Omega\text{-m}$ . A conductor worked at a current density  $J$  (in amperes per square metre) has a specific loss (watts per kilogram) of  $\rho J^2 / 8900$ . If  $J = 2.75 \text{ MA/m}^2$  (or  $2.75 \text{ A/mm}^2$ ), the specific loss at 75°C is  $17.8 \text{ W/kg}$ , and its rate of self-heating is  $17.8/375 = 0.048^\circ\text{C/s}$ .

#### 2.2.2.2 Continuous heating

Under prolonged steady heating a body will reach a temperature rise above the ambient medium of  $\theta_m = p/A\lambda$ , where  $A$  is the cooling surface area and  $\lambda$  the specific heat dissipation (joules per second per square metre of surface per degree Celsius temperature rise above ambient). The expression is based on the assumption, roughly true for moderate temperature rises, that the rate of heat emission is proportional to the temperature rise. The specific heat dissipation  $\lambda$  is compounded of the effects of *radiation*, *conduction* and *convection*.

**Radiation** The heat radiated by a surface depends on the absolute temperature  $T$  (given by  $T = \theta + 273$ , where  $\theta$  is the Celsius temperature), and on its character (surface smoothness or roughness, colour, etc.). The Stefan law of heat radiation is

$$p_r = 5.7eT^4 \times 10^{-8} \text{ watts per square metre}$$

where  $e$  is the coefficient of radiant emission, always less than unity, except for the perfect 'black body' surface, for which  $e = 1$ . The radiation from a body is independent of the temperature of the medium in which it is situated. The process of radiation of a body to an exterior surface is accompanied by a re-absorption of part of the energy when re-radiated by that surface. For a small spherical radiating body inside a large and/or black spherical cavity, the radiated power is given by the Stefan-Boltzmann law:

$$p_r = 5.7e_1[T_1^4 - T_2^4]10^{-8} \text{ watts per square metre}$$

where  $T_1$  and  $e_1$  refer to the body and  $T_2$  to the cavity.

The emission of radiant heat from a perfect black body surface is independent of the roughness or corrugation of the surface. If  $e < 1$ , however, there is some increase of radiation if the surface is rough.

**Conduction** The conduction of heat is a function of the thermal or temperature gradient and the thermal resistivity, the latter being defined as the temperature difference in degrees Celsius across a path of unit length and unit section required for the continuous transmission of 1 W. Thus, the heat conducted per unit area along a path of length  $x$  in a material of thermal resistivity  $\rho_\theta$  for a temperature difference of  $\theta$  is

$$p_d = \theta / \rho_\theta \text{ watts}$$

Resistivities for metals are very low. For insulating materials such as paper,  $\rho_\theta = 5-10$ ; for still air,  $\rho_\theta = 20$  W per °C per m and per m<sup>2</sup>, approximately.

**Convection** Convection currents in liquids and gases (e.g. oil and air) are always produced near a heated surface unless baffled. Convection adds greatly to heat dissipation, especially if artificially stimulated (as in force cooling by fans). Experiment shows that a rough surface dissipates heat by convection more readily than a smooth one, and that high fluid speeds are essential to obtain turbulence as opposed to stream-line flow, the former being much more efficacious.

Convection is physically a very complex phenomenon, as it depends on small changes in buoyancy resulting from temperature rise due to heating. Formulae for dissipation of heat by convection have a strongly empirical basis, the form and orientation of the convection surfaces having considerable influence.

**Cooling coefficient** For electrical purposes the empirically derived coefficient of emission  $\lambda$ , or its reciprocal  $1/\lambda$ , are employed for calculations on cooling and temperature rise of wires, resistors, machines and similar plant.

### 2.2.2.3 Measurement of temperature rise

The temperature rise of a device developing heat can be measured (a) by a thermometer placed in contact with the surface whose temperature is required, (b) by resistance-temperature detectors or thermocouples on the surface of, or embedded in, the device, or (c) by the measurement of resistance (in the case of conducting circuits), using the known resistance-temperature coefficient. These methods measure different temperatures, and do not give merely alternative estimates of the same thing.

### 2.2.2.4 Heating and cooling cycles

In some cases a device (such as a machine or one of its parts) developing internal heat may be considered as sufficiently homogeneous to apply the exponential law. Suppose the device to have a temperature rise  $\theta$  after the lapse of a time  $t$ . In an element of time  $dt$  a small temperature rise  $d\theta$  takes place. The heat developed is  $p \cdot dt$ , the heat stored is  $Gh \cdot d\theta$ , and the heat dissipated is  $A\theta \lambda \cdot dt$ . Since the heat stored and dissipated together equal the total heat produced,

$$Gh \cdot d\theta + A\theta \lambda \cdot dt = p \cdot dt$$

the solution of which is

$$\theta = \theta_m [1 - \exp(-t/\tau)]$$

where  $\theta_m$  is the final steady temperature rise, calculated from  $\theta_m = p/A\lambda$ , and  $\tau = Gh/A\lambda$  is called the *heating time constant*. For the lapse of time  $t$  equal to the time constant

$$\theta = \theta_m [1 - \exp(-1)] = 0.632\theta_m$$

When a heated body cools owing to a reduction or cessation of internal heat production, the temperature-time relation is the exponential function

$$\theta = \theta_m \exp(-t/\tau_1)$$

where  $\tau_1$  is the *cooling time constant*, not necessarily the same as that for heating conditions.

Both heating and cooling as described are examples of *thermal transients*, and the laws governing them are closely analogous to those concerned with transient electric currents, in which exponential time relations also occur.

### 2.2.2.5 Fusing currents

For a given diameter  $d$ , the heat developed by a wire carrying a current  $I$  is inversely proportional to  $d^3$ , because an increase of diameter reduces the current density in proportion to the increase of area, and the emitting surface is increased in proportion to the diameter. The temperature rise is consequently proportional to  $I^2/d^3$ . If the temperature is raised to the fusing or melting point,  $\theta = t^2/d^3$  and the fusing current is

$$I = \sqrt{(\theta d^3/a)} = k d^{3/2}$$

This is *Preece's law*, from which an estimate may be made of the fusing current of a wire of given diameter, provided that  $k$  is known. The exponent  $3/2$  and the value of  $k$  are both much affected by enclosure, conduction of heat by terminals, and similar physical conditions.

It is obvious that any rule regarding suitable current densities giving a value regardless of the diameter is likely to be uneconomically low for small wires and excessive for large ones. Further, the effects of length and enclosure make a direct application of Preece's law unreliable. For small wires the exponent  $x$  in the term  $d^x$  may be 1.25-1.5, and for larger wires it may exceed 1.5.

### 2.2.2.6 Thermo-e.m.f.s

An effect known as the *thermoelectric effect* or *Seebeck effect* is that by which an e.m.f. is developed due to a difference of temperature between two junctions of dissimilar conductors in the same circuit. The *Thomson effect* or *Kelvin effect* is (a) that an e.m.f. is developed due to a difference of temperature between two parts of the same conductor, and (b) that an absorption or liberation of heat takes place when a current flows from a hotter to a colder part of the same material. The *Peltier effect* describes the liberation or absorption of heat at a joint where current passes from one material to another, whereby the joint becomes heated or cooled.

In Figure 2.6(a)-(c) the symbols are absolute temperature  $T$ , thermo-e.m.f.  $E$  and rate of heat production or absorption  $Q$ . The *Seebeck coefficient* ( $a$ ) is the e.m.f. per degree difference between hot and cold junctions:

$$\alpha_s = E/\Delta T$$

Figure 2.6 Thermo-e.m.f.

Typical e.m.f.s for a number of common junctions are given in Table 2.3. In the Peltier effect (b) a rate of heat generation (reversible, and distinct from the irreversible  $I^2R$  heat) results from the passage of a current  $i$  through the different conductors A and B. The *Peltier coefficient* is

$$\alpha_P = \mathcal{Q}/i$$

The Thomson effect (c) concerns the rate of reversible heat when a current  $i$  flows through a length of homogeneous conductor across which there is a temperature difference. The *Thomson coefficient* is

$$\alpha_T = \Delta \mathcal{Q}/i \cdot \Delta T$$

The relation between the Seebeck and Peltier coefficients is important: it is

$$\alpha_S = \alpha_P/T$$

The Seebeck coefficient is the more easily measured, but the Peltier coefficient determines the cooling effect of a thermoelectric refrigerator.

**Table 2.3** Thermocouple e.m.f.s (mV): cold junction at 0 °C

Hot-junction temperature (°C)	Platinum/ <sup>87</sup> Pt – <sup>13</sup> Rh	Chromel/ Alumel	Iron/ Eureka	Copper/ Eureka
100	0.65	4.1	5	4
200	1.46	8.1	11	9
400	3.40	16.4	22	21

### 2.2.2.7 Thermoelectric devices

If a current flows through a thermocouple (Figure 2.6(b)), with one junction in thermal contact with a heat sink, the other removes heat from a source. The couple must comprise conductors with positive and negative Seebeck coefficients, respectively. The arrangement is a *refrigerator* with the practical advantages of simplicity and silence.

A heat source applied to a junction develops an e.m.f. that will circulate a current in an external load (Figure 2.6(d)). If semiconductors of low thermal conductivity are used in place of metals for the couple elements, a better efficiency is obtainable because heat loss by conduction is reduced. The couples in Figure 2.7(a) of a thermoelectric power generator are constructed with p- and n-type materials. The efficiency, limited by Carnot cycle considerations, does not at present exceed 10 %.

A thermocouple generator in which one element is an electron stream or plasma is the *thermionic generator*, in effect a diode with flat cathode and anode very close together. By virtue of their kinetic energy, electrons emitted from the cathode reach the anode against a small, negative anode potential, providing current for an external circuit (Figure 2.7(b)). The work function of the anode material must be less

**Figure 2.7** Thermoelectric devices

than for the cathode. The device is a heat engine operating over the cathode–anode temperature fall, with electrons providing the ‘working fluid’.

Outputs of 2 kW/m<sup>2</sup> at an efficiency of 25 % may be reached when the device has been fully developed and the space charge effects overcome. Cathode heating by solar energy is a possibility.

## 2.3 Electrochemical effects

### 2.3.1 Electrolysis

If a liquid conductor undergoes chemical changes when a current is passed through it, the effect is ascribed to the movement of constituent parts of the molecules of the liquid *electrolyte*, called *ions*, which have a positive or negative electric charge. Positive ions move towards the negative electrode (*cathode*) and negative ions to the positive electrode (*anode*). The ionic movement is the reason for the current conduction. Ions reaching the electrodes have their charges neutralised and may be subject to chemical change. Hydrogen and metal ions are electropositive: non-metals of the chlorine family (Cl, Br, I and F) and acid radicals (such as SO<sub>4</sub> and NO<sub>3</sub>) form negative ions in solution. As examples, hydrochloric acid, HCl, forms H<sup>+</sup> and Cl<sup>−</sup> ions; sulphuric acid forms 2H<sup>+</sup> and SO<sub>4</sub><sup>−</sup> ions; and sodium hydroxide, NaOH, yields Na<sup>+</sup> and OH<sup>−</sup> ions. The products of electrolysis depend on the nature of the electrolyte. Basic solutions of sodium or similar hydroxides produce H<sub>2</sub> and O<sub>2</sub> gases at the cathode and anode, respectively. Acid solutions give products depending on the nature of the electrodes. Solutions of metal salts with appropriate electrodes result in electrodeposition.

The mass of the ion of an element of radical deposited on, dissolved from or set free at either electrode is proportional to the quantity of electricity passed through the electrolytic cell and to the ionic weight of the material, and inversely proportional to the valency of the ion; whence the mass  $m_e$  in kilogram-equivalents is the product ( $z$  in kilogram-equivalents per coulomb)  $\times \mathcal{Q}$  in coulombs. The value of  $z$  is a natural constant 0.001 036. Representative figures (for convenience in milligrams per coulomb) are given in Table 2.4.

To pass a current through an electrolyte, a p.d. must be applied to the electrodes to overcome the drop in resistance of the electrolyte, and to overcome the e.m.f. of *polarisation*. The latter is due to a drop across a thin film of gas, or through a strong ionic concentration, at an electrode.

Every chemical reaction may be represented as two electrode reactions. The algebraic p.d. between the two is a measure of the reactivity. A highly negative p.d. represents a spontaneous reaction that might be utilised to generate a current. A high positive p.d. represents a reaction requiring an external applied p.d. to maintain it.

#### 2.3.1.1 Uses of electrolysis

Ores of copper, zinc and cadmium may be electrolytically treated with sulphuric acid to deposit the metal. Copper may be deposited by use of a low voltage at the cathode, while oxygen is emitted at the anode. Electrorefining by deposition may be employed with copper, nickel, tin, silver, etc., produced by smelting or electrowinning, by using the impure metal as anode, which is dissolved away and redeposited on the cathode, leaving at the bottom of the cell the impurities in the form of sludge. Electroplating is similar to electrorefining except that pure metal or alloy is used as the anode.

**Table 2.4** Electrochemical equivalents  $z$  (mg/C)

## 2.3.2 Cells

### 2.3.2.1 Primary cells

An elementary cell comprising electrodes of copper (positive) and zinc (negative) in sulphuric acid develops a p.d. between copper and zinc. If a circuit is completed between the electrodes, a current will flow, which acts in the electrolyte to decompose the acid, and causes a production of hydrogen gas round the copper, setting up an e.m.f. of polarisation in opposition to the original cell e.m.f. The latter therefore falls considerably. In practical primary cells the effect is avoided by the use of a *depolariser*. The most widely used primary cell is the Leclanché. It comprises a zinc and a carbon electrode in a solution of ammonium chloride,  $\text{NH}_4\text{Cl}$ . When current flows, zinc chloride,  $\text{ZnCl}_2$ , is formed, releasing electrical energy. The  $\text{NH}_4$  positive ions travel to the carbon electrode (positive), which is packed in a mixture of manganese dioxide and carbon as depolariser. The  $\text{NH}_4$  ions are split up into  $\text{NH}_3$  (ammonia gas) and  $\text{H}$ , which is oxidised by the  $\text{MnO}_2$  to become water. The removal of the hydrogen prevents polarisation, provided that the current taken from the cell is small and intermittent.

The *wet* form of Leclanché cell is not portable. The *dry* cell has a paste electrolyte and is suitable for continuous moderate discharge rates. It is exhausted by use or by ageing and drying up of the paste. The 'shelf life' is limited. The *inert* cell is very similar in construction to the dry cell, but is assembled in the dry state, and is activated when required by moistening the active materials. In each case the cell e.m.f. is about 1.5 V.

### 2.3.2.2 Standard cell

The Weston normal cell has a positive element of mercury, a negative element of cadmium, and an electrolyte of cadmium sulphate with mercurous sulphate as depolariser. The open-

circuit e.m.f. at 20°C is about 1.018 30 V, and the e.m.f./temperature coefficient is of the order of  $-0.04 \text{ mV}/^\circ\text{C}$ .

### 2.3.2.3 Secondary cells

In the *lead-acid* storage cell or accumulator, lead peroxide reacts with sulphuric acid to produce a positive charge at the anode. At the cathode metallic lead reacts with the acid to produce a negative charge. The lead at both electrodes combines with the sulphate ions to produce the poorly soluble lead sulphate. The action is described as

Both electrode reactions are reversible, so that the initial conditions may be restored by means of a 'charging current'.

In the *alkaline* cell, nickel hydrate replaces lead peroxide at the anode, and either iron or cadmium replaces lead at the cathode. The electrolyte is potassium hydroxide. The reactions are complex, but the following gives a general indication:

### 2.3.2.4 Fuel cell

Whereas a storage battery cell contains all the substances in the electrochemical oxidation-reduction reactions involved and has, therefore, a limited capacity, a fuel cell is supplied with its reactants externally and operates continuously as long as it is supplied with fuel. A practical fuel cell for direct conversion into electrical energy is the hydrogen-oxygen cell (Figure 2.8). Microporous electrodes serve to bring the gases into intimate contact with the electrolyte (potassium hydroxide) and to provide the cell terminals. The hydrogen and oxygen reactants are fed continuously into the cell from externally, and electrical energy is available on demand.

At the fuel ( $\text{H}_2$ ) electrode,  $\text{H}_2$  molecules split into hydrogen atoms in the presence of a catalyst, and these combine with  $\text{OH}^-$  ions from the electrolyte, forming  $\text{H}_2\text{O}$  and releasing electrons  $e$ . At the oxygen electrode, the oxygen molecules ( $\text{O}_2$ ) combine (also in the presence of a catalyst) with water molecules from the electrolyte and with pairs of electrons arriving at the electrode through the external load from the fuel electrode. Peroxydyl ions ( $\text{O}_2\text{H}^-$ ) and hydroxyl ions ( $\text{OH}^-$ ) are produced: the latter enter the electrolyte, while the more resistant  $\text{O}_2\text{H}^-$  ions, with special catalysts, can be

**Figure 2.8** Fuel cell

reduced to  $\text{OH}^-$  ions and oxygen. The overall process can be summarised as:

In a complete reaction 2 kg hydrogen and 16 kg oxygen combine chemically (not explosively) to form 18 kg of water with the release of 400 MJ of electrical energy. For each kiloamp/hour the cell produces 0.33 l of water, which must not be allowed unduly to weaken the electrolyte. The open-circuit e.m.f. is 1.1 V, while the terminal voltage is about 0.9 V, with a delivery of 1 kA/m<sup>2</sup> of plate area.

## 2.4 Magnetic field effects

The space surrounding permanent magnets and electric circuits carrying currents attains a peculiar state in which a number of phenomena occur. The state is described by saying that the space is threaded by a *magnetic field of flux*. The field is mapped by an arrangement of *lines of induction* giving the strength and direction of the flux. Figure 2.9 gives a rough indication of the flux pattern for three simple cases of magnetic field due to a current. The diagrams show the conventions of polarity, direction of flux and direction of current adopted. Magnetic lines of induction form closed loops in a *magnetic circuit* linked by the circuit current wholly or in part.

### 2.4.1 Magnetic circuit

By analogy with the electric circuit, the magnetic flux produced by a given current in a magnetic circuit is found from the magnetomotive force (m.m.f.) and the circuit reluctance. The m.m.f. produced by a coil of  $N$  turns carrying a current  $I$  is  $F = NI$  ampere-turns. This is expended over any closed path linking the current  $I$ . At a given point in a magnetic field in free space the m.m.f. per unit length or magnetising force  $H$  gives rise to a magnetic flux density  $B_0 = \mu_0 H$ , where  $\mu_0 = 4\pi/10^7$ . If the medium in which the field exists has a relative permeability  $\mu_r$ , the flux density established is

$$B = \mu_r B_0 = \mu_r \mu_0 H = \mu H$$

The summation of  $H \cdot dl$  round any path linking an  $N$ -turn circuit carrying current  $I$  is the total m.m.f.  $F$ . If the distribution of  $H$  is known, the magnetic flux density  $B$  or  $B_0$  can be

Figure 2.9 Magnetic fields

Figure 2.10 Magnetic circuits

found for all points in the field, and a knowledge of the area  $a$  of the magnetic path gives  $\Phi = Ba$ , the total magnetic flux.

Only in a few cases of great geometrical simplicity can the flux due to a given system of currents be found precisely. Among these are the following.

*Long straight isolated wire* (Figure 2.10(a)): This is not strictly a realisable case, but the results are useful. Assume a current of 1 A. The m.m.f. around any closed linking path is therefore 1 A-t. Experiment shows that the magnetic field is symmetrical about, and concentric with, the axis of the wire. Around a closed path of radius  $x$  metres there will be a uniform distribution of m.m.f. so that

$$H = F/2\pi x = 1/2\pi x (\text{A-t/m}) \leftarrow$$

Consequently, in free space the flux density ( $T$ ) at radius  $x$  is

$$B_0 = \mu_0 H = \mu_0/2\pi x$$

In a medium of constant permeability  $\mu = \mu_r \mu_0$  the flux density is  $B = \mu_r B_0$ . There will be magnetic flux following closed circular paths within the cross-section of the wire itself: at any radius  $x$  the m.m.f. is  $F = (x/r)^2$  because the circular path links only that part of the (uniformly distributed) current within the path. The magnetising force is  $H = F/2\pi x = x/2\pi r^2$  and the corresponding flux density in a non-magnetic conductor is

$$B_0 = \mu_0 H = \mu_0 x/2\pi r^2$$

and  $\mu_r$  times as much if the conductor material has a relative permeability  $\mu_r$ . The expressions above are for a conductor current of 1 A.

*Concentric conductors* (Figure 2.10(b)): Here only the inner conductor contributes the magnetic flux in the space between the conductors and in itself, because all such flux can link only the inner current. The flux distribution is found exactly as in the previous case, but can now be summed in defined limits. If the outer conductor is sufficiently thin radially, the flux in the interconductor space, per metre axial length of the system, is

$$\Phi = \int_r^R \frac{\mu_0}{2\pi x} dx = \frac{\mu_0}{2\pi} \ln \frac{R}{r}$$

*Toroid* (Figure 2.10(c)): This represents the closest approach to a perfectly symmetrical magnetic circuit, in which the m.m.f. is distributed evenly round the magnetic path and the m.m.f. per metre  $H$  corresponds at all points exactly to the flux density existing at those points. The magnetic flux is therefore wholly confined to the path. Let the mean radius of

the toroid be  $R$  and its cross-sectional area be  $A$ . Then, with  $N$  uniformly distributed turns carrying a current  $I$  and a toroid core of permeability  $\mu$ ,

$$F = \mathcal{H}I; \quad H = F/2\pi R; \quad B = \mu H; \quad \Phi = \mathcal{H}FA/2\pi R$$

This applies approximately to a long solenoid of length  $l$ , replacing  $R$  by  $l/2\pi$ . The permeability will usually be  $\mu_0$ .

**Composite magnetic circuit containing iron (Figure 2.10(d)):** For simplicity practical composite magnetic circuits are arbitrarily divided into parts along which the flux density is deemed constant. For each part

$$F = \mathcal{H}l = Bl/\mu = B\Lambda/\mu A = \Phi S$$

where  $S = l/\mu A$  is the *reluctance*. Its reciprocal  $\Lambda = 1/S = \mu A/l$  is the *permeance*. The expression  $F = \Phi S$  resembles  $E = IR$  for a simple d.c. circuit and is therefore sometimes called the *magnetic Ohm's law*.

The total excitation for the magnetic circuit is

$$F = \mathcal{H}_1 l_1 + H_2 l_2 + H_3 l_3 + \dots \leftarrow$$

for a series of parts of length  $l_1, l_2, \dots$ , along which magnetic field intensities of  $H_1, H_2, \dots$  (A-t/m) are necessary. For free space, air and non-magnetic materials,  $\mu_r = 1$  and  $B_0 = \mu_0 H$ , so that  $H = B_0/\mu_0 \approx 800\,000\,B_0$ . This means that an excitation  $F = 800\,000\,A\text{-t}$  is required to establish unit magnetic flux density (1 T) over a length  $l = 1\text{ m}$ . For ferromagnetic materials it is usual to employ  $B$ - $H$  graphs (*magnetisation curves*) for the determination of the excitation required, because such materials exhibit a *saturation* phenomenon. Typical  $B$ - $H$  curves are given in Figures 2.11 and 2.12.

#### 2.4.1.1 Permeability

Certain *diamagnetic* materials have a relative permeability slightly less than that of vacuum. Thus, bismuth has  $\mu_r = 0.9999$ . Other materials have  $\mu_r$  slightly greater than unity: these are called *paramagnetic*. Iron, nickel, cobalt, steels, Heusler alloy (61% Cu, 27% Mn, 13% Al) and a number of others of great metallurgical interest have *ferromagnetic* properties, in which the flux density is not directly proportional to the magnetising force but which under suitable conditions are strongly magnetic. The more usual constructional materials employed in the magnetic circuits of electrical machinery may have peak permeabilities in the neighbourhood of 5000–10000. A group of nickel-iron alloys, including *mumetal* (73% Ni, 22% Fe, 5% Cu),

Figure 2.11 Magnetisation curves

Figure 2.12 Magnetisation and permeability curves

*permalloy 'C'* (77.4% Ni, 13.3% Fe, 3.7% Mo, 5% Cu) and *hypernik* (50% Ni, 50% Fe), show much higher permeabilities at low densities (Figure 2.12). Permeabilities depend on exact chemical composition, heat treatment, mechanical stress and temperature conditions, as well as on the flux density. Values of  $\mu_r$  exceeding  $5 \times 10^5$  can be achieved.

#### 2.4.1.2 Core losses

A ferromagnetic core subjected to cycles of magnetisation, whether alternating (reversing), rotating or pulsating, exhibits *hysteresis*. Figure 2.13 shows the cycle  $B$ - $H$  relation typical of this phenomenon. The significant quantities *remnant flux density* and *coercive force* are also shown. The area of the *hysteresis loop* figure is a measure of the energy loss in the cycle per unit volume of material. An empirical expression for the *hysteresis loss* in a core taken through  $f$  cycles of magnetisation per second is

$$p_h = k_h f B_m^x \text{ watts per unit mass or volume}$$

Here  $B_m$  is the maximum induction reached and  $k_h$  is the hysteresis constant depending on the molecular quality and structure of the core metal. The exponent  $x$  may lie between 1.5 and 2.3. It is often taken as 2.

A further cause of loss in the same circumstances is the *eddy current loss*, due to the  $I^2 R$  losses of induced currents. It can be shown to be

$$p_e = k_e t^2 F^2 B^2 \text{ watts per unit mass or volume}$$

the constant  $k_e$  depending on the resistivity of the metal and  $t$  being its thickness, the material being laminated to decrease the induced e.m.f. per lamina and to increase the resistance of the path in which the eddy currents flow. In practice, curves of loss per kilogram or per cubic metre for various flux densities are employed, the curves being constructed from the results of

Figure 2.13 Hysteresis

careful tests. It should be noted that hysteresis loss is dependent on the maximum flux density  $B_m$ , while the eddy current loss is a function of r.m.s. induced current and e.m.f., and therefore of the r.m.s. flux density  $B$ , and not the maximum density  $B_m$ .

### 2.4.1.3 Permanent magnets

Permanent magnets are made from heat-treated alloys, or from ferrites and rare earths, to give the material a large hysteresis loop. Figure 2.14 shows the demagnetisation  $B/H$  quadrant of the loop of a typical material. In use, a magnet produces magnetic energy in the remainder of the magnetic circuit derived from a measure of self-demagnetisation: consequently, the working point of the magnet is on the loop between the coercive force/zero flux point and the zero force/remnant flux point. Different parts of the magnet will work at different points on the loop, owing to leakage, and the conditions become much more complex if the reluctance of the external magnetic circuit fluctuates.

In designing a magnet it is necessary to allow for leakage by use of an m.m.f. allowance  $F_a$  (normally not more than 1.25) and a flux allowance  $\Phi_a$ , which may be anything from 2 to 20, being greater for a high ratio between gap length and gap section.

If  $H_g$  is the field strength in gap,  $l_g$  the gap length,  $A_g$  the gap section,  $B_m$  the working density in the magnet,  $H_m$  the working demagnetising field strength in the magnet,  $l_m$  the magnet length and  $A_m$  the magnet section, then it may be shown that

$$H_g = \sqrt{[(B_m H_m / F_a \Phi_a)(A_m l_m / A_g l_g)]} \leftarrow$$

i.e. it is greatest when  $B_m H_m$  is a maximum. This occurs for a working point at  $(BH)_{\max}$ . The magnet length and section must be proportioned to suit the alloy and the gap dimensions to secure the required condition. The section is  $A_m = (H_g A_g \Phi_a / B_m)$  and the length  $l_m = (H_g l_g F_a / H_m)$ . To calculate these the  $B_m$  and  $H_m$  values at the  $(BH)_{\max}$  point must be known. Alternatively, if the three points corresponding to the remanent flux density  $B_r$ , the  $(BH)_{\max}$  and the coercive force  $H_c$  are given, the working values can be calculated from

$$B_m = \sqrt{[(BH)_{\max} (B_r / H_c)]} \leftarrow \text{and } H_m = \sqrt{[(BH)_{\max} (H_c / B_r)]} \leftarrow$$

### 2.4.2 Magnetomechanical effects

Mechanical forces are developed in magnetic field systems in such a way that the resulting movement increases the flux linkage with the electric circuit, or lowers the m.m.f. required for a given flux. In the former case an increase of linkage requires more energy from the circuit, making mechanical energy available; in the latter, stored magnetic energy is released in mechanical form.

Systems in which magnetomechanical forces are developed are shown diagrammatically in Figure 2.15.

Figure 2.14 Ideal permanent magnet conditions

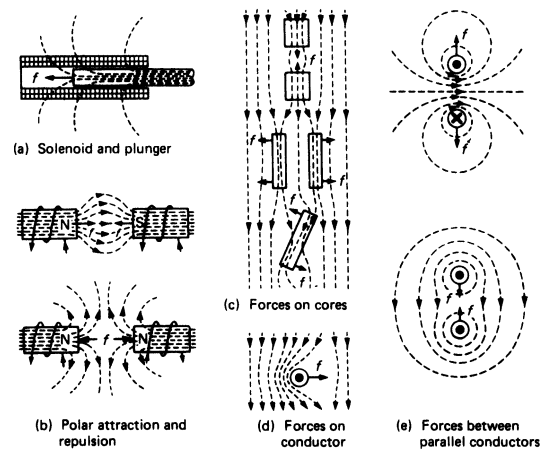

Figure 2.15 Magnetomechanical forces

(a) *Solenoid and magnetic core*: The core is drawn into the solenoid, increasing the magnetic flux and, in consequence, the circuit's flux linkages.

(b) *Attraction or repulsion of magnetised surfaces*: The attraction in (b) increases the flux by reducing the reluctance of the intergap. Repulsion gives more space for the opposing fluxes and again reduces the reluctance.

(c) *Forces on magnetic cores in a magnetic field*: Cores in line with the field attract each other, cores side by side repel each other, and a core out of line with the general field direction experiences a force tending to align it.

(d) *Electromagnetic force on current-carrying conductor*: A current-carrying conductor lying in an externally produced (or 'main') field tends to move so as to increase the flux on that side where its own field has the same direction as the main field.

(e) *Electromagnetic force between current-carrying conductors*: Two parallel conductors carrying currents in opposite directions repel, for in moving apart they provide a greater area for the flux between them. If carrying currents in the same direction, they attract, tending to provide a shorter path for the common flux.

It is worth noting as a guide to the behaviour of magnetic field problems (although not a physical explanation of that behaviour) that the forces observed are in directions such as would cause the flux lines to shorten their length and to expand laterally, as if they were stretched elastic threads.

The calculation of the force developed in the cases is based on the movement of the force-system by an amount  $dl$  and the amount of mechanical energy  $dW$  thereby absorbed or released. Then the force is

$$f = dW/dl$$

With energy in joules and displacement in metres, the force is given in newtons. The calculation is only directly possible in a few simple cases, as below. The references are to the diagrams in Figure 2.15.

*Case (c)*: The energy stored per cubic metre of a medium in which a magnetising force  $H$  produces a density  $B$  is  $\frac{1}{2}BH = \frac{1}{2}B^2/\mu_r\mu_0$  joules. At an iron surface in air, a movement of the surface into a space originally occupied by air results, for a constant density  $B$ , in a reduction of the energy per cubic metre from  $B^2/2\mu_0$  to  $B^2/2\mu_r\mu_0$ , since for air  $\mu_r = 1$ . The force must therefore be

$$f = \frac{B^2}{2\mu_0} \left(1 - \frac{1}{\mu_r}\right) \approx \frac{B^2}{2\mu_0} \text{ newtons per square metre}$$

the latter expression being sufficiently close when  $\mu_r \gg 1$ .

*Case (d):* This case is of particular importance, as it is the basic principle of normal motors and generators, and of moving-coil permanent magnet instruments. Consideration of the mechanical energy gives, for a current  $I$  of length  $l$  lying perpendicular to the main field, a force

$$f = BIl$$

where  $B$  is the flux density. The force, as indicated in *Figure 2.15(d)*, is at right angles to  $B$  and to  $I$ . Suppose the conductor to be moved in the direction of the force (either with it or against it): the work done in a displacement of  $x$  is

$$fx = W = BIlx = \Phi I \text{ joules}$$

where  $\Phi = Blx$  is the total flux cut across by the conductor.

### 2.4.3 Electromagnetic induction

A magnetic field is a store of energy. When it is increased or decreased, the amount of stored energy increases or decreases. Where the energy is obtained from, or restored to, an associated electric circuit, the energy delivered or received is in the form of a current flowing by reason of an *induced e.m.f.* for a time (specified by the conditions), these three being the essential associated quantities determining electrical energy. The relative directions of e.m.f. and current depend on the direction of energy flow. This is described by *Lenz's law* (*Figure 2.16*), which states that the direction of the e.m.f. induced by a change of linked magnetic field is such as would oppose the change if allowed to produce a current in the associated circuit.

*Faraday's law* states that the e.m.f. induced in a circuit by the linked magnetic field is proportional to the rate of change of flux linkage with time. The flux linkage is the summation of products of magnetic flux with the number of turns of the circuit linked by it. Then

$$e = -d\psi/dt = -\Sigma N(d\Phi/dt) \leftarrow$$

the negative sign being indicative of the direction of the e.m.f. as specified in Lenz's law.

Consider a circuit of  $N$  turns linked completely with a flux  $\Phi$ . The linkage  $\psi = N\Phi$  may change in a variety of ways.

- (1) Supposing the flux is constant in value, the circuit may move through the flux (relative motion of flux and circuit: the *motional* or *generator effect*).
- (2) Supposing the coil is stationary with reference to the magnetic path of the flux, the latter may vary in magnitude (flux pulsation: the *pulsational* or *transformer effect*).
- (3) Both changes may occur simultaneously (movement of coil through varying flux: combination of the effects in (1) and (2)).

The generator effect is associated with conversion of energy between the electrical and mechanical form, using an inter-

Figure 2.16 Faraday-Lenz law

mediate magnetic form; the transformer effect concerns the conversion of electrical energy into or from magnetic energy.

#### 2.4.3.1 Generator effect

In simplified terms applicable to heteropolar rotating electrical machines (*Figure 2.17*) the instantaneous e.m.f. due to rate of change of linkage resulting from the motion at speed  $u$  of an  $N$ -turn full-pitch coil of effective length  $l$  is  $e = 2NBlu$ , where  $B$  is the flux density in which the coil sides move at the instant considered.

On this expression as a basis, well-known formulae for the motional e.m.f.s of machines can be derived. For example, consider the arrangement (right) in *Figure 2.17*, where the flux density  $B$  is considered to be uniform; let the coil rotate at angular velocity  $\omega_r$  rad/s corresponding to a speed  $n = \omega_r/2\pi$  rev/s. Then the peripheral speed of the coil is  $u = \omega_r R$  if its radius is  $R$ . Let the coil occupy a position perpendicular to the flux axis when time  $t = 0$ . At  $t = \theta/\omega_r$  it will be in a position making the angle  $\theta$ . Its rate of moving across the flux is  $\omega_r R \sin \theta$ , and the instantaneous coil e.m.f. is

$$e = \omega_r RNB \sin \theta \neq \omega_r N\Phi_m \sin \theta \psi$$

where  $\Phi_m = 2BR$  is the maximum flux embraced, i.e. at  $\theta = 0$ . The e.m.f. is thus a sine function of frequency  $\omega_r/2\pi \psi$  and the values peak:

$$e_m = \omega_r N\Phi_m \text{ r.m.s.; } E = (1/\sqrt{2})\omega_r N\Phi_m$$

The same result is obtained by a direct application of the Faraday law. At  $t = 0$  the linked flux is  $\Phi_m$ ; at  $t = \theta/\omega_r$  it is  $\Phi_m \cos \theta = \Phi_m \cos \omega_r t$ . The instantaneous e.m.f. is

$$e = -d\psi/dt = -N\Phi_m d(\cos \omega_r t)/dt = \omega_r N\Phi_m \sin \theta \psi$$

as before.

#### 2.4.3.2 Transformer effect

The practical case concerns a coil of  $N$  turns embracing a varying flux  $\Phi$ . If the flux changes sinusoidally with time it can be expressed as

$$\Phi = \Phi_m \cos \omega t = \Phi_m \cos 2\pi ft$$

where  $\Phi_m$  is its time maximum value,  $f$  is its frequency, and  $\omega = 2\pi f$  is its angular frequency. The instantaneous e.m.f. in the coil is

$$e = -N(d\Phi/dt) = \omega N\Phi_m \sin \omega t$$

This relation forms the basis of the e.m.f. induced in transformers and induction motors. The e.m.f. and flux relationship is that of *Figures 2.16* and *2.21(c)*.

#### 2.4.3.3 Calculation of induced e.m.f.

The two methods of calculating electromagnetically induced e.m.f.s are: (1) the change-of-flux law, and (2) the flux-cutting law.

Figure 2.17 Motional e.m.f.

*Flux change:* This law has the basic form

$$e = -N(d\Phi/dt) \leftarrow$$

and is applicable where a circuit of constant shape links a changing magnetic flux.

*Flux cutting:* Where a conductor of length  $l$  moves at speed  $u$  at right angles to a uniform magnetic field of density  $B$ , the e.m.f. induced in the conductor is

$$e = Blu$$

This can be applied to the motion of conductors in constant magnetic fields and when sliding contacts are involved.

*Linkage change:* Where coils move in changing fluxes, and both flux-pulsation and flux-cutting processes occur, the general expression.

$$e = -d\psi/dt$$

must be used, with variation of the linkage expressed as the result of both processes.

#### 2.4.3.4 Constant linkage principle

The linkage of a *closed* circuit cannot be changed instantaneously, because this would imply an instantaneous change of associated magnetic energy, i.e. the momentary appearance of infinite power. It can be shown that the linkage of a closed circuit of *zero resistance* and no internal source cannot be changed at all. The latter concept is embodied in the following theorem.

*Constant linkage theorem* The linkage of a closed passive circuit of zero resistance is a constant. External attempts to change the linkage are opposed by induced currents that effectively prevent any net change of linkage.

The theorem is very helpful in dealing with transients in highly inductive circuits such as those of transformers, synchronous generators, etc.

#### 2.4.3.5 Ideal transformer

An ideal transformer comprises two resistanceless coils embracing a common magnetic circuit of infinite permeability and zero core loss (Figure 2.18). The coils produce no leakage flux: i.e. the whole flux of the magnetic circuit completely links both coils. When the primary coil is energised by an alternating voltage  $V_1$ , a corresponding flux of peak value  $\Phi_m$  is developed, inducing in the  $N_1$ -turn primary coil an e.m.f.  $E_1 = V_1$ . At the same time an e.m.f.  $E_2$  is induced in the  $N_2$ -turn secondary coil. If the terminals of the secondary coil are connected to a load taking a current  $I_2$ , the primary coil must accept a balancing current  $I_1$  such that  $I_1 N_1 = I_2 N_2$ , as the core requires zero excitation. The operating conditions are therefore

$$N_1/N_2 = E_1/E_2 = I_2/I_1; \quad \text{and} \quad E_1 I_1 = E_2 I_2$$

The secondary load impedance  $Z_2 = E_2/I_2$  is reflected into the primary to give the impedance  $Z_1 = E_1/I_1$  such that

Figure 2.18 Ideal transformer

$$Z_1 = (N_1/N_2)^2 Z_2$$

A practical power transformer differs from the ideal in that its core is not infinitely permeable and demands an excitation  $N_1 I_0 = N_1 I_1 - N_2 I_2$ ; the primary and secondary coils have both resistance and magnetic leakage; and core losses occur. By treating these effects separately, a practical transformer may be considered as an ideal transformer connected into an external network to account for the defects.

#### 2.4.3.6 Electromagnetic machines

An electromagnetic machine links an electrical energy system to a mechanical one, by providing a reversible means of energy flow between them in the common or 'mutual' magnetic flux linking stator and rotor. Energy is stored in the field and released as work. A current-carrying conductor in the field is subjected to a mechanical force and, in moving, does work and generates a counter e.m.f. Thus the force-motion product is converted to or from the voltage-current product representing electrical power.

The energy-rate balance equations relating the mechanical power  $p_e$ , and the energy stored in the magnetic field  $w_f$ , are:

$$\text{Motor: } p_e = p_m = dw_f/dt$$

$$\text{Generator: } p_m = p_e + dw_f/dt$$

The mechanical power term must account for changes in stored kinetic energy, which occur whenever the speed of the machine and its coupled mechanical loads alter.

*Reluctance motors* The force between magnetised surfaces (Figure 2.15(b)) can be applied to rotary machines (Figure 2.19(a)). The armature tends to align itself with the field axis, developing a *reluctance torque*. The principle is applied to miniature rotating-contact d.c. motors and synchronous clock motors.

*Machines with armature windings* Consider a machine rotating with constant angular velocity  $\omega_r$  and developing a torque  $M$ . The mechanical power is  $p_m = M\omega_r$ ; the electrical power is  $p_e = ei$ , where  $e$  is the counter e.m.f. due to the reaction of the mutual magnetic field. Then  $ei = M\omega_r + dw_f/dt$  at every instant. If the armature conductor  $a$  in Figure 2.19(b) is running in a non-time-varying flux of local density  $B$ , the e.m.f. is entirely rotational and equal to  $e_r = Blu = B\omega_r R$ . The tangential force on the conductor is  $f = Bi$  and the torque is  $M = BliR$ . Thus,  $e_r i = M\omega_r$  because  $dw_f/dt = 0$ . This case applies to constant flux (d.c., three-phase synchronous and induction) machines.

If the armature in Figure 2.19(b) is given two conductors  $a$  and  $b$  they can be connected to form a turn. Provided the turn is of full pitch, the torques will always be additive. More turns in series form a winding. The total flux in the machine results from the m.m.f.s of all current-carrying conductors, whether on stator or rotor, but the torque arises from that component of the total flux at right angles to the m.m.f. axis of the armature winding.

Armature windings (Figure 2.19(c)) may be of the commutator or phase (tapped) types. The former is closed on itself, and current is led into and out of the winding by fixed brushes which include between them a constant number of conductors in each armature current path. The armature m.m.f. coincides always with the brush axis. Phase windings have separate external connections. If the winding is on the rotor, its current and m.m.f. rotate with it and the external connections must be made through slip-rings. Two (or three) such windings with two-phase (or three-phase) currents can produce a resultant m.m.f. that rotates with respect to the windings.

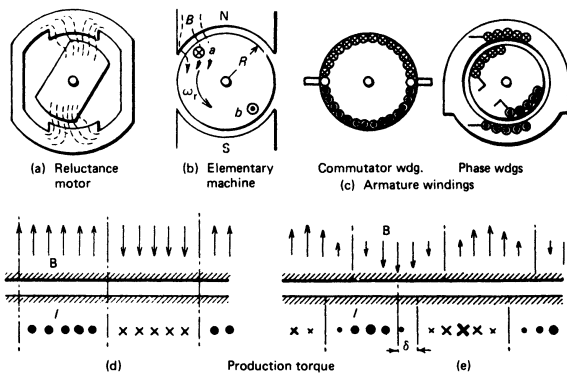

Figure 2.19 Electromagnetic machines

**Torque** Figure 2.19(d) shows a commutator winding arranged for maximum torque: i.e. the m.m.f. axis of the winding is displaced electrically  $\pi/2$  from the field pole centres. If the armature has a radius  $R$  and a core length  $l$ , the flux has a constant uniform density  $B$ , and there are  $Z$  conductors in the  $2p$  pole pitches each carrying the current  $I$ , the torque is  $BRlIZ/2p$ . This applies to a d.c. machine. It also gives the mean torque of a single-phase commutator machine if  $B$  and  $I$  are r.m.s. values and the factor  $\cos \phi \psi$  introduced for any time phase angle between them.

The torque of a phase winding can be derived from Figure 2.19(e). The flux density is assumed to be distributed sinusoidally, and reckoned from the pole centre to be  $B_m \cos \alpha$ . The current in the phase winding produces the m.m.f.  $F_a$ , having an axis displaced by angle  $\delta\psi$  from the pole centre. The total torque is then

$$M = \pi B_m F_a l R \sin \delta\psi = \frac{1}{2} \pi \Phi F_a \sin \delta\psi$$

per pole pair. This case applies directly to the three-phase synchronous and induction machines.

**Types of machine** For unidirectional torque, the axes of the pole centres and armature m.m.f. must remain fixed relative to one another. Maximum torque is obtained if these axes are at right angles. The machine is technically better if the field flux and armature m.m.f. do not fluctuate with time (i.e. they are d.c. values): if they do alternate, it is preferable that they be co-phased.

Workable machines can be built with (1) concentrated ('field') or (2) phase windings on one member, with (A) commutator or (B) phase windings on the other. It is basically immaterial which function is assigned to stator and which to rotor, but for practical convenience a commutator winding normally rotates. The list of chief types below gives the type of winding (1, 2, A, B) and current supply (d or a), with the stator first:

**D.C. machine, 1d/Ad:** The arrangement is that of Figure 2.19(d). A commutator and brushes are necessary for the rotor.

**Single-phase commutator machine, 1a/Aa:** The physical arrangement is the same as that of the d.c. machine. The field flux alternates, so that the rotor m.m.f. must also alternate at the same frequency and preferably in time phase. Series connection of stator and rotor gives this condition.

**Synchronous machine, Ba/1d:** The rotor carries a concentrated d.c. winding, so the rotor m.m.f. must rotate with it at corresponding (synchronous) speed, requiring a.c. (normally three-phase) supply. The machine may be inverted (1d/Ba).

**Induction machine, 2a/Ba (Figure 2.19(e)):** The polyphase stator winding produces a rotating field of angular velocity  $\omega_1$ . The rotor runs with a slip  $s$ , i.e. at a speed  $\omega_1(1-s)$ . The torque is maintained unidirectional by currents induced in the rotor winding at frequency  $s\omega_1$ . With d.c. supplied to the rotor (2a/Bd) the rotor m.m.f. is fixed relatively to the windings and unidirectional torque is maintained only at synchronous speed ( $s=0$ ).

All electromagnetic machines are variants of the above.

#### 2.4.3.7 Magnetohydrodynamic generator

Magnetohydrodynamics (m.h.d.) concerns the interaction between a conducting fluid in motion and a magnetic field. If a fast-moving gas at high temperature (and therefore ionised) passes across a magnetic field, an electric field is developed across the gaseous stream exactly as if it were a metallic conductor, in accordance with Faraday's law. The electric field gives rise to a p.d. between electrodes flanking the stream, and a current may be made to flow in an external circuit connected to the electrodes. The m.h.d. generator offers a direct conversion between heat and electrical energy.

#### 2.4.3.8 Hall effect

If a flat conductor carrying a current  $I$  is placed in a magnetic field of density  $B$  in a direction normal to it (Figure 2.20), then an electric field is set up across the width of the conductor. This is the Hall effect, the generation of an e.m.f. by the movement of conduction electrons through the magnetic field. The Hall e.m.f. (normally a few microvolts) is picked off by tappings applied to the conductor edges, for the measurement of  $I$  or for indication of high-frequency powers.

### 2.4.4 Inductance

The e.m.f. induced in an electric circuit by change of flux linkage may be the result of changing the circuit's own current. A magnetic field always links a current-carrying circuit, and the linkage is (under certain restrictions) proportional to the current. When the current changes, the linkage also changes and an e.m.f. called the *e.m.f. of self-induction* is induced. If the linkage due to a current  $i$  in the circuit is  $\Phi N = Li$ , the e.m.f. induced by a change of current is

$$e = -d\psi/dt = -N(d\Phi/dt) = -L(di/dt) \Leftarrow$$

$L$  is a coefficient giving the linkage per ampere: it is called the *coefficient of self-induction*, or, more usually, the *inductance*. The unit is the henry, and in consequence of its relation to linkage, induced e.m.f., and stored magnetic energy, it can be defined as follows.

A circuit has unit inductance (1 H) if: (a) the energy stored in the associated magnetic field is  $\frac{1}{2}$  J when the current is 1 A; (b) the induced e.m.f. is 1 V when the current is changed at

Figure 2.20 Hall effect

the rate 1 A/s; or (c) the flux linkage is 1 Wb-t when the current is 1 A.

#### 2.4.4.1 Voltage applied to an inductor

Let an inductor (i.e. an inductive coil or circuit) devoid of resistance and capacitance be connected to a supply of constant potential difference  $V$ , and let the inductance be  $L$ . By definition (b) above, a current will be initiated, growing at such a rate that the e.m.f. induced will counterbalance the applied voltage  $V$ . The current must rise uniformly at  $V/L$  amperes per second, as shown in Figure 2.21(a), so long as the applied p.d. is maintained. Simultaneously the circuit develops a growing linked flux and stores a growing amount of magnetic energy. After a time  $t_1$  the current reaches  $I_1 = (V/L)t_1$ , and has absorbed a store of energy at voltage  $V$  and average current  $I_1/2$ , i.e.

$$W_1 = V \cdot \frac{1}{2} I_1 \cdot t_1 = \frac{1}{2} V I_1 t_1 = \frac{1}{2} L I_1^2 \text{ joules}$$

since  $V = I_1 L / t_1$ . If now the supply is removed but the circuit remains closed, there is no way of converting the stored energy, which remains constant. The current therefore continues to circulate indefinitely at value  $I_1$ .

Suppose that  $V$  is applied for a time  $t_1$ , then reversed for an equal time interval, and so on, repeatedly. The resulting current is shown in Figure 2.21(b). During the first period  $t_1$  the current rises uniformly to  $I_1 = (V/L)t_1$  and the stored energy is then  $\frac{1}{2} L I_1^2$ . On reversing the applied voltage the current performs the same rate of change, but negatively so as to reduce the current magnitude. After  $t_1$  it is zero and so is the stored energy, which has all been returned to the supply from which it came.

If the applied voltage is sinusoidal and alternates at frequency  $f$ , such that  $v = v_m \cos 2\pi f t = v_m \cos \omega t$ , and is switched on at instant  $t = 0$  when  $v = v_m$ , the current begins to rise at rate  $v_m/L$  (Figure 2.21(c)); but the immediate reduction and subsequent reversal of the applied voltage require corresponding changes in the rate of rise or fall of the current. As  $v = L(di/dt)$  at every instant, the current is therefore

$$i = \int \frac{v}{L} dt = \frac{v_m}{\omega L} \sin \omega t$$

The peak current reached is  $i_m = v_m/\omega L$  and the r.m.s. current is  $I = V/\omega L = V/X_L$ , where  $X_L = \omega L = 2\pi f L$  is the inductive reactance.

Figure 2.21 Voltage applied to a pure inductor

Should the applied voltage be switched on at a voltage zero (Figure 2.21(d)), the application of the same argument results in a sine-shaped current, unidirectional but pulsating, reaching the peak value  $2i_m = 2v_m/\omega L$ , or twice that in the symmetrical case above. This is termed the *doubling effect*. Compare with Figure 2.21(b).

#### 2.4.4.2 Calculation of inductance

To calculate inductance in a given case (a problem capable of reasonably exact solution only in cases of considerable geometrical simplicity), the approach is from the standpoint of definition (c). The calculation involves estimating the magnetic field produced by a current of 1 A, summing the linkage  $\Phi N$  produced by this field with the circuit, and writing the inductance as  $L = \Sigma \Phi N$ . The cases illustrated in Figure 2.10 and 2.22 give the following results.

**Long straight isolated conductor (Figure 2.10(a))** The magnetising force in a circular path concentric with the conductor and of radius  $x$  is  $H = I/2\pi x = 1/2\pi x$ ; this gives rise to a circuit flux density  $B_0 = \mu_0 H = \mu_0/2\pi x$ . Summing the linkage from the radius  $r$  of the conductor to a distance  $s$  gives

$$= (\mu_0/2\pi) \ln(s/r) \text{ weber-turn per metre of conductor length.}$$

If  $s$  is infinite, so is the linkage and therefore the inductance: but in practice it is not possible so to isolate the conductor.

There is a magnetic flux following closed circular paths within the conductor, the density being  $B_i = \mu x/2\pi r^2$  at radius  $x$ . The effective linkage is the product of the flux by that proportion of the conductor actually enclosed, giving  $\mu/8\pi$  henry/metre length. It follows that the internal linkage produces a contribution  $L_i = \mu/8\pi$  henry/metre, regardless of the conductor diameter on the assumption that the current is uniformly distributed. The absolute permeability  $\mu$  of the conductor material has a considerable effect on the internal inductance.

**Concentric cylindrical conductors (Figure 2.10(b))** The inductance of a metre length of concentric cable carrying equal currents oppositely directed in the two parts is due to the flux in the space between the central and the tubular conductor set up by the inner current alone, since the current in the outer conductor cannot set up internal flux. Summing the linkages and adding the internal linkage of the inner conductor:

$$L = (\mu/8\pi) + (\mu_0/2\pi) \ln(R/r) \text{ henry/metre}$$

**Parallel conductors (Figure 2.22)** Between two conductors (a) carrying the same current in opposite directions, the linkage is found by summing the flux produced by conductor

Figure 2.22 Parallel conductors

A in the space  $a$  assuming conductor B to be absent, and doubling the result. Provided that  $a \gg r$ , this gives for the loop

$$L = (\mu/4\pi) + (\mu_0/\pi) \ln(a/r) \text{ henry/metre}$$

It is permissible to regard one-half of the linkage as associated with each conductor, to give for each the *line-to-neutral* inductance

$$L_0 = (\mu/8\pi) + (\mu_0/2\pi) \ln(a/r) \Leftarrow$$

A three-phase line (b) has the same line-to-neutral inductance if the conductors are symmetrically spaced. If, however, the spacing is asymmetric but the conductors are cyclically transposed (c), the expression applies with  $a = \sqrt[3]{(a_1 a_2 a_3)}$ , the geometric mean spacing.

**Toroid** (Figure 2.10(c)) For a core of permeability  $\mu$ , the inductance is

$$L = \mu N^2 A / 2\pi R = \mu N^2 A / l \text{ henry}$$

where  $l = 2\pi R$  is the mean circumference and  $A$  is the effective cross-sectional area of the core.

**Solenoid** A solenoid having a ratio length/diameter of at least 20 has an inductance approximating to that of the toroid above. A short solenoidal coil of overall diameter  $D$ , length  $l$ , radial thickness  $d$ , and  $N$  turns has an inductance given approximately by

$$L = \frac{6.4\mu_0 N^2 D^2}{3.5D + 8l} \cdot \frac{D - 2.25d}{D}$$

For the best ratio of inductance to resistance,  $l = d$ , giving a square winding cross-section, and  $D = 4.7d$ . Then  $L = (0.8 \times 10^{-6}) N^2 D$ .

**Inductor with ferromagnetic circuit** (Figure 2.10(d))

Saturation makes it necessary to obtain the m.m.f.  $F$  for a series of magnetic circuit fluxes  $\Phi$ . Then with an  $N$ -turn exciting coil the inductance is  $L = N\Phi/I$ , where  $I = F/N$ . Thus,  $L$  is a function of  $I$ , decreasing with increase of current. The variation can be mitigated by the inclusion in the magnetic circuit of an air gap to 'stiffen' the flux.

#### 2.4.4.3 Mutual inductance

If two coils (primary and secondary) are so oriented that the flux developed by a current in one links the other, the two have mutual inductance. The pair have unit mutual inductance (1 H) if: (a) the energy stored in the common magnetic field is 1 J when the current in each circuit is 1 A; or (b) the e.m.f. induced in one is 1 V when the current in the other changes at the rate 1 A/s, or (c) the secondary linkage is 1 Wb-t when the primary current is 1 A.

Figure 2.23 Mutual inductance

Figure 2.23(a) shows two coils on a common magnetic circuit: it is assumed that all the flux due to a primary current also links the secondary (a condition approached in a transformer). Let 1 A in the two-turn primary produce 2 Wb. The primary self-inductance is consequently  $L_1 = 2 \times 2 = 4$  Wb-t/A = 4 H. The secondary linkage is  $4 \times 2 = 8$  Wb-t, so that the mutual inductance is  $L_{21} = 8$  H. Let now a current of 1 A circulate instead in the secondary (b): it develops double the m.m.f. of that developed by the primary in (a) and twice the flux, i.e. 4 Wb. The self-inductance is  $L_2 = 4 \times 4 = 16$  H. The primary linkage is  $2 \times 4 = 8$ , i.e.  $L_{12} = 8$  H. Thus,  $L_{12} = L_{21}$ .

In Figure 2.23(c) the coils are connected in *series aiding*. With a current of 1 A, the total m.m.f. is  $2 + 4 = 6$ , the common flux is 6 Wb and the total inductance is  $6 \times 6 = 36$  H, which can be shown to be

$$L = L_1 + L_2 + L_{12} + L_{21} = 4 + 16 + 2(8) = 36 \text{ H}$$

For the *series opposing* connection (d) the m.m.f.s oppose with a net value  $4 - 2 = 2$ , and the resulting flux is 2 Wb. The linkages oppose, amounting to  $(4 \times 2) - (2 \times 2) = 4$ . The total inductance is 4 H, obtained by

$$L = L_1 + L_2 - L_{12} - L_{21} = 4 + 16 - 2(8) = 4 \text{ H}$$

The example shows that  $L_{12} = L_{21} = \sqrt{(L_1 L_2)}$ . Normally the linkages are less complete, and the ratio  $L_{12}/\sqrt{(L_1 L_2)} = k$ , the *coefficient of coupling*.

#### 2.4.4.4 Connection of inductors

In the absence of mutual inductance, the total inductance of a circuit consisting of inductors  $L_1, L_2, \dots$ , is  $L = L_1 + L_2 + \dots$ , if they are in series, and  $L = 1/[1/(L_1) + 1/(L_2) + \dots]$  if they are in parallel. When there is mutual inductance, it is necessary to set up a circuit equation including the mutual inductance coefficients  $L_{12}, L_{13}, L_{23}, \dots$ . For two inductors the inductance, as already discussed, is

$$L = L_1 + L_2 \pm 2L_{12}$$

With coils associated on a common ferromagnetic circuit,  $L_{12}$  may differ from  $L_{21}$  because of saturation effects.

## 2.5 Electric field effects

When two conductors are separated by a dielectric medium and are maintained at a potential difference, an electric field exists between them. Consider two such conductors A and B (Figure 2.24): the application of a p.d. causes a transfer of conduction electrons from A to B, leaving A positive and making B negative, and setting up the electric field

Figure 2.24 Capacitor charge and discharge

(Figure 2.24(a)). The positive charge on A prevents more than a given number of electrons leaving this conductor, depending on the p.d., the size and configuration, and the spacing. Similarly, the surplus of electrons on B repels others arriving, so that here, too, an equilibrium is established. If, as in (b), the spacing is reduced, a further electron transfer takes place until equilibrium is again reached; the charge and the electric field have been intensified by the increase in *capacitance*. If now the switch is opened, the charge, p.d. and field remain as a store of electric field energy (c). Let the supply be removed (d) and the switch closed through a resistor; the charges on the conductors are dissipated by an electron current from B to A, and the field energy is converted into heat in the resistor.

### 2.5.1 Electrostatics

The lines used to depict the pattern of an electric field begin on a positive charge and terminate on an equal negative one. Two similar point charges of  $q_1$  and  $q_2$  coulombs, spaced  $d$  metres apart in free space (or air) develop a force

$$f = q_1 q_2 / 4\pi\epsilon_0 d^2 \text{ newtons}$$

of repulsion if the charges have the same polarity, of attraction if they have opposite polarity,  $\epsilon_0$  being the electric space constant. The force on  $q_2$  can be considered as due to its immersion in the electric field  $E_1$  of  $q_1$ , i.e.  $f = E_1 q_2$ ; whence

$$E_1 = q_1 / 4\pi\epsilon_0 d^2 \text{ volts per metre}$$

defining the electric field strength at distance  $d$  from a concentrated charge  $q_1$ . Thus, a unit charge (1 C) is that which repels a similar charge at unit distance (1 m) with a force of  $1/4\pi\epsilon_0$  newton. Similarly, a field of unit strength (1 V/m) produces a mechanical force of 1 N on a unit charge placed in it.

To charge a system like that in Figure 2.24, a quantity of electricity has been moved under an applied electric force—i.e. work has been done measured by the charge transferred and the p.d. Unit p.d. (1 V) exists between two points in an electric field when unit work (1 J) is done in moving unit charge (1 C) between them. The two conductors are equipotential surfaces, and potential levels or equipotential lines can be drawn at right angles to the field lines (Figure 2.25). Equipotential lines resemble contour lines on the map of a hill: the closer they are, the greater is the voltage gradient. The change of potential in a given direction is

$$V = - \int E \cdot dx$$

where  $E$  is the electric field strength, or potential gradient, in the direction  $x$ ; whence  $E = -dV/dx$ .

Figure 2.25 Electric fields

### 2.5.2 Capacitance

The configuration and geometry of the conductor system in Figure 2.24 depends on the relation between the charge  $q$  on each conductor and the p.d.,  $V$ , between them. Then  $q = CV$ , where  $C$  is the capacitance of the *capacitor* formed by the system. A capacitor has unit capacitance (1 F) if (a) the energy stored in the associated electric field is  $\frac{1}{2}$  J for a p.d. of 1 V, or (b) the p.d. is 1 V for a charge of 1 C. Definition (a) follows from the energy storage property: if the p.d. across a capacitor is raised uniformly from zero to  $V_1$ , a charge  $q_1 = CV_1$  is established at an average p.d.  $\frac{1}{2}V_1$ , so that the energy input is

$$W = \frac{1}{2}V_1 \cdot q_1 = \frac{1}{2}V_1 \cdot CV_1 = \frac{1}{2}CV_1^2$$

#### 2.5.2.1 Dielectrics

Up to this point it has been assumed that the electric field between the plates of a capacitor has been established through vacuous space. If a material insulator is used—gas, liquid or solid—the electric field will exist therein. It will act on the molecules of the *dielectric* material in accordance with electrostatic principles to ‘stretch’ or ‘rotate’ them, and so to orientate the positive and negative molecular charges in opposite directions. This *polarisation* of the dielectric may be imagined to take place as in Figure 2.26. Before the p.d. is applied, the molecules of the dielectric material are neutral and unstrained. As the p.d. is raised from zero as in (a), the electric field acts to separate the positive and negative elements, the small charge displacement forming a *polarisation* current.

The effect of the application of a p.d. to a capacitor with a material dielectric, then, is to displace a surface charge  $q_d$  of polarisation, having a polarity opposite to that of the adjacent capacitor plate  $q_c$ . The electric field in the dielectric is due to the resultant or net charge  $q = q_c - q_d$ . The field strength (and therefore the p.d.) is less than would be expected for the charge  $q_c$  on the plates: the relative reduction is found to be approximately constant for a given dielectric. It is called the *relative permittivity*, symbol  $\epsilon_r$ . The same field strength as for a vacuum will exist in the dielectric for  $\epsilon_r$  times as much charge on the capacitor plates, so that the capacitor has  $\epsilon_r$  times the capacitance of a similar capacitor having free space between its plates.

Permittivity effects can thus be taken into account either by assigning to a dielectric a relative permittivity or by considering its polarisation. The latter is of use where internal dielectric forces are concerned, and in dielectric breakdown (Figure 2.26(b)).

#### 2.5.2.2 Calculation of capacitance

The capacitance of capacitors of simple geometry can be found by assigning, respectively, charges of +1 C and -1 C to the plates or other electrodes, between which the total

Figure 2.26 Dielectric polarisation and breakdown

electric flux is 1 C. From the field pattern the electric flux density  $D$  at any point is found. Then the electric field strength at the point is  $E = D/\epsilon$ , where  $\epsilon = \epsilon_r \epsilon_0$  is the absolute permittivity of the insulating medium in which the electric flux is established. Integration of  $E$  over any path from one electrode to the other gives the p.d.  $V$ , whence the capacitance is  $C = 1/V$ .

**Parallel plates (Figure 2.27(a))** The electric flux density is uniform except near the edges. By use of a *guard ring* maintained at the potential of the plate that it surrounds, the capacitance of the inner part is calculable on the reasonable assumption of uniform field conditions. With a charge of 1 C on each plate, and plates of area  $S$  spaced  $a$  apart, the electric flux density is  $D = 1/S$ , the electric field intensity is  $E = D/\epsilon = 1/S\epsilon$ , the potential difference is  $V = Ea = a/S\epsilon$ , and the capacitance is therefore

$$C = q/V = \epsilon(S/a) \Leftarrow$$

A case of interest is that of a parallel plate arrangement (Figure 2.27(b)), with two dielectric materials, of thickness  $a_1$  and  $a_2$  and absolute permittivity  $\epsilon_1$  and  $\epsilon_2$ , respectively. The voltage gradient is inversely proportional to the permittivity, so that  $E_1\epsilon_1 = E_2\epsilon_2$ . The field pattern makes it evident that the difference in polarisation produces an interface charge, but in terms of the charge  $q_c$  on the plates themselves the electric flux density is constant throughout. The total voltage between the plates is  $V = V_1 + V_2 = E_1a_1 + E_2a_2$ , from which the total capacitance can be obtained.

**Concentric cylinders (Figure 2.27(c))** With a charge of 1 C per metre length, the electric flux density at radius  $x$  is  $1/2\pi x$ , whence  $E_x = 1/2\pi x\epsilon$ . Integrating for the p.d. gives

$$V = (1/2\pi\epsilon) \ln(R/r) \Leftarrow$$

The capacitance is consequently

$$C = 2\pi\epsilon / \ln(R/r) \text{ farad/metre}$$

The electric field strength (voltage gradient)  $E$  is inversely proportional to the radius, over which it is distributed hyperbolically. The maximum gradient occurs at the surface of the inner conductor and amounts to

$$E_m = V/r \ln(R/r) \Leftarrow$$

At any other radius  $x$ ,  $E_x = E_m(r/x)$ . For a given p.d.  $V$  and gradient  $E_m$  there is one value of  $r$  to give minimum overall radius  $R$ : this is

$$r = V/E_m \text{ and } R = 2.72r$$

For the cylindrical capacitor (d) with two dielectrics, of permittivity  $\epsilon_1$  between radii  $r$  and  $\rho$  and  $\epsilon_2$  between  $\rho$  and  $R$ , the maximum gradients are related by  $E_{m1}\epsilon_1 r = E_{m2}\epsilon_2 \rho$ .

Figure 2.27 Capacitance and voltage gradient

**Parallel cylinders (Figure 2.27(e))** The calculation leads to the value

$$C = \pi\epsilon / \ln(a/r) \text{ farad/metre}$$

for the capacitance between the conductors, provided that  $a \gg r$ . It can be considered as composed of two series-connected capacitors each of

$$C_0 = 2\pi\epsilon / \ln(a/r) \text{ farad/metre}$$

$C_0$  being the *line-to-neutral* capacitance. A three-phase line has a line-to-neutral capacitance identical with  $C_0$ , the interpretation of the spacing  $a$  for transposed asymmetrical lines being the same as for their inductance.

The voltage gradient of a two-wire line is shown in Figure 2.27(e). If  $a \gg r$ , the gradient in the immediate vicinity of a wire may be taken as due to the charge thereon, the further wire having little effect: consequently,

$$E_m = V/r \ln(a/r) \Leftarrow$$

is the voltage gradient at a conductor surface.

### 2.5.2.3 Connection of capacitors

If a bank of capacitors of capacitance  $C_1, C_2, C_3, \dots$ , be connected in *parallel* and raised in combination each to the p.d.  $V$ , the total charge is the sum of the individual charges  $VC_1, VC_2, VC_3, \dots$ , whence the total combined capacitance is

$$C = C_1 + C_2 + C_3 + \dots \Leftarrow$$

With a *series* connection, the same displacement current occurs in each capacitor and the p.d.  $V$  across the series assembly is the sum of the individual p.d.s:

$$\begin{aligned} V &= V_1 + V_2 + V_3 + \dots \Leftarrow \\ &= q[(1/C_1) + (1/C_2) + (1/C_3) + \dots] \Leftarrow \\ &= q/C \end{aligned}$$

so that the combined capacitance is obtained from

$$C = 1/[(1/C_1) + (1/C_2) + (1/C_3) + \dots] \Leftarrow$$

### 2.5.2.4 Voltage applied to a capacitor

The basis for determining the conditions in a circuit containing a capacitor to which a voltage is applied is that the p.d.  $v$  across the capacitor is related definitely by its capacitance  $C$  to the charge  $q$  displaced on its plates:  $q = Cv$ .

Let a direct voltage  $V$  be suddenly applied to a circuit devoid of all characteristic parameters except that of capacitance  $C$ . At the instant of its application, the capacitor must accept a charge  $q = Cv$ , resulting in an infinitely large current flowing for a vanishingly short time. The energy stored is  $W = \frac{1}{2} Vq = \frac{1}{2} CV^2$  joules. If the voltage is raised or lowered uniformly, the charge must correspondingly change, by a constant charging or discharging current flowing during the change (Figure 2.28(a)).

Figure 2.28 Voltage applied to a pure capacitor

If the applied voltage is sinusoidal, as in (b), such that  $v = v_m \cos 2\pi ft = v_m \cos \omega t$ , the same argument leads to the requirement that the charge is  $q = q_m \cos \omega t$ , where  $q_m = C v_m$ . Then the current is  $i = dq/dt$ , i.e.

$$i = -\omega C v_m \sin \omega t$$

with a peak  $i_m = \omega C v_m$  and an r.m.s. value  $I = \omega C V = V/X_c$ , where  $X_c = 1/\omega C$  is the *capacitive reactance*.

### 2.5.3 Dielectric breakdown

A dielectric material must possess: (a) a high insulation resistivity to avoid leakage conduction, which dissipates the capacitor energy in heat; (b) a permittivity suitable for the purpose—high for capacitors and low for insulation generally; and (c) a high electric strength to withstand large voltage gradients, so that only thin material is required. It is rarely possible to secure optimum properties in one and the same material.

A practical dielectric will break down (i.e. fail to insulate) when the voltage gradient exceeds the value that the material can withstand. The breakdown mechanism is complex.

#### 2.5.3.1 Gases

With gaseous dielectrics (e.g. air and hydrogen), ions are always present, on account of light, heat, sparking, etc. These are set in motion, making additional ionisation, which may be cumulative, causing glow discharge, sparking or arcing unless the field strength is below a critical value. A field strength of the order of 3 MV/m is a limiting value for gases at normal temperature and pressure. The dielectric strength increases with the gas pressure.

The polarisation in gases is small, on account of the comparatively large distances between molecules. Consequently, the relative permittivity is not very different from unity.

#### 2.5.3.2 Liquids

When very pure, liquids may behave like gases. Usually, however, impurities are present. A small proportion of the molecules forms positive or negative ions, and foreign particles in suspension (fibres, dust, water, droplets) are prone to align themselves into semiconducting filaments: heating produces vapour, and gaseous breakdown may be initiated. Water, because of its exceptionally high permittivity, is especially deleterious in liquids such as oil.

#### 2.5.3.3 Solids

Solid dielectrics are rarely homogeneous, and are often hygroscopic. Local space charges may appear, producing absorption effects; filament conducting paths may be present; and local heating (with consequent deterioration) may occur. Breakdown depends on many factors, especially thermal ones, and is a function of the time of application of the p.d.

#### 2.5.3.4 Conduction and absorption

Solid dielectrics in particular, and to some degree liquids also, show conduction and absorption effects. Conduction appears to be mainly ionic in nature. Absorption is an apparent storing of charge *within* the dielectric. When a capacitor is charged, an initial quantity is displaced on its plates due to the *geometric* capacitance. If the p.d. is maintained, the charge gradually grows, owing to *absorptive* capacitance, probably a result of the slow orientation of permanent dipolar molecules.

The current finally settles down to a small constant value, owing to conduction.

Absorptive charge leaks out gradually when a capacitor is discharged, a phenomenon observable particularly in cables after a d.c. charge followed by momentary discharge.

#### 2.5.3.5 Grading

The electric fields set up when high voltages are applied to electrical insulators are accompanied by voltage gradients in various parts thereof. In many cases the gradients are anything but uniform: there is frequently some region where the field is intense, the voltage gradient severe and the dielectric stress high. Such regions may impose a controlling and limiting influence on the insulation design and on the working voltage. The process of securing improved dielectric operating conditions is called *grading*. The chief methods available are:

- (1) The avoidance of sharp corners in conductors, near which the gradient is always high.
- (2) The application of high-permittivity materials to those parts of the dielectric structure where the stress tends to be high, on the principle that the stress is inversely proportional to the permittivity: it is, of course, necessary to correlate the method with the dielectric strength of the material to be employed.
- (3) The use of intersheath conductors maintained at a suitable intermediate potential so as to throw less stress on those parts which would otherwise be subjected to the more intense voltage gradients.

Examples of (1) are commonly observed in high-voltage apparatus working in air, where large rounded conductors are employed and all edges are given a large radius. The application of (2) is restricted by the fact that the choice of materials in any given case is closely circumscribed by the mechanical, chemical and thermal properties necessary. Method (3) is employed in capacitor bushings, in which the intersheaths have potentials adjusted by correlation of their dimensions.

### 2.5.4 Electromechanical effects

Figure 2.29 summarises the mechanical force effects observable in the electric field. In (a), (b) and (c) are sketched the field patterns for cases already mentioned in connection with the laws of electrostatics. The surface charges developed on high- $\epsilon$  materials are instrumental in producing the forces indicated in (d). Finally, (e) shows the forces on pieces of dielectric material immersed in a gaseous or liquid insulator and subjected to a non-uniform electric field. The force

Figure 2.29 Electromechanical forces

direction depends upon whether the piece has a higher or lower permittivity than the dielectric medium in which it lies. Thus, pieces of high permittivity are urged towards regions of higher electric field strength.

## 2.6 Electromagnetic field effects

Electromagnetic field effects occur when electric charges undergo acceleration. The effects may be negligible if the rate of change of velocity is small (e.g. if the operating frequency is low), but other conditions are also significant, and in certain cases effects can be significant even at power frequencies.

### 2.6.1 Movement of charged particles

Particles of small mass, such as electrons and protons, can be accelerated in vacuum to very high speeds.

**Static electric field** The force developed on a particle of mass  $m$  carrying a positive charge  $q$  and lying in an electric field of intensity (or gradient)  $E$  is  $f = qE$  in the direction of  $E$ , i.e. from a high-potential to a low-potential region (Figure 2.30(a)). (If the charge is negative, the direction of the force is reversed.) The acceleration of the particle is  $a = f/m = E(q/m)$ ; and if it starts from rest its velocity after time  $t$ , is  $u = at = E(q/m)t$ . The kinetic energy  $\frac{1}{2}mu^2$  imparted is equal to the change of potential energy  $Vq$ , where  $V$  is the p.d. between the starting and finishing points in the electric field. Hence, the velocity attained from rest is

$$u = \sqrt{[2V(q/m)]} \ll$$

For an electron ( $q = -1.6 \times 10^{-19}$  C,  $m_0 = 0.91 \times 10^{-30}$  kg) falling through a p.d. of 1 V the velocity is 600 km/s and the kinetic energy is  $w = Vq = 1.60 \times 10^{-19}$  J, often called an electron-volt, 1 eV.

If  $V = 2.5$  kV, then  $u = 30\,000$  km/s; but the speed cannot be indefinitely raised by increasing  $V$ , for as  $u$  approaches  $c = 300\,000$  km/s, the free-space electromagnetic wave velocity, the effective mass of the particle begins to acquire a rapid relativistic increase to

$$m = m_0/[1 - (u/c)^2] \ll$$

compared with its 'rest mass'  $m_0$ .

**Static magnetic field** A charge  $q$  moving at velocity  $u$  is a current  $i = qu$ , and is therefore subject to a force if it moves across a magnetic field. The force is at right angles to  $u$  and to  $B$ , the magnetic flux density, and in the simple case of Figure 2.30(b) we have  $f = quB = ma = mu^2/R$ , the particle being constrained by the force to move in a circular path of radius  $R = (u/B)(m/q)$ . For an electron  $R = 5.7 \times 10^{-22}$  (u/B).

**Combined electric and magnetic fields** The two effects described above are superimposed. Thus, if the  $E$  and  $B$  fields are coaxial, the motion of the particle is helical.

Figure 2.30 Motion of charged particles

The influence of static (or quasi-static) fields on charged particles is applied in cathode ray oscilloscopes and accelerator machines.

### 2.6.2 Free space propagation

In Section 1.5.3 the Maxwell equations are applied to propagation of a plane electromagnetic wave in free space. It is shown that basic relations hold between the velocity  $u$  of propagation, the electric and magnetic field components  $E$  and  $H$ , and the electric and magnetic space constants  $\epsilon_0$  and  $\mu_0$ . The relations are:

$$u = 1/\sqrt{(\mu_0\epsilon_0)} \simeq 3 \times 10^8 \text{ metre/second}$$

is the free space propagation velocity. The electric and magnetic properties of space impose a relation between  $E$  (in volts per metre) and  $H$  (in amps per metre) given by

$$E/H = \sqrt{(\mu_0/\epsilon_0)} = 377 \Omega \cdot \psi$$

called the *intrinsic impedance* of space. Furthermore, the energy densities of the electric and magnetic components are the same, i.e.

$$\frac{1}{2}\epsilon_0 E^2 = \frac{1}{2}\mu_0 H^2$$

Propagation in power engineering is not (at present) by space waves but by guided waves, a conducting system being used to direct the electromagnetic energy more effectively in a specified path. The field pattern is modified (although it is still substantially transverse), but the essential physical propagation remains unchanged. Such a guide is called a transmission line, and the fields are normally specified in terms of the inductance and capacitance properties of the line configuration, with an effective impedance  $z_0 = \sqrt{(L/C)}$  differing from 377  $\Omega$ .

### 2.6.3 Transmission line propagation (see also Section 36)

If the two wires of a long transmission line, originally dead, are suddenly connected to a supply of p.d.  $v$ , an energy wave advances along the line towards the further end at velocity  $u$  (Figure 2.31). The wave is characterised by the fact that the advance of the voltage charges the line capacitance, for which an advancing current is needed; and the advance of the current establishes a magnetic field against a counter-e.m.f., requiring the voltage for maintaining the advance. Thus, current and voltage are propagated simultaneously. Let losses be neglected, and  $L$  and  $C$  be the inductance and capacitance per unit length of line. In a brief time interval  $dt$ , the waves advance by a distance  $u \cdot dt$ . The voltage is established across a capacitance  $Cu \cdot dt$  and the rate of charge, or current, is

$$i = vCu \cdot dt/dt = vCu$$

Figure 2.31 Transmission-line field

The current is established in an inductance  $Lu \cdot dt$  producing the magnetic linkages  $iLu \cdot dt$  in time  $dt$ , and a corresponding counter-e.m.f. overcome by

$$v = iLu \cdot dt/dt = iLu$$

These two expressions, by simple manipulation, yield

$$\text{Propagation velocity } u = 1/\sqrt{LC} \Leftarrow$$

$$\text{Surge impedance } z_0 = v/i = \sqrt{L/C} \Leftarrow$$

$$\text{Energy components } \frac{1}{2}Li^2 = \frac{1}{2}Cv^2$$

For a line in air consisting of parallel conductors of radius  $r$  spaced  $a$  between centres, the inductance (neglecting internal linkage) and capacitance per unit length are

$$L = (\mu_0/\pi) \ln(a/r); \quad C = \pi\epsilon_0/\ln(a/r) \Leftarrow$$

whence  $u = 1/\sqrt{(\mu_0\epsilon_0)} \simeq 3 \times 10^8$  m/s, exactly as for free space propagation. For lines in which the relative permittivity (and/or, rarely, the relative permeability) of the medium conveying the electromagnetic wave is greater than unity, the speed is reduced by the factor  $1/\sqrt{(\mu_r\epsilon_r)}$ . Line loss and internal linkage slightly reduce the speed of propagation. With the  $L$  and  $C$  values quoted, the surge impedance is

$$z_0 = 120 \ln(a/r) \Leftarrow$$

which is usually in the range 300–600  $\Omega$ . For cables the different geometry and the relative permittivity give a much lower value.

### 2.6.3.1 Reflection of surges

The relation of p.d. and current direction in a pair of wires forming a long transmission line is determined by the direction in which the energy is travelling (*Figure 2.31*). The current flows in the direction of propagation in the positive conductor, and returns in the negative. Two waves travelling in opposite directions on a line must have *either* the currents *or* the p.d.s in opposite senses. If two such waves meet, either the currents are subtractive and the voltage additive, or the reverse. In each case the natural ratio  $v/i = z_0$  for each wave is not apparent: in fact, if the resultant voltage/current ratio is not  $z_0$ , the actual distribution of current and voltage must be due to two component waves having opposite directions of propagation. Such conditions arise when a surge is *reflected* at the end of a line.

Consider a steep-fronted surge which reaches the *open-circuited* end of its guiding line. At the point the current must be zero, which requires an equal reflected surge current of opposite sense. The voltages have the same sense and combined to give a doubling effect (*Figure 2.32(a)*). Reversal of the energy flow imposed by the line discontinuity, i.e. reflection, is thus accompanied by voltage doubling and an elimination of current. In unit length of a surge, the total energy is  $\frac{1}{2}Li^2 + \frac{1}{2}Cv^2$ ; when two surges (one incident, one reflected) are superimposed, the total energy is electrostatic and of value  $\frac{1}{2}C(2v)^2 = 2Cv^2$ , which, of course, is equal to the total energy per unit length of the two waves:  $2(\frac{1}{2}Cv^2 + \frac{1}{2}Li^2) = Cv^2 + Li^2 = 2Cv^2$ .

If the sending-end generator has zero impedance and remains closed on to the line, the returning surge is again reflected at voltage  $v$  and the to-and-fro 'oscillation' is maintained indefinitely. In practice, the presence of the losses reduces the reflections and the voltage settles down finally to the steady value  $v$ , with a current determined by line admittance.

An incident surge which reaches the *short-circuited* end of a line is presented with a condition of termination across which no p.d. can be maintained. The voltage collapses to

Figure 2.32 Surge reflection

zero, initiating a doubling of the current and reflection with reversed voltage (*Figure 2.32(b)*).

If the sending-end generator has zero impedance and remains closed on to the line, reflections take place repeatedly with an increase of  $i$  in the current each time, building up eventually to an infinite value—as would be expected in a lossless line with its end short circuited. Under realisable conditions the current rises with steps of reducing size to a value limited by the series line impedance.

**Terminated line** If a line is terminated on an impedance  $z$ , only partial reflection will take place, some of the incident surge energy being dissipated as heat in the resistive part of  $z$ . Let the incident surge be  $v_1i_1$  such that  $v_1/i_1 = z_0$ ; and let the reflected wave be  $v_2i_2$ , with  $v_2/i_2 = -z_0$ . The negative sign is required algebraically to take account of the reversal of either current or voltage by reflection. The voltage  $v$  and current  $i$  at the termination  $z$  during the reflection are such that  $v = v_1 + v_2$  and  $i = i_1 + i_2$ . But  $v = iz$ , so that, for the reflected current and voltage,

$$v_2 = v_1 \frac{z - z_0}{z + z_0} = \alpha v_1 \quad \text{and} \quad i_2 = -i_1 \frac{z - z_0}{z + z_0}$$

where  $\alpha$  is the *reflection factor*. At the termination itself

$$v = v_1 \frac{2z}{z + z_0} = \beta v_1 \quad \text{and} \quad i = i_1 \frac{2z_0}{z + z_0}$$

where  $\beta = 1 + \alpha$  is the *absorption factor*. The characteristic impedance is resistive, and reflection takes place unless  $z = z_0$  and is also resistive. In the latter case  $v_2$  and  $i_2$  vanish, there is no reflection, and the energy in the incident surge  $v_1i_1$  is absorbed in  $z$  at the same rate as that at which it arrives.

**Line junction or discontinuity** A line having an abrupt change of surge impedance from  $z_0$  to  $z_0'$  (as, for example, at the junction of a branch line, or at line-cable connection) can be treated as above, substituting  $z_0'$  for  $z$ . The voltage  $v = \beta v_1$  is then characteristic of the *transmitted surge*, and  $\beta$  becomes the *transmission factor*.

Writing  $v = 2v_1 \cdot z/(z + z_0)$ , it is seen that  $v$  can be considered as the voltage across the load  $z$  of a voltage generator of e.m.f.  $2v_1$  and internal impedance  $z_0$ . Any line termination of reasonable simplicity can now be dealt with. The discontinuity  $z$  may be a shunt load, or any combination of loads and extension lines reducible to an equivalent  $z$ . If  $z$  is resistive, the calculation of the terminal  $v$  and  $i$  is straightforward; but if  $z$  contains a time function (i.e. if it contains inductive and/or capacitive elements), the expressions

$v = \beta v_1$  and  $v_2 = \alpha v_1$  become integro-differential equations, to be solved by the methods given in Chapter 5. For  $z$  resistive, reflection and transmission (or absorption) of surges takes place without change of shape: for  $z$  containing terms in  $L$  and  $C$ , the shape of the incident surge is modified.

**Single reflections** Applying the equivalent circuit, a line on open-circuit has  $z = \infty$ , giving  $v = 2v_1$  and  $v_2 = v_1$ . For a short-circuited line,  $z = 0$ ,  $v = 0$  and  $v_2 = -v_1$ . These cases are shown in Figure 2.32.

**Shunt inductor termination:** Because  $L$  offers infinite opposition to infinite rate of current rise, it acts as an open circuit at the instant of surge arrival, degenerating with time constant  $L/z_0$  to a condition of short-circuit. Thus the voltage at the termination is

$$v = 2v_1 \exp(-t \cdot z_0/L) \leftarrow$$

**Shunt capacitor termination:**  $C$  is initially the equivalent of a short circuit, but charges as the surge continues to arrive, and eventually approaches the charged state, for which it acts as an open circuit. The voltage across it is consequently

$$v = 2v_1 [1 - \exp(-t/Cz_0)] \leftarrow$$

**Series inductor termination:** If an inductor is inserted into a line of surge impedance  $z_0$ , the equivalent circuit is made up of the generator of voltage  $2v_1$ , loaded with  $z_0$ ,  $L$  and  $z_0$  in series. The voltage transmitted into the line extension is then

$$v' = v_1 [1 - \exp(-t \cdot 2z_0/L)] \leftarrow$$

showing the reduction of wavefront steepness produced. This roughly represents the action of a series surge modifier.

**Multiple reflections** Surges on power networks will be subject to repeated reflections at terminations, junctions, towers and similar discontinuities. Such cases are handled by developing the appropriate reflection and transmission (or absorption) factors  $\alpha$  and  $\beta$  for each discontinuity and each direction. Procedure is facilitated by the use of Bewley's 'lattice diagram': a horizontal scale (of distance along a system in the direction of the initial surge) is combined with a downward vertical scale of time. A lattice of distance-time lines occupies the plane, the lines being sloped to correspond with the velocities of propagation in the system. The lines are marked with their surge voltage values in terms of  $v_1$  and the various transmission and reflection coefficients.

The process is illustrated by the example in Figure 2.33. A 500 kV steep-fronted surge reaches the junction P of an overhead transmission line with a cable PQ, 1 km long. At Q the cable is connected to a second overhead line having a short circuit at S, distant 2 km from Q. The overhead lines have a propagation velocity of  $u = 0.30$  km/ $\mu$ s and surge impedances  $z_0$  respectively of 500 and 600  $\Omega$ ; corresponding values for the cable are 0.20 km/ $\mu$ s and 70  $\Omega$ . Assuming the surge impedances to be purely resistive and neglecting attenuation, the Bewley lattice diagram is to be drawn for the system and the surge-voltage distribution found for an instant 19  $\mu$ s after the surge wavefront reaches P.

Five sets of transmission and reflection factors are required, one at S and two each at P and Q for the two directions of propagation. The reflection factor is  $\alpha = (z - z_0)/(z + z_0)$  and the transmission (or absorption) factor is  $\beta = (1 + \alpha)$ . Then

**Direction left to right :**

$$\text{At P: } \alpha_{lr} = (70 - 500)/(70 + 500) = -0.75; \beta_{lr} = +0.25$$

$$\text{At Q: } \alpha_{lr} = (600 - 70)/(600 + 70) = +0.79; \beta_{lr} = +1.79$$

$$\text{At S: } \alpha_{lr} = (0 - 600)/(0 + 600) = -1.0; \beta_{lr} = 0$$

Figure 2.33 Bewley's lattice diagram

**Direction right to left :**

$$\text{At P: } \alpha_{rl} = (500 - 70)/(500 + 70) = +0.75; \beta_{rl} = +1.75$$

$$\text{At Q: } \alpha_{rl} = (70 - 600)/(70 + 600) = -0.79; \beta_{rl} = +0.21$$

The lattice diagram has distance plotted horizontally. The distance scale for the cable section PQ is enlarged by the factor 3/2 to take account of its lower propagation velocity. Time is plotted vertically with time zero at the instant that the surge voltage reaches P. Starting from the upper left-hand side, a sloping straight line is drawn to show the position at any instant of the surge wavefront. Reflection occurs at each junction, so that corresponding lines of the same slope (but running downward to the left) are drawn. The junctions are now marked with the appropriate voltages, using the calculated reflection and transmission factors  $\alpha$  and  $\beta$ . Thus the incident surge at P is reflected with  $\alpha = -0.75$  to give -375 kV; the transmitted voltage, with  $\beta = +0.25$ , is 125 kV. The former is turned back at P and is superimposed on the incident surge, while the latter proceeds in the direction PQ, to be split at Q into reflected and transmitted components. At any junction the marked voltages must sum on each side to the same total. The surge-voltage distribution for 19  $\mu$ s is found by summing the voltages marked on the sloping lines up to this instant.

## 2.7 Electrical discharges

### 2.7.1 Introduction

Electric currents may be induced to flow through normally insulating materials by the formation of an electrical

discharge. The discharge is maintained by the creation and movement of ions and electrons which in many discharges constitute a plasma (see Section 10.8). Such discharges may be produced between two electrodes which form part of an electrical network and across which a sufficient potential difference exists to ionise the insulation. Alternatively, discharges may be electromagnetically induced, for instance by strong radiofrequency fields.

Electrical discharges may be characterised for electrical network applications in terms of the current and voltage values needed for their occurrence (*Figure 2.34*).

### 2.7.2 Types of discharge

Discharges have historically been subdivided into two categories namely *self-sustaining* and *non-self-sustaining* discharges. The transition between the two forms (which constitutes the electrical breakdown of the gas) is sudden and occurs through the formation of a *spark*.

Non-self-sustaining discharges occur at relatively low currents ( $\sim 10^{-8}$  A) (region 0A, *Figure 2.34*) of which *Townsend discharges* are a particular type. The form of the current–voltage characteristic in this region is governed firstly by a current increase caused by primary electrons ionising the gas by collision to produce secondary electrons, and subsequently by the positive ions formed in this process gaining sufficient energy to produce further ionisation. Such discharges may be induced by irradiating the gas in between two electrodes to produce the initial ionisation. They are non-sustaining because the current flow ceases as soon as the ionising radiation is removed.

When the voltage across the electrodes reaches a critical value  $V_s$  (*Figure 2.34*), current level  $\sim 40^{-5}$  A, the current increases rapidly via a *spark* to form a self-sustaining discharge. The sparking potential  $V_s$  for ideal operating conditions (uniform electric field) varies with the product of gas pressure ( $p$ ) and electrode separation ( $d$ ) according to Paschen's law (*Figure 2.35*). There is a critical value of  $pd$  for which the breakdown voltage  $V_s$  is a minimum.

The self-sustaining discharge following breakdown may be either a *glow* or *arc* discharge (regions B–C and D–F, respectively, in *Figure 2.34*) depending on the discharge path and the nature of the connected electric circuit.

The region between  $V_s$  and B (*Figure 2.34*) is known as a '*normal*' glow discharge and is characterised by the potential

**Figure 2.34** Current–voltage characteristic for electrical discharges. 0A, Townsend discharge; B, normal glow; C, abnormal glow; DF, arc;  $V_s$ , spark;  $V_0$ – $I_0$ , load line

**Figure 2.35** Breakdown voltage as a function of the pressure–electrode separation product (Paschen's law)

difference across the discharge being nearly independent of current, extending to at least  $10^{-3}$  A if not several amperes. For higher currents the voltage increases to form the '*abnormal*' glow discharge (region C, *Figure 2.34*).

The glow discharge is manifest as a diffusely luminous plasma extending across the discharge volume but may consist of alternate light and dark regions extending from the cathode in the order: Aston dark space, cathode glow, cathode dark space, negative glow, Faraday dark space, positive glow (which is extensive in volume), the anode glow and the anode dark space (*Figure 2.36*). The glowing regions correspond to ionisation and excitation processes being particularly active and their occurrence and extent depends on the particular operating conditions.

The voltage across the glow discharge consists of two major components: the cathode fall and the positive column (*Figure 2.36a*). Most of the voltage drop occurs across the cathode fall.

For sharply curved surfaces (e.g. wires) and long electrode separations the gas near the surface breaks down at a voltage less than  $V_s$  to form a local glow discharge known as a *corona*.

The electric arc is a self-sustained discharge requiring only a low voltage for its sustenance and capable of causing currents from typically  $10^{-1}$  A to above  $10^5$  A to flow.

A major difference between arc and glow discharges is that the current density at the cathode of the arc is greater than that at the glow cathode (*Figure 2.37*). The implication is that the electron emission process for the arc is different from that of the glow and is often thermionic in nature. At higher gas pressures both the anode and cathode of the arc may be at the boiling temperature of the electrode material. Materials having high boiling points (e.g. carbon and tungsten) have lower cathode current densities (ca.  $5 \times 40^2$  A/cm<sup>2</sup>) than materials with lower boiling points (e.g. copper and iron; ca.  $5 \times 40^3$  A/cm<sup>2</sup>).

The arc voltage is the sum of three distinct components (*Figure 2.36(b)*): the cathode and anode falls and the positive column. Cathode and anode fall voltages are each typically about 10 V. Short arcs are governed by the electrode fall regions, whereas longer arcs are dominated by the positive column.

**Figure 2.36** Voltage distributions between discharge electrodes: (a) glow; (b) arc

**Figure 2.37** Cathode current density distinction between glow and arc discharges

At low pressures the arc may be luminously diffuse and the plasma is not in thermal equilibrium. The temperature of the gas atoms and ions is seldom more than a few hundred degrees Celsius whereas the temperature of the electrons may be as high as  $4 \times 10^4$  K (Figure 2.38).

At atmospheric pressure and above, the arc discharge is manifest as a constricted, highly luminous core surrounded by a more diffusely luminous aureole. The arc plasma column is generally, although not exclusively, in thermal equilibrium.

The arc core is typically at temperatures in the range  $5 \times 10^3$  to  $30 \times 10^3$  K so that the gas is completely disso-

**Figure 2.38** Typical electron and gas temperature variations with pressure for arc plasma

ciated and highly ionised. Conversely, the temperature of the aureole spans the range over which dissociation and chemical reactions occur (ca.  $2 \times 10^3$  to  $5 \times 10^3$  K).

The current voltage characteristic of the long electric arc is governed by the electric power ( $VI$ ) dissipated in the arc column to overcome thermal losses. At lower current levels ( $10^{-1}$  to  $10^2$  A) the arc column is governed by thermal conduction losses leading to a negative gradient for the current-voltage characteristic. At higher current levels radiation becomes the dominant loss mechanism yielding a positive gradient characteristic (Figure 2.34).

Thermal losses and hence electric power dissipation increase with arc length (e.g. longer electrode separation), gas pressure, convection (e.g. arcs in supersonic flows) and radiation (e.g. entrained metal vapours). As a result the arc voltage at a given current is also increased, causing the discharge characteristic (Figure 2.34) to be displaced parallel to the voltage axis.

### 2.7.3 Discharge-network interaction

For quasi-steady situations the interaction between an electrical discharge and the interconnected network is governed by the intersection of the load line  $V_o I_o$  (Figure 2.34)

$$V = V_o - IR$$

(where  $R$  is the series-network resistance and  $V_o$  is the source voltage) and the current-voltage characteristic of the discharge.

The negative gradient of the low current arc branch of the discharge characteristic produces a negative incremental resistance which makes operation at point D (Figure 2.34) unstable whereas operation at point E or B is stable.

In practice the operating point is determined by the manner in which the discharge is initiated. Initiation by electrode separation (e.g. circuit breaker contact opening) or by fuse rupture leads to arc operation at E. However, if the discharge is initiated by reducing the series resistance  $R$  gradually so that the load line is rotated about  $V_o$ , operation as a glow discharge at B may be maintained. If the cathode is heated to provide a large supply of electrons a transition from B to E may occur.

A variation of the source voltage  $V_o$  causes the points of intersection of the load line and discharge characteristic to

vary so that new points of stability are produced. When the voltage falls below a value, which makes the load line tangential to the negative characteristic, the arc is, in principle, not sustainable. However, in practice, the thermal inertia of the arc plasma may maintain ionisation and so delay eventual arc extinction.

The behaviour of electric arcs in a.c. networks is governed by the competing effects of the thermal inertia of the arc column (due to the thermal capacity of the arc plasma) and the electrical inertia of the network (produced by circuit inductance and manifest as a phase difference between current and voltage). The current–voltage characteristic of the discharge changes from the quasi-steady (d.c.) form of *Figure 2.34* (corresponding to arc inertia being considerably less than the electrical inertia) via an intermediate form (when the thermal and electrical inertias are comparable) to an approximately resistive form (when the thermal inertia is considerably greater than the electrical inertia) (*Figure 2.39*).

### 2.7.4 Discharge applications

Electrical discharges occur in a number of engineering situations either as limiting or as essential operating features of systems and devices.

Spark discharges are used in applications which utilise their transitional nature. These include spark gaps for protecting equipment against high frequency, high voltage transients and as rapid acting make switches for high power test equipment or pulsed power applications. They are also used for spark erosion in machining materials to high tolerances.

Glow discharges are utilised in a variety of lamps, in gas lasers, in the processing of semiconductor materials and for the surface hardening of materials (e.g. nitriding). Operational problems in all cases involve maintaining the discharge against extinction during the low current part of the driving a.c. at one extreme and preventing transition

into an arcing mode (which could lead to destructive thermal overload) at the other extreme.

Glow discharge lamps either rely on short discharge gaps in which all the light is produced from the negative glow covering the cathode (e.g. neon indicator lamps) or long discharge gaps in which all the light comes from the positive column confined in a long tube (e.g. neon advertising lights).

In materials processing the glow is used to provide the required active ionic species for surface treating the material which forms a cathodic electrode. Both etching of surface layers and deposition of complex layers can be achieved with important applications for the production of integrated circuits for the electronics industry. Metallic surfaces (e.g. titanium steel) may be hardened by nitriding in glow discharges.

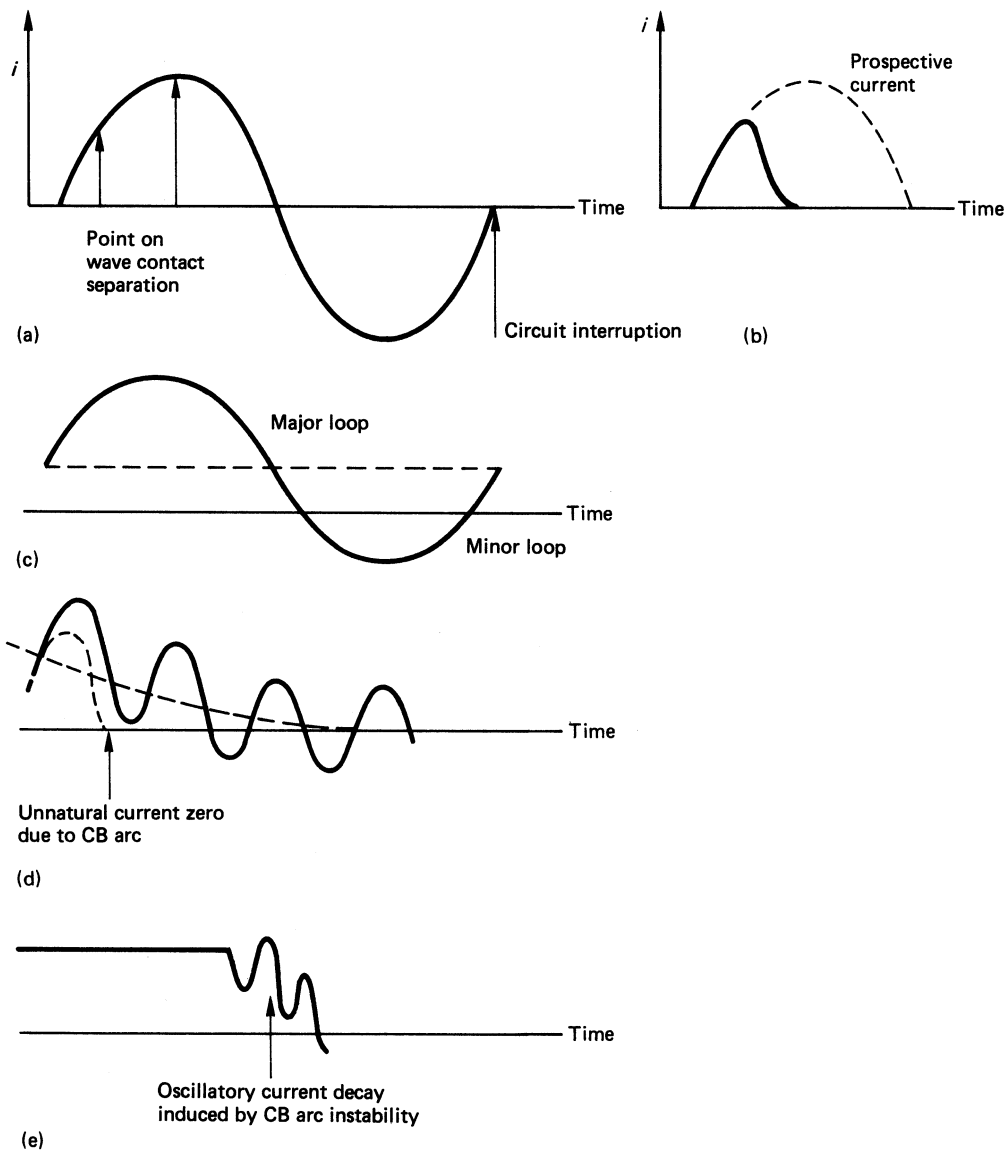

Corona on high voltage transmission lines constitute a continuous power loss which for long-distance transmission may be substantial and economically undesirable. Furthermore, such corona can cause a deterioration of insulating materials through the combined action of the discharges (ion bombardment) and the effect of chemical compounds (e.g. ozone and nitrogen oxides) formed in the discharge on the surface.

Arc discharges are used in high pressure lamps, gas lasers, welding, and arc heaters and also occur in current-interruption devices. The distinction between the needs of the two classes of applications is that for lamps and heaters the arc needs to be stably sustained whereas for circuit interruption the arc needs to be extinguished in a controlled manner. The implication is that, when for the former applications an a.c. supply is used, the arc thermal inertia needs to be relatively long compared with the electrical inertia of the network (e.g. to minimise lamp flicker). For circuit-interruption applications the opposite is required in order to accelerate arc extinction and provide efficient current interruption. Such applications require that a number of different current waveforms (*Figure 2.40*) should be interruptible in a controlled manner. High voltage a.c. networks need to be interrupted as the current passes naturally through zero to avoid excessive transient voltages being produced by the inductive nature of such networks. Low voltage, domestic type networks benefit from interruption via the current limiting action of a rapidly lengthening arc. High voltage d.c. network interruption relies upon the arc producing controlled instabilities to force the current artificially to zero.

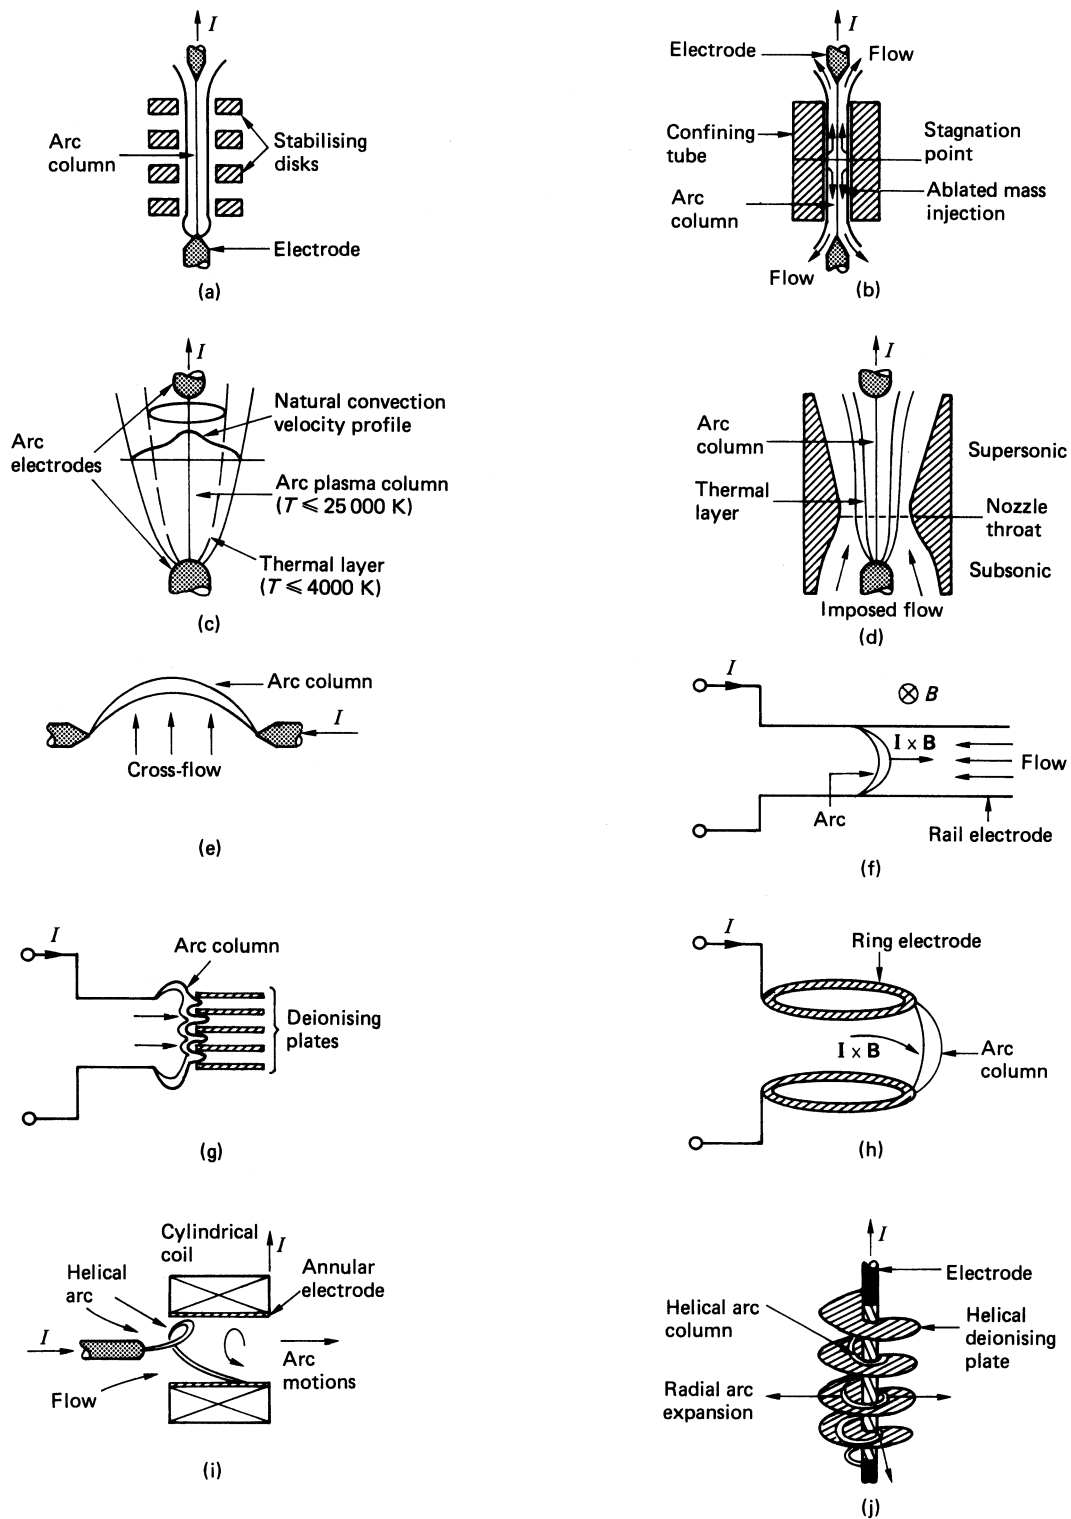

The arc discharges which are utilised for these applications are configured in a number of different ways. Some basic forms are shown in *Figure 2.41*. These may be divided into two major categories corresponding to the symmetry of the arc. Axisymmetrical arcs include those which are free burning vertically (so that symmetry is maintained by buoyancy forces) wall stabilised arcs, ablation stabilised arcs (which essentially represent arcs in fuses) and axial convection controlled arcs (which are used for both gas heating, welding and high voltage circuit interruption). Non-axisymmetric arcs include the crossflow arc, the linearly driven electromagnetic arc (which has potential for the electromagnetic drive of projectiles or by driving the arc into deionising plates for circuit interruption), the rotary driven electromagnetic arc (which may be configured either between ring electrodes and used for circuit interruption, or helically and used both for gas heating and circuit interruption) and the spiral arc with wall stabilisation.

**Figure 2.39** Arc current–voltage characteristics for a.c. conditions having different thermal/electrical inertia ratios: (1) thermal  $\ll$  electrical inertia (d.c. case); (2) thermal  $\approx$  electrical inertia; (3) thermal  $\gg$  electrical inertia (e.g. high frequency, resistive case)

### 3.1 Introduction

In an electrical network, electrical energy is conveyed from *sources* to an array of interconnected *branches* in which energy is converted, dissipated or stored. Each branch has a characteristic voltage–current relation that defines its *parameters*. The analysis of networks is concerned with the solution of source and branch currents and voltages in a given *network configuration*. Basic and general network concepts are discussed in Section 3.2. Section 3.3 is concerned with the special techniques applied in the analysis of power-system networks.

## 3.2 Basic network analysis

### 3.2.1 Network elements

Given the sources (generators, batteries, thermocouples, etc.), the network configuration and its branch parameters, then the network solution proceeds through network equations set up in accordance with the Kirchhoff laws.

#### 3.2.1.1 Sources

In most cases a source can be represented as in Figure 3.1(a) by an electromotive force (e.m.f.)  $E_0$  acting through an internal series impedance  $Z_0$  and supplying an external 'load'  $Z$  with a current  $I$  at a terminal voltage  $V$ . This is the Helmholtz–Thevenin *equivalent voltage generator*. As regards the load voltage  $V$  and current  $I$ , the source could equally well be represented by the Helmholtz–Norton *equivalent current generator* in Figure 3.1(b), comprising a source current  $I_0$  shunted by an internal admittance  $Y_0$  which is effectively in parallel with the load of admittance  $Y$ . Comparing the two forms for the same load current  $I$  and terminal voltage  $V$  in a load of impedance  $Z$  or admittance  $Y = 1/Z$ , we have:

Voltage generator	Current generator
$V = E_0 - IZ_0$	$I = I_0 - VY_0$
$I = (E_0 - V)/Z_0$	$V = (I_0 - I)/Y_0$
$= E_0/Z_0 - V/Z_0$	$= I_0/Y_0 - I/Y_0$
$= I_0 - VY_0$	$= E_0 - IZ_0$

These are identical provided that  $I_0 = E_0/Z_0$  and  $Y_0 = 1/Z_0$ . The identity applies only to the *load* terminals, for internally the sources have quite different operating conditions. The two forms are *duals*. Sources with  $Z_0 = 0$  and  $Y_0 = 0$  (so that  $V = E_0$  and  $I = I_0$ ) are termed *ideal* generators.

#### 3.2.1.2 Parameters

When a real *physical* network is set up by interconnecting sources and loads by conducting wires and cables, all parts (including the connections) have associated electric and magnetic fields. A resistor, for example, has resistance as the

Figure 3.1 (a) Voltage and (b) current sources

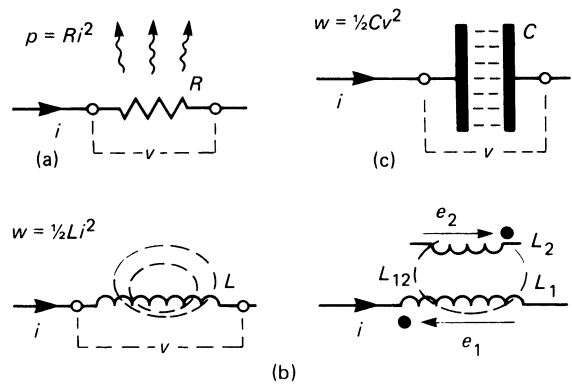

Figure 3.2 Pure parameters

prime property, but the passage of a current implies a magnetic field, while the potential difference (p.d.) across the resistor implies an electric field, both fields being present in and around the resistor. In the *equivalent* circuit drawn to represent the physical one it is usual to lump together the significant resistances into a limited number of *lumped* resistances. Similarly, electric-field effects are represented by lumped capacitance and magnetic-field effects by lumped inductance. The equivalent circuit then behaves like the physical prototype if it is so constructed as to include all significant effects.

The lumped parameters can now be considered to be free from 'residuals' and *pure* in the sense that simple laws of behaviour apply. These are indicated in Figure 3.2.

(a) *Resistance* For a pure resistance  $R$  carrying an instantaneous current  $i$ , the p.d. is  $v = Ri$  and the rate of heat production is  $p = vi = R^2 i^2$ . Alternatively, if the conductance  $G = 1/R$  is used, then  $i = Gv$  and  $p = vi = Gv^2$ . There is a constant relation

$$v = Ri = v/G; \quad i = Gv = v/R; \quad p = Ri^2 = Gv^2$$

(b) *Inductance* With a *self*-inductance  $L$ , the magnetic linkage is  $Li$ , and the source voltage is required only when the linkage changes, i.e.  $v = d(Li)/dt = L(di/dt)$ . An inductor stores in its magnetic field the energy  $w = \frac{1}{2} Li^2$ . The behaviour equations are

$$v = L(di/dt); \quad i = (1/L) \int v dt; \quad w = \frac{1}{2} Li^2$$

Two inductances  $L_1$  and  $L_2$  with a common magnetic field have a *mutual* inductance  $L_{12} = L_{21}$  such that an e.m.f. is induced in one when current changes in the other:

$$e_1 = L_{12}(di_2/dt); \quad e_2 = L_{21}(di_1/dt) \leftarrow$$

The direction of the e.m.f.s depends on the change (increase or decrease) of current and on the 'sense' in which the inductors are wound. The 'dot convention' for establishing the sense is to place a dot at one end of the symbol for  $L_1$ , and a dot at that end of  $L_2$  which has the same polarity as the dotted end of  $L_1$  for a given change in the common flux.

(c) *Capacitance* The stored charge  $q$  is proportional to the p.d. such that  $q = Cv$ . When  $v$  is changed, a charge must enter or leave at the rate  $i = dq/dt = C(dv/dt)$ . The electric-field energy in a charged capacitor is  $w = \frac{1}{2} Cv^2$ . Thus

$$i = C(dv/dt); \quad v = (1/C) \int i dt; \quad w = \frac{1}{2} Cv^2$$

It can be seen that there is a duality between the inductor and the capacitor. Some typical cases of the behaviour of pure parameters are given in Figures 2.3, 2.21 and 2.28.

A more concise representation of the behaviour of pure parameters uses the differential operator  $p$  for  $d/dt$  and the inverse  $1/p$  for the integral operator: then

- (a) Resistance:  $v = Ri = v/G$ ;  $i = Gv = (1/R)v$   
 (b) Self-inductance:  $v = Lp i$ ;  $i = (1/Lp)v$   
 Mutual inductance:  $e_1 = L_{12}p i_2$ ;  $e_2 = L_{21}p i_1$   
 (c) Capacitance:  $v = (1/Cp)i$ ;  $i = Cp v$

For the steady-state direct-current (d.c.) case,  $p = 0$ . For steady-state sinusoidal alternating current (a.c.),  $p = j\omega$ , giving for  $L$  and  $C$  the forms  $j\omega L$  and  $1/j\omega C$  where  $\omega$  is the angular frequency. In general,  $Lp$  and  $1/Cp$  are the operational impedance parameters.

### 3.2.1.3 Configuration

The assembly of sources and loads forms a network of branches that interconnect nodes (junctions) and form meshes. The seven-branch network shown in Figure 3.3 has five nodes (a, b, c, d, e) and four meshes (1, 2, 3, 4). Branch ab contains a voltage source; the other branches have (unspecified) impedance parameters. Inspection shows that not all the meshes are independent: mesh 4, for example, contains branches already accounted for by meshes 1, 2 and 3. Further, if one node (say, e) is taken as a *reference* node, the voltages of nodes a, b, c and d can be taken as their p.d.s with respect to node e. The network is then taken as having  $b = 7$  branches,  $m = 3$  independent meshes and  $n = 4$  independent nodes. In general,  $m = b - n$ .

## 3.2.2 Network laws

The behaviour of networks (i.e. the branch currents and node voltages for given source conditions) is based on the two Kirchhoff laws (Figure 3.4).

- (1) **Node law** The total current flowing into a node is zero,  $\sum i = 0$ . The sum of the branch currents flowing into a node must equal the sum of the currents flowing from it; this is a result of the 'particle' nature of conduction current.
- (2) **Mesh law** The sum of the voltages around a closed mesh is zero,  $\sum v = 0$ . A rise of potential in sources is absorbed by a fall in potential in the successive branches forming the mesh. This is the result of the nature of a network as an energy system.

Figure 3.3 Network configuration

Figure 3.4 The Kirchhoff laws

The Kirchhoff laws apply to all networks. Whether the evaluation of node voltages and mesh currents is tractable or not depends not only on the complexity of the network configuration but also on the branch parameters. These may be active or passive (i.e. containing or not containing sources), linear or non-linear. Non-linearity, in which the parameters are not constant but depend on the voltage and/or current magnitude and polarity, is in fact the normal condition, but where possible the minor non-linearities are ignored in order to permit the use of greatly simplified analysis and the principle of superposition.

### 3.2.2.1 Superposition

In a strictly linear network, the current in any branch is the sum of the currents due to each source acting *separately*, all other sources being replaced meantime by their internal impedances. The principle applies to voltages and currents, but not to powers, which are current-voltage products.

## 3.2.3 Network solution

A general solution presents the voltages and currents everywhere in the network; it is initiated by the solution simultaneously of the network equations in terms of voltages, currents and parameters.

The Kirchhoff laws can be applied systematically by use of the *Maxwell circulating-current* process. To each mesh is assigned a circulating current, and the laws are applied with due regard to the fact that certain branches, being common to two adjacent meshes, have net currents given by the superposition of the individual mesh currents postulated. Generalising, the network can be considered as either (i) a set of independent nodes with appropriate node-voltage equations, or (ii) a set of independent meshes with corresponding mesh-current equations.

### 3.2.3.1 Mesh-current equations

This is a formulation of the Maxwell circulating-current process. If source e.m.f.s are written as  $E$ , currents as  $I$  and impedances as  $Z$ , then for the  $m$  independent meshes

$$\begin{aligned} E_1 &= \mathcal{A}_1 Z_{11} + I_2 Z_{12} + \dots \mp I_m Z_{1m} \\ E_2 &= \mathcal{A}_2 Z_{21} + I_2 Z_{22} + \dots \mp I_m Z_{2m} \\ &\vdots \\ E_m &= \mathcal{A}_m Z_{m1} + I_2 Z_{m2} + \dots \mp I_m Z_{mm} \end{aligned}$$

Here  $Z_{11}, Z_{22}, \dots, Z_{mm}$  are the *self-impedances* of meshes 1, 2, ...,  $m$ , i.e. the total series impedance around each of the chosen meshes; and  $Z_{12}, Z_{pq}, \dots$  are the *mutual impedances* of meshes 1 and 2,  $p$  and  $q$ , ..., i.e. the impedances common to the designated meshes.

The mutual impedance is defined as follows.  $Z_{pq}$  is the p.d. per ampere of  $I_q$  in the direction of  $I_p$ , and  $Z_{qp}$  is the p.d. per ampere of  $I_p$  in the direction of  $I_q$ . The sign of a mutual impedance depends on the current directions chosen for the meshes concerned. If the network is co-planar (i.e. it can be drawn on a diagram with no cross-over) it is usual to select a single consistent direction—say clockwise—for each mesh current. In such a case the mutual impedances are *negative* because the currents are oppositely directed in the common branches.

### 3.2.3.2 Node-voltage equations

Of the network nodes, one is chosen as a reference node to which all other node voltages are related. The sources are represented by current generators feeding specified currents into their respective nodes and the branches are in terms of admittance  $Y$ . Then for the  $n$  independent nodes

$$I_a = V_a Y_{aa} + V_b Y_{ab} + \cdots + V_n Y_{an}$$

$$I_b = V_a Y_{ba} + V_b Y_{bb} + \cdots + V_n Y_{bn}$$

$$\vdots \quad \quad \quad \vdots \quad \quad \quad \vdots$$

$$I_n = V_a Y_{na} + V_b Y_{nb} + \cdots + V_n Y_{nn}$$

Here  $Y_{aa}, Y_{bb}, \dots, Y_{nn}$  are the *self-admittances* of nodes  $a, b, \dots, n$ , i.e. the sum of the admittances terminating on nodes  $a, b, \dots, n$ ; and  $Y_{ab}, Y_{ba}, \dots$  are the *mutual admittances*, those that link nodes  $a$  and  $b, p$  and  $q, \dots$ , respectively, and which are usually negative.

The mesh-current and node-voltage methods are general and basic; they are applicable to all network conditions. Simplified and auxiliary techniques are applied in special cases.

### 3.2.3.3 Techniques

**Steady-state conditions** Transient phenomena are absent. For d.c. networks the constant current implies absence of inductive effects, and capacitors (having a constant charge) are equivalent to an open circuit. Only resistance is taken into account, using the Ohm law.

For a.c. networks with sinusoidal current and voltage, complexor algebra, phasor diagrams, locus diagrams and symmetrical components are used, while for a.c. networks with periodic but non-sinusoidal waveforms harmonic analysis with superposition of harmonic components is employed.

**Transient conditions** Operational forms of stimuli and parameters are used and the solutions are found using Laplace transforms.

## 3.2.4 Network theorems

Network theorems can simplify complicated networks, facilitate the solution of specific network branches and deal with particular network configurations (such as two-ports). They are applicable to linear networks for which *superposition* is valid, and to any form (scalar, complexor, or operational) of voltage, current, impedance and admittance. In the following, the Ohm and Kirchhoff laws, and the reciprocity and compensation theorems, are basic; star-delta transformation and the Millman theorem are applied to network simplification; and the Helmholtz-*Thévenin* and Helmholtz-*Norton* theorems deal with specified branches of a network. Two-ports are dealt with in Section 3.2.5.

### 3.2.4.1 Ohm (Figure 3.2(a))

For a branch of resistance  $R$  or conductance  $G$ ,

$$I = \mathcal{E}/R = \mathcal{E}G; \quad V = \mathcal{E}/R = \mathcal{E}/G; \quad R = V/I = \mathcal{E}/G$$

Summation of resistances  $R_1, R_2, \dots$ , in series or parallel gives

$$\text{Series: } R = R_1 + R_2 + \cdots \Leftarrow \text{or } G = 1/(1/G_1 + 1/G_2 + \cdots) \Leftarrow$$

$$\text{Parallel: } R = 1/(1/R_1 + 1/R_2 + \cdots) \Leftarrow \text{or } G = G_1 + G_2 + \cdots \Leftarrow$$

The Ohm law is generalised for a.c. and transient cases by  $I = V/Z$  or  $I(p) = V(p)/Z(p)$ , where  $p$  is the operator  $d/dt$ .

### 3.2.4.2 Kirchhoff (Figure 3.4)

The node and mesh laws are

$$\text{Node: } i_1 + i_2 + \cdots \Leftarrow \sum i = 0$$

$$\text{Mesh: } e_1 + e_2 + \cdots \Leftarrow \sum e = 0 \quad \text{or} \quad \sum e = \sum iZ$$

### 3.2.4.3 Reciprocity

If an e.m.f. in branch P of a network produces a current in branch Q, then the same e.m.f. in Q produces the same current in P. The ratio of the e.m.f. to the current is then the *transfer impedance* or admittance.

### 3.2.4.4 Compensation

For given circuit conditions, any impedance  $Z$  in a network that carries a current  $I$  can be replaced by a generator of zero internal impedance and of e.m.f.  $E = -IZ$ . Further, if  $Z$  is changed by  $\Delta Z$ , then the effect on all other branches is that which would be produced by an e.m.f.  $-I\Delta Z$  in series with the changed branch. By use of this theorem, if the network currents have been solved for given conditions, the effect of a changed branch impedance can be found without re-solving the entire network.

### 3.2.4.5 Star-delta (Figure 3.5)

At a given frequency (including zero) a three-branch star impedance network can be replaced by a three-branch delta network, and conversely. For a star  $Z_a, Z_b, Z_c$  to be equivalent between terminals AB, BC, CA to a delta  $Z_1, Z_2, Z_3$ , it is necessary that

$$Z_a = Z_3 Z_1 / Z; \quad Z_1 = Z_a + Z_b + Z_a Z_b / Z_c$$

$$Z_b = Z_1 Z_2 / Z; \quad Z_2 = Z_b + Z_c + Z_b Z_c / Z_a$$

$$Z_c = Z_2 Z_3 / Z; \quad Z_3 = Z_c + Z_a + Z_c Z_a / Z_b$$

where  $Z = Z_1 + Z_2 + Z_3$ . The *general* star-mesh conversion concerns the replacement of an  $n$ -branch star by a mesh of  $\frac{1}{2}n(n-1)$  branches, but *not* conversely; and as the number of mesh branches is greater than the number of star branches when  $n > 3$ , the conversion is only rarely of use.

Figure 3.5 Star-delta conversion

Figure 3.6 The Millman theorem

### 3.2.4.6 Millman (Figure 3.6)

The Millman theorem is also known as the *parallel-generator* theorem. The common terminal voltage of a number of sources connected in parallel to a common load of impedance  $Z$  is  $V = I_{sc}Z_p$ , where  $I_{sc}$  is the sum of the short-circuit currents of the individual source branches and  $Z_p$  is the effective impedance of all the branches in parallel, including the load  $Z$ . If  $E_1$  and  $E_2$  are the e.m.f.s of two sources with internal impedances  $Z_1$  and  $Z_2$  connected in parallel to supply a load  $Z$ , and if  $I_1$  and  $I_2$  are the currents contributed by these sources to the load  $Z$ , then their common terminal voltage  $V$  must be

$$V = (I_1 + I_2)Z = [(E_1 - V)/Z_1 + (E_2 - V)/Z_2]Z$$

whence

$$V(1/Z + 1/Z_1 + 1/Z_2) = E_1/Z_1 + E_2/Z_2$$

The term in parentheses on the left-hand side of the equation is the effective admittance of all the branches in parallel. The right-hand side of the equation is the sum of the individual source short-circuit currents, totalling  $I_{sc}$ . Thus  $V = I_{sc}Z_p$ . The theorem holds for any number of sources.

### 3.2.4.7 Helmholtz–Thevenin (Figure 3.7)

The current in any branch  $Z$  of a network is the same as if that branch were connected to a voltage source of e.m.f.  $E_0$  and internal impedance  $Z_0$ , where  $E_0$  is the p.d. appearing across the branch terminals when they are open-circuited and  $Z_0$  is the impedance of the network looking into the branch terminals with all sources represented by their internal impedance.

In Figure 3.7, the network has a branch AB in which it is required to find the current. The branch impedance  $Z$  is removed, and a p.d.  $E_0$  appears across AB. With all sources replaced by their internal impedance, the network presents the impedance  $Z_0$  to AB. The current in  $Z$  when it is replaced into the original network is

$$I = E_0/(Z_0 + Z) \Leftarrow$$

The whole network apart from the branch AB has been replaced by an equivalent *voltage* source, resulting in the simplified condition of Figure 3.1(a).

### 3.2.4.8 Helmholtz–Norton

The Helmholtz–Norton theorem is the dual of the Helmholtz–Thevenin theorem. The voltage across any branch  $Y$  of a network is the same as if that branch were connected to a current source  $I_0$  with internal shunt admittance  $Y_0$ , where  $I_0$  is

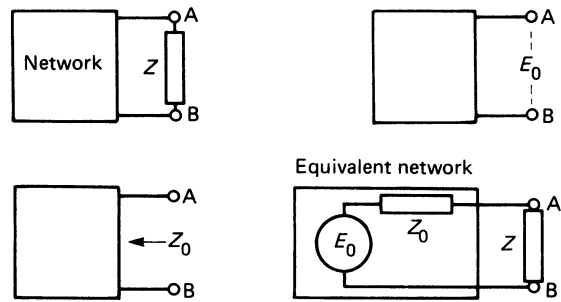

Figure 3.7 The Helmholtz–Thevenin theorem

the current between the branch terminals when short circuited and  $Y_0$  is the admittance of the network looking into the branch terminals with all sources represented by their internal admittance. Then across the terminals AB in Figure 3.7 the voltage is

$$V = I_0/(Y_0 + Y) \Leftarrow$$

Thus the whole network apart from the branch AB has been replaced by an equivalent *current* source, i.e. the system in Figure 3.1(b).

## 3.2.5 Two-ports

In power and signal transmission, input voltage and current at one port (i.e. one terminal-pair) yield voltage and current at another port of the interconnecting network. Thus in Figure 3.8a voltage source at the input port 1 delivers to the passive network a voltage  $V_1$  and a current  $I_1$ . The corresponding values at the output port 2 are  $V_2$  and  $I_2$ .

### 3.2.5.1 Lacour

According to the theorem originated by Lacour, any passive linear network between two ports can be replaced by a two-mesh or T network, and in general no simpler form can be found. Such a result is obtained by iterative star–delta conversion to give the T equivalent; by one more star–delta conversion the  $\Pi$ -equivalent is obtained (Figure 3.9). In general, the equivalent networks are asymmetric; in some cases, however, they are symmetric. It can be shown that a passive two-port has the input and output voltages and currents related by

$$V_1 = AV_2 + BI_2 \quad \text{and} \quad I_1 = CV_2 + DI_2$$

where  $ABCD$  are the general two-port parameters, constants for a given frequency and with  $AD - BC = 1$ . The conventions for voltage polarity and current direction are those given in Figure 3.8.

Figure 3.8 Two-port network

Figure 3.9 T and Π two-ports

### 3.2.5.2 T network

Consider the asymmetric T in Figure 3.9. Application of the Kirchhoff laws gives

$$I_1 = I_2 + (V_2 + I_2 Z_2)Y = V_2 Y + I_2(1 + YZ_2) \Leftarrow \\ V_1 = V_2(1 + YZ_1) + I_2(Z_1 + Z_2 + Z_1 Z_2 Y) \Leftarrow$$

Hence in terms of the series and parallel branch components

$$A = 1 + YZ_1 \\ B = Z_1 + Z_2 + Z_1 Z_2 Y \\ C = Y \\ D = 1 + YZ_2$$

Multiplication shows that  $AD - BC = 1$ .

For the symmetric T with  $Z_1 = Z_2 = \frac{1}{2}Z$ ,

$$A = 1 + \frac{1}{2}YZ = D; \quad B = Z + \frac{1}{4}YZ^2; \quad C = Y$$

### 3.2.5.3 Π network

In a similar way, the general parameters for the asymmetric case are

$$A = 1 + Y_2 Z; \quad B = Z; \quad C = Y_1 + Y_2 + Y_1 Y_2 Z; \quad D = 1 + Y_1 Z$$

which reduce with symmetry to

$$A = 1 + \frac{1}{2}YZ = D; \quad B = Z; \quad C = Y + \frac{1}{4}Y^2 Z$$

The values of the  $ABCD$  parameters, in matrix form,

$$\begin{pmatrix} A & B \\ C & D \end{pmatrix}$$

are set out in Table 3.1 for a number of common cases.

### 3.2.5.4 Characteristic impedance

If the output terminals of a two-port are closed through an impedance  $V_2/I_2 = Z_0$ , and if the input impedance  $V_1/I_1$  is then also  $Z_0$ , the quantity  $Z_0$  is the *characteristic impedance*. Consider a symmetrical two-port ( $A = D$ ) so terminated: if  $V_1/I_1$  is to be  $Z_0$  we have

$$\frac{V_1}{I_1} = \frac{V_2 A + I_2 B}{V_2 C + I_2 A} = \frac{V_2(A + B/Z_0)}{I_2(A + CZ_0)} = Z_0 \frac{A + B/Z_0}{A + CZ_0}$$

which is  $Z_0$  for  $B/Z_0 = CZ_0$ . Thus the characteristic impedance is  $Z_0 = \sqrt{B/C}$ . The same result is obtainable from the input impedances with the output terminals first open circuited ( $I_2 = 0$ ) giving  $Z_{oc}$ , then short circuited ( $V_2 = 0$ ) giving  $Z_{sc}$ : thus

$$Z_{oc} = A/C; \quad Z_{sc} = B/A; \quad Z_0 = \sqrt{Z_{oc} Z_{sc}} = \sqrt{B/C} \Leftarrow$$

### 3.2.5.5 Propagation coefficient

The parameters  $ABCD$  are functions of frequency, and  $Z_0$  is a complex operator. For the  $Z_0$  termination of a symmetrical two-port (for which  $A^2 - BC = 1$ ) the input/output voltage or current ratio is

$$V_1/V_2 = I_1/I_2 = A + \sqrt{BC} = A + \sqrt{A^2 - 1} \Leftarrow \\ = \exp(\gamma) = \exp(\alpha + j\beta) \Leftarrow$$

The magnitude of  $V_1$  exceeds that of  $V_2$  by the factor  $\exp(\alpha)$  and leads it by the angle  $\beta$ , where  $\alpha$  is the *attenuation coefficient*,  $\beta$  is the *phase coefficient* and the combination  $\gamma = \alpha + j\beta$  is the *propagation coefficient*.

### 3.2.5.6 Alternative two-port parameters

There are other ways of expressing two-port relationships. For generality, both terminal voltages are taken as *applied* and both currents are *input* currents. With this convention it is necessary to write  $-I_2$  for  $I_2$  in the general parameters so far discussed. The mesh-current and node-voltage methods (Section 3.2.4) give  $V_1 = I_1 z_{11} + I_2 z_{12}$ , etc., and  $I_1 = \frac{1}{Z_{11}} V_1 + \frac{1}{Z_{12}} V_2$ , etc., respectively. A further method relates  $V_1$  and  $I_2$  to  $I_1$  and  $V_2$  by hybrid (impedance and admittance) parameters. The four relationships are then obtained as follows:

General	Impedance
$\begin{pmatrix} V_1 \\ I_1 \end{pmatrix} = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} V_2 \\ -I_2 \end{pmatrix}$	$\begin{pmatrix} V_1 \\ V_2 \end{pmatrix} = \begin{pmatrix} z_{11} & z_{12} \\ z_{21} & z_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ I_2 \end{pmatrix}$
Admittance	Hybrid
$\begin{pmatrix} I_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} y_{11} & y_{12} \\ y_{21} & y_{22} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \end{pmatrix}$	$\begin{pmatrix} V_1 \\ I_2 \end{pmatrix} = \begin{pmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{pmatrix} \begin{pmatrix} I_1 \\ V_2 \end{pmatrix}$

If the networks are passive, then  $z_{12} = z_{21}$ ,  $y_{12} = y_{21}$  and  $h_{12} = -h_{21}$ . If, in addition, the networks are symmetrical, then  $A = D$ ,  $z_{11} = z_{22}$  and  $y_{11} = y_{22}$ . If the networks are active (i.e. they contain sources), then reciprocity does not apply and there is no necessary relation between the terms of the  $2 \times 2$  matrix.

## 3.2.6 Network topology

In multibranch networks the solution process is aided by representing the network as a graph of nodes and interconnections. The topology is the scheme of interconnections. A network is planar if it can be drawn on a closed spherical (or plane) surface without cross-overs. A non-planar network cannot be so drawn: a single cross-over can be eliminated if the network is drawn on a more complicated surface resembling a doughnut, and more cross-overs require closed surfaces with more holes.

The nomenclature employed in topology is as follows.

**Graph** A diagram of the network showing all the nodes, with each branch represented by a plain line.

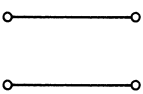

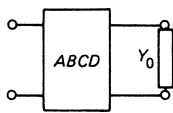

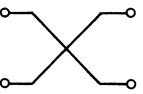

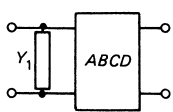

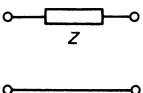

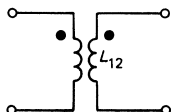

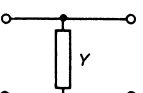

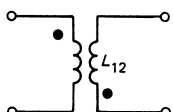

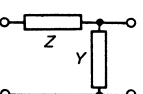

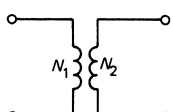

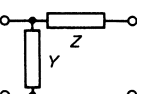

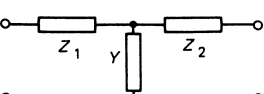

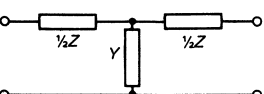

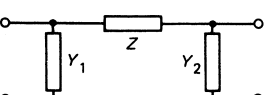

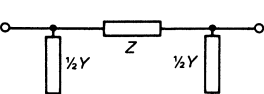

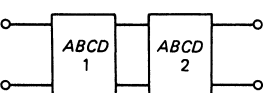

**Tree** Any arrangement of branches that connects all nodes together without forming loops. A *tree branch* is one branch of such a tree.

**Link** A branch that, added to a tree, completes a closed loop.

**Tie set** A loop of branches with one a link and the others tree branches.

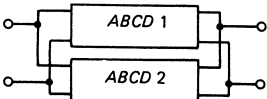

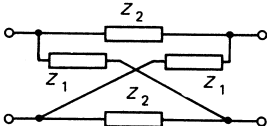

**Cut set** A set of branches comprising one tree branch, the other branches being tree links. A cut set dissociates two main portions of a network in such a way that replacing any one element destroys the dissociation.

**Table 3.1** General **ABCD** two-port parameters

Network	Matrix	Network	Matrix
	Direct connection $\begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}$		Loaded network $\begin{pmatrix} A + \mathcal{B}Y_0 & \mathcal{B} \\ C + \mathcal{D}Y_0 & \mathcal{D} \end{pmatrix}$
	Cross-connection $\begin{pmatrix} -1 & 0 \\ 0 & -1 \end{pmatrix}$		Shunted network $\begin{pmatrix} A & \mathcal{B} \\ C + \mathcal{A}Y_1 & \mathcal{D} + \mathcal{B}Y_1 \end{pmatrix}$

	Symmetrical Π network $\begin{pmatrix} 1 + \mathcal{A}Z/2 & Z \\ Y(1 + \mathcal{A}Z/4) & 1 + \mathcal{A}Z/2 \end{pmatrix}$		
	Cascaded networks $\begin{pmatrix} A_1A_2 + \mathcal{B}_1C_2 & A_1B_2 + \mathcal{B}_1D_2 \\ A_2C_1 + \mathcal{C}_2D_1 & B_2C_1 + \mathcal{D}_1D_2 \end{pmatrix}$		

cont'd

Table 3.1 (continued)

Network	Matrix
	<p>Parallel networks</p> $\begin{pmatrix} (A_1 B_2 + A_2 B_1)/(B_1 + B_2) & B_1 B_2/(B_1 + B_2) \\ C_1 + C_2 + \frac{(A_1 - A_2)(D_1 - D_2)}{B_1 + B_2} & \frac{B_1 D_2 + B_2 D_1}{B_1 + B_2} \end{pmatrix}$
	<p>Symmetrical lattice network</p> $\begin{pmatrix} (Z_1 + Z_2)(Z_1 - Z_2) & 2Z_1 Z_2/(Z_1 - Z_2) \\ 2/(Z_1 - Z_2) & (Z_1 + Z_2)/(Z_1 - Z_2) \end{pmatrix}$

Before setting up the equations for network solution, some guide is necessary in forming the proper number of independent equations. Given the network (a) in Figure 3.10, the first step is to draw the graph (b). Two of its possible trees are shown in (c). The trees are then used to set up the equations.

### 3.2.6.1 Network equations

**Voltage** The network diagram for the upper tree in Figure 3.10(c) is drawn in (d). Specifying the tree-branch voltages specifies also the voltages across the links. It is convenient to choose  $r$  as a reference node, leaving  $n-1$  independent nodes requiring  $n-1$  voltage equations.

**Current** A tree has no closed paths. As the links are added with specified currents, each creates one loop. Then the sum of the links  $m$  is the number of currents to be evaluated. For a network of  $b$  branches and  $n$  independent nodes, the number of independent meshes is  $m = b - n$ .

Figure 3.10 Network topology

Figure 3.11 Conversion to a passive network

### 3.2.6.2 Ports

It is often helpful to place the sources outside the network and to regard their connections to the (now passive) remainder as ports. Again, branches of interest can be taken outside and used to terminate ports, as in Figure 3.11.

A multiport network (Figure 3.12) has the following characteristic definitions:

- (a) All ports but one are open-circuited: a voltage  $V_1$  is applied to port 1 and a current  $I_1$  flows into it. Then  $V_1/I_1$  is the *open-circuit (o.c.) driving-point impedance*

Figure 3.12 A multiport network

- at port 1,  $V_k/I_1$  is the *o.c. transfer impedance* from port 1 to port  $k$ , and  $V_k/V_1$  is the *o.c. voltage ratio* of port  $k$  to port 1.
- (b) All ports but one are short circuited: a current  $I_1$  (requiring a voltage  $V_1$ ) is fed in at port 1. Then  $I_1/V_1$  is the *short-circuit (s.c.) driving-point admittance* at port 1,  $I_k/V_1$  is the *s.c. transfer admittance* from port 1 to port  $k$ , and  $I_k/I_1$  is the *s.c. current ratio* of port  $k$  to port 1.

### 3.2.7 Steady-state d.c. networks

The steady state implies that energy storage in electric and magnetic fields does not change, and only the resistance is significant. In *Figure 3.13* a source of constant e.m.f.  $E$  and internal resistance  $r$  provides a current  $I$  at terminal voltage  $V$  to a network represented by an equivalent resistance  $R$ . On open circuit ( $R = \infty$ ),  $I = 0$  and  $V = E$ . As  $R$  is reduced the source provides a current  $I = E/(R + r) = (E - V)/r$ . The greatest output power  $P = VI$  occurs for the condition  $R = r$ ; further reduction of  $R$  reduces the network power, down to a short-circuit condition for  $R = 0$  and  $V = 0$  when the source power is dissipated entirely in  $r$ . The maximum-power condition is utilised only with sources whose power capability is very small.

### 3.2.8 Steady-state a.c. networks

An a.c. flows alternately in the specified *positive* direction and then in the *negative* direction in a circuit, repeating this cycle continuously. A graph of current or voltage to a time base shows the *waveform* as a succession of *instantaneous values*. In general there will be a maximum or *peak* value in both positive and negative half-periods where the current or voltage is greatest. The time for one complete *cycle* is the *period*  $T$ . The number of periods per second is the *frequency*  $f = 1/T$ .

An a.c. is produced by an alternating voltage. Two such quantities may have a difference of *phase*, to which a precise meaning can be given only when the quantities are both sinusoidal functions of time.

#### 3.2.8.1 Root-mean-square (r.m.s.) value

The numerical value assigned to an a.c. or voltage is normally defined in terms of mean power in a pure resistor. An a.c. of 1 A is that which produces heat energy at the same mean rate as a direct current of 1 A in the same non-reactive resistor. If  $i$  is the instantaneous value of an a.c. in a pure resistance  $R$ ,

**Table 3.2** Values of alternating quantities (peak =  $a$ )

Waveform	r.m.s.	Mean	$K_f$	$K_p$
Sinusoidal	$a/\sqrt{2}$	$a(2/\pi)$	1.11	1.41
Half-wave rectified sine	$a/2$	$a/\pi$	1.57	2.0
Full-wave rectified sine	$a/\sqrt{2}$	$a(2/\pi)$	1.11	1.41
Rectangular	$a$	$a$	1.0	1.0
Triangular	$a/\sqrt{3}$	$a/2$	1.16	1.73

the heat developed in a time element  $dt$  is  $dw = i^2 R dt$ . The mean rate (i.e. the mean power) over a complete period  $T$  is

$$P = (1/T) \oint dw = (1/T) \oint i^2 R dt = I^2 R$$

and  $I$  is the r.m.s. value of the current. An *alternating voltage* is defined in a similar way; the instantaneous power is  $v^2/R$ , and the mean is  $V^2/R$  where  $V$  is the square root of the mean  $v^2$ .

In some cases the *peak* or the *mean* value of the current or voltage waveform is more significant, particularly with asymmetric, pulse or rectified waveforms. The value to be understood by the term 'mean' is then obvious. In the case of a symmetrical wave, the *half-period mean* value is intended, as the mean over a complete period is zero. *Table 3.2* gives the mean and r.m.s. values for a number of typical waveforms, together with the values of

Form factor  $K_f = \text{r.m.s.}/\text{mean}$

Peak factor  $K_p = \text{peak}/\text{r.m.s.}$

The techniques developed for the solution of steady-state a.c. networks depend on the waveform. One technique applies to purely sinusoidal quantities, another to periodic but non-sinusoidal waveforms. In each case the network is assumed to be linear so that the principle of superposition is valid.

### 3.2.9 Sinusoidal alternating quantities

For pure sinusoidal waveforms, a current can be expressed as a function of time,  $i = i_m \sin(2\pi ft) = i_m \sin(\omega t)$ , completing  $f$  cycles in 1 s with a period  $T = 1/f$ . The quantity  $2\pi f$  is contracted to  $\omega$ , the *angular frequency*. The sine-wave shape has the advantages that (i) it is mathematically simple and its integral and differential are both cosinusoidal, (ii) it is a waveform desirable for power generation, transmission and utilisation, and (iii) it lends itself to phasor and complexor representation.

The graph of a sinusoidal current or voltage of frequency  $f$  can be plotted to a time-angle base  $\omega t$  by use of trigonometric tables. Alternatively it can be represented by the projection of a line of length equal to the peak value and rotating counter-clockwise at angular speed  $\omega$  about one end O. A *stationary* line can represent the sine wave, particularly in relation to other sine waves of the same frequency but 'out of phase'. Two such waves, say  $v$  and  $i$  with peak values  $v_m$  and  $i_m$ , respectively, can be written

$$v = v_m \sin \omega t \quad \text{and} \quad i = i_m \sin(\omega t - \phi) \leftarrow$$

and drawn as in *Figure 3.14*, the phase difference or phase angle between them being  $\phi$  rad. Then two lines, OA and OB, having an angular displacement  $\phi$ , can represent the two waves in peak magnitude and relative time phase.

Although developed from rotating lines of peak-value length, it is more convenient to change the scale and treat the lengths as r.m.s. values. The processes of addition and

**Figure 3.13** A d.c. system

Figure 3.14 Phasors

subtraction of r.m.s. values are performed as if the lines were co-planar vector forces in mechanics. Physically, however, the lines are not vectors: they substitute for scalar quantities, alternating sinusoidally with time. They are termed *phasors*. Certain associated quantities, such as impedance, admittance and apparent power, can also be represented by directed lines, but as they are not sinusoids they are termed *complexors* or *complex operators*. Both phasors and complexors can be dealt with by application of the theory of complex numbers. The definitions concerned are listed below.

**Complexor** A generic term for a non-vector quantity expressed as a complex number.

**Phasor** A complexor (e.g. voltage or current) derived from a time-varying sinusoidal quantity and expressed as a complex number.

**Complex operator** A complexor derived for the ratio of two phasors (e.g. impedance and admittance); or a complexor which, operating on a phasor, gives another phasor (e.g.  $V = IZ$ , in which  $V$  and  $I$  are phasors, but  $Z$  is a complex operator).

### 3.2.9.1 Complexor algebra

The four arithmetic processes for complexors are applications of the theory of complex numbers. Complexor  $a$  in Figure 3.15 can be expressed by its magnitude  $a$  and its angle  $\theta$  (with respect to an arbitrary 'datum' direction (here taken as horizontal) as the simple *polar* form  $a = a \angle \theta$ . Alternatively it can be written as  $a = p + jq$ , the *rectangular* form, in terms of its projection  $p$  on the datum and  $q$  on a quadrature axis at right angles thereto:  $q$  (as a scalar magnitude along the datum) is rotated counter-clockwise by angle  $\frac{1}{2}\pi$ /rad ( $90^\circ$ ) by the operator  $j$ . Two successive operations by  $j$  (written as  $j^2$ ) give a rotation of  $\pi$ /rad ( $180^\circ$ ), making the original  $+q$  into  $-q$ , in effect a multiplication by  $-1$ . Three operations ( $j^3$ ) give  $-jq$  and four give  $+q$ . Thus any complexor can be located in the complex datum-quadrature plane. Further obvious forms are the *trigonometric*,  $a = a(\cos \theta + j \sin \theta)$ , and the *exponential*,  $a = a \exp(j\theta)$ . Summarising, the four descriptions are:

Polar:  $a = a \angle \theta$

Rectangular:  $a = p + jq$

Figure 3.15 Complexors

Exponential:  $a = a \exp(j\theta)$

Trigonometric:  $a = a(\cos \theta + j \sin \theta)$

where  $a = \sqrt{p^2 + q^2}$  and  $\theta = \arctan(q/p)$ .

Consider complexors  $a = p + jq = a \angle \alpha$  and  $b = r + js = b \angle \beta$ . The basic manipulations are:

**Addition**  $a + b = (p + r) + j(q + s)$

**Subtraction**  $a - b = (p - r) + j(q - s)$

**Multiplication** The exponential and polar forms are more direct than the rectangular or trigonometric:

$ab = (pr - qs) + j(qr + ps)$

$= ab \exp[j(\alpha + \beta)] = ab \angle (\alpha + \beta)$

**Division** Here also the angular forms are preferred:

$a/b = [(pr + qs) + j(qr - ps)]/(r^2 + s^2)$

$= (a/b) \exp[j(\alpha - \beta)] = (a/b) \angle (\alpha - \beta)$

**Conjugate** The conjugate of a complexor  $a = p + jq = a \angle \alpha$  is  $a^* = p - jq = a \angle (-\alpha)$ , the quadrature component (and therefore the angle) being reversed. Then

$aa^* = ab \angle (\alpha - \beta)$

$a^*b = ab \angle (\beta - \alpha)$

$a^*a = aa^* = a^2 = p^2 + q^2$

The last expression is used to 'rationalise' the denominator in the complexor division process.

### 3.2.9.2 Impedance and admittance operators

Sinusoidal voltages and currents can be represented by phasors in the expressions  $V = IZ = I/Y$  and  $I = VY = V/Z$ . Current and voltage phasors are related by multiplication or division with the complex operators  $Z$  and  $Y$ . Series resistance  $R$  and reactance  $jX$  can be arranged as a right-angled triangle of hypotenuse  $Z = \sqrt{R^2 + X^2}$  and the angle between  $Z$  and  $R$  is  $\theta = \arctan(X/R)$ . The relation between  $Z$  and  $Y$  for the same series network elements with  $Z = R + jX$  is

$$Y = \frac{1}{Z} = \frac{1}{R + jX} = \frac{R - jX}{(R + jX)(R - jX)} = \frac{R - jX}{R^2 + X^2} \\ = R/Z^2 - j(X/Z^2) = G - jB$$

where  $G$  and  $B$  are defined in terms of  $R$ ,  $X$  and  $Z$ . The *series* components  $R$  and  $X$  become *parallel* branches in  $Y$ , one a pure conductance, the other a pure susceptance. Further, a positive-angled impedance has, as inverse equivalent, a negative-angled admittance (Figure 3.16).

The impedance and phase angle of a number of circuit combinations are given in Table 3.3.

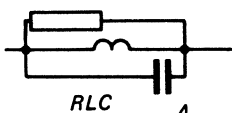

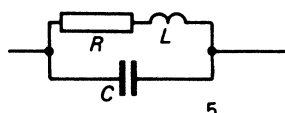

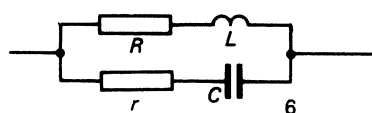

Figure 3.16 Impedance and admittance triangles

**Table 3.3** Impedance of network elements at angular frequency  $\omega$  (rad/s)

Impedance:	$Z = R + jX =  Z  \angle \theta$	$ Z  = \sqrt{(R^2 + X^2)}$	$\theta = \arctan(X/R)$			
Admittance:	$Y = 1/Z =  Y  \angle (-\theta)$	$ Y  = \sqrt{[(R/Z^2)^2 + (X/Z^2)^2]}$	$\theta = -\arctan(X/R)$			
						
$Z: R$ $\theta: 0$	$1/j\omega C$ $-\pi/2$	$j\omega L$ $+\pi/2$	$(C_1 + C_2)/j\omega C_1 C_2$ $-\pi/2$	$j\omega(L_1 + 2L_{12})$ $+\pi/2$	$R + j\omega L$ $\arctan(\omega L/R)$	$R + 1/j\omega C$ $-\arctan(j\omega CR)$
						
$Z: j(\omega L - 1/\omega C)$ $\theta: \pm \pi/2$	$R + j(\omega L - 1/\omega C)$ $\arctan[(\omega L - 1/\omega C)/R]$	$\omega LR \frac{\omega L + jR}{R^2 + \omega^2 L^2}$ $\arctan(R/\omega L)$	$R \frac{1 - j\omega CR}{1 + \omega^2 C^2 R^2}$ $-\arctan(\omega CR)$	$\frac{j\omega L}{1 - \omega^2 LC}$ $\pm \pi/2$		
						
$Z: \frac{1/R - j(\omega C - 1/\omega L)}{(1/R)^2 + (\omega C - 1/\omega L)^2}$	$\frac{R + j\omega[L(1 - \omega^2 LC) - CR^2]}{(1 - \omega^2 LC)^2 + \omega^2 C^2 R^2} \angle \pm$	$\frac{A + jB}{(R + r)^2 + (\omega L - 1/\omega C)^2}$ $A = Rr(R + r) + \omega^2 L^2 r + R/\omega^2 C^2$ $B = \omega Lr^2 - R^2/\omega C - (L/C)(\omega L - 1/\omega C)$ $\arctan(B/A)$				
$\theta: -\arctan[R(\omega C - 1/\omega L)]$		$\arctan \{ \omega[L(1 - \omega^2 LC) - CR^2]/R \}$				
Resonance conditions for LC networks numbered 1–6 above, for $\omega = \omega_0 = 1/\sqrt{LC}$ :						
(1) $ Z  = 0$ , $\theta = 0$ ; (2) $ Z  = R$ , $\theta = 0$ ; (3) $ Z  = \infty$ , $\theta = 0$ ; (4) $ Z  = R$ , $\omega = 0$ ;						
(5) $ Z  = L/CR$ , $\theta = -\arctan(\omega CR)$ for $R \ll \omega L$ ; (6) $ Z  = R$ (const.) for $R = r = \sqrt{L/C}$						

**Impedance and admittance loci** If the characteristics of a device or a circuit can be expressed in terms of an equivalent circuit in which the impedances and/or admittances vary according to some law, then the current taken for a given applied voltage (or the voltage for a given current) can be obtained graphically by use of an admittance or impedance locus diagram.

In Figure 3.17(a), let OP represent an impedance  $Z = R + jX$  and OQ the corresponding admittance  $Y = G - jB$ . Point Q is obtained from P by finding first the geometric inverse point  $Q'$  such that  $OQ' = 1/OP$  to scale, and then reflecting  $OQ'$  across the datum line to give OQ and thus a reversed angle  $-\theta$ , a process termed *complexor inversion*. If Z has successive values  $Z_1, Z_2, \dots$ , on the impedance locus, the corresponding admittances  $Y_1, Y_2, \dots$  lie on the admittance locus. The inversion process may be point-by-point, but in many cases certain propositions can reduce the labour:

(1) *Inverse of a straight line*—the geometric inverse of a straight line AB about a point O not on the line is a circle passing through O with its centre M on the perpendicular OC from O to AB (Figure 3.17(b)). Then  $A'$  is the geometric inverse of A,  $B'$  of B, etc.; also, A is the inverse of  $A'$ , B of  $B'$ , etc.

**Figure 3.17** Inversion

(2) *Inverse of a circle*—from the foregoing, the geometric inverse of a circle about a point O on its circumference is a straight line. If, however, O is not on the circumference, the inverse is a second circle between the same tangents; but the distances OM and  $OM'$  from the origin O to the centres M and  $M'$  of the circles are not inverses of each other.

The choice of scales arises in the inversion process: for example, the inverse of an impedance  $Z = 50 \angle 70^\circ \Omega$  is  $Y = 0.02 \angle (-70^\circ) \text{ S}$ . It is usually possible to decide on a scale by taking a salient feature (such as a circle diameter) as a basis.

### 3.2.9.3 Power

The instantaneous power delivered to a load is the product of the instantaneous voltage  $v$  and current  $i$ . Let  $v = v_m \sin \omega t$  and  $i = i_m \sin(\omega t - \phi)$  as in Figure 3.18(a); then the instantaneous power is

$$p = \frac{1}{2} v_m i_m [\cos \phi - \cos(2\omega t - \phi)]$$

This is a quantity fluctuating at angular frequency  $2\omega$  with, in general, excursions into negative power (i.e. that returned by the load to the source). Over an integral number of periods the mean power is

$$P = \frac{1}{2} v_m i_m \cos \phi = VI \cos \phi$$

where  $V$  and  $I$  are r.m.s. values.

Now resolve  $i$  into the active and reactive components

$$i_p = (i_m \cos \phi) \sin \omega t \text{ and } i_q = (i_m \sin \phi) \sin(\omega t - \frac{1}{2}\pi)$$

as in Figure 3.18(b); then the instantaneous power can be written

$$p = (v_m (i_m \cos \phi) \sin^2 \omega t - v_m (i_m \sin \phi) \sin \omega t \cos \omega t)$$

Over a whole number of periods the average of the first term is

$$P = \frac{1}{2} v_m i_m \cos \phi = VI \cos \phi$$

giving the *average* rate of energy transfer from source to load. The second term is a double-frequency sinusoid of average value zero, the energy flow changing direction rhythmically between source and load at a *peak* rate

$$Q = \frac{1}{2} v_m i_m \sin \phi = VI \sin \phi$$

The power conditions thus summarise to the following:

**Active power  $P$**  The *mean* of the instantaneous power over an integral number of periods giving the mean rate of energy transfer from source to load in watts (W).

**Reactive power  $Q$**  The *maximum* rate of energy interchange between source and load in reactive volt-amperes (var).

Figure 3.18 Active and reactive power

**Apparent power  $S$**  The product of the r.m.s. voltage and current in volt-amperes (V-A).

Both  $P$  and  $Q$  represent real power. The apparent power  $S$  is not a power at all, but is an arbitrary product  $VI$ . Nevertheless, because of the way in which  $P$  and  $Q$  are defined, we can write

$$P^2 + Q^2 = (VI)^2 (\cos^2 \phi + \sin^2 \phi) = (VI)^2$$

whence  $S = \sqrt{(P^2 + Q^2)}$ , a convenient combination of mean active power with peak power circulation.

**Complex power** The active and reactive powers can be determined for voltage and current phasors by

$$S = P \pm jQ = VI^* \text{ or } S = V^* I$$

using the conjugate of either  $I$  or  $V$ .

**Power factor** The ratio of active to apparent power,  $P/S = \cos \phi$  for sinusoidal conditions.

### 3.2.9.4 Resonance

A condition of resonance occurs when the load contains two forms of energy-storing element ( $L$  and  $C$ ) such that, at the frequency of operation, the two energies are equal. The reactive power requirements are then satisfied internally, as the inductor releases energy at the rate that the capacitor requires it. The source supplies only the active power demand of the energy-dissipating load components, the load externally appearing to be purely resistive.

**Acceptor resonance** The series  $RLC$  circuit in Figure 3.19(a) has, at angular frequency  $\omega$ , the impedance  $Z = R + jX$ , where  $X = \omega L - 1/\omega C$ , which for  $\omega = \omega_0 = 1/\sqrt{LC}$  is zero. The impedance is then  $Z = R$  and the input current has a maximum  $I_0 = V/R$ , conditions of *acceptor* resonance. Internally, large voltages appear across the reactive components, viz.

$$V_L = I_0 \omega L = V \omega_0 (L/R) \text{ and } V_C = I_0 (1/\omega_0 C) = V/\omega_0 (CR) \Leftarrow$$

The terms  $L/R$  and  $1/CR$  are the time constants of the reactive elements, and  $\omega_0 L/R$  is the  $Q$  value of a practical inductor of

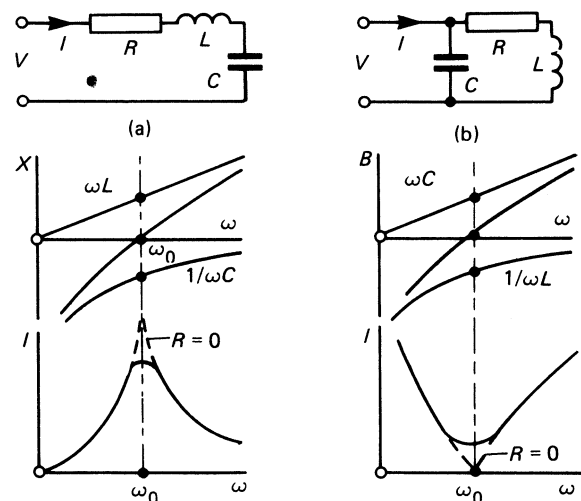

Figure 3.19 Resonance

inductance  $L$  and loss-resistance  $R$ . The  $Q$  value may be large (e.g. 100) for resonance at a high frequency.

**Rejector resonance** This occurs in a parallel combination of  $L$  and  $C$ , the energies circulating around the closed  $LC$  loop. If in Figure 3.19(b) the resistance  $R$  is zero, the terminal input admittance vanishes at angular frequency  $\omega_0 = 1/\sqrt{LC}$ , with  $\omega_0 C = 1/\omega_0 L$  and an input susceptance  $B = 0$ . Where the circuit contains resistance  $R$  the resonance conditions are less definite. Three possible criteria are: (i)  $\omega_0 = 1/\sqrt{LC}$ , (ii) the input admittance is a minimum, and (iii) the input admittance is purely conductive. All three criteria are satisfied simultaneously in the simple acceptor circuit, but differ in rejector conditions; however, where resonance is an intended property of the circuit, the differences are small.

Some expressions for resonance are given for six circuit arrangements in Table 3.3.

### 3.2.10 Non-sinusoidal alternating quantities

Periodic but non-sinusoidal currents occur: (i) with non-sinusoidal e.m.f. sources, (ii) with sinusoidal sources applied to non-linear loads, and (iii) with any combination of (i) and (ii).

#### 3.2.10.1 Fourier series

Any univalued periodic waveform can be represented as a summation of sine waves comprising a *fundamental*, where frequency is that of the periodic occurrence, and a series of *harmonic* waves of frequency 2, 3, ...,  $n$  times that of the fundamental. The Fourier series for a periodic function  $y = f(x)$  takes either of the following equivalent forms:

$$\begin{aligned} (1) \quad y &= c_0 + c_1 \sin(x + \alpha_1) + c_2 \sin(2x + \alpha_2) + \dots \Leftarrow \\ (2) \quad y &= c_0 + a_1 \cos x + a_2 \cos 2x + \dots + a_n \cos nx \\ &\quad + b_1 \sin x + b_2 \sin 2x + \dots + b_n \sin nx \end{aligned}$$

where  $c_0$  is a constant,  $c_n = \sqrt{(a_n^2 + b_n^2)}$  and  $\alpha_n = \arctan(a_n/b_n)$ . The coefficients of the terms are given by

$$\begin{aligned} c_0 &= (1/2\pi) \int_0^{2\pi} f(x) dx = \text{mean of the wave over one period} \\ a_n &= (1/\pi) \int_0^{2\pi} f(x) \cos nx dx \\ b_n &= (1/\pi) \int_0^{2\pi} f(x) \sin nx dx \end{aligned}$$

These can be evaluated mathematically for simple cases. The work may sometimes be reduced by inspection: thus  $c_0 = 0$  for a wave symmetrical about the baseline; or only odd-order harmonics may be present.

#### 3.2.10.2 Analysis

The series for a range of mathematically tractable waveforms are given in Table 1.10. For experimentally derived waveforms there are several methods, but none yields the amplitude of higher order harmonics without considerable labour, unless a computer program is available.

A particular harmonic, say the  $n$ th, may be found by superimposing  $n$  copies of the wave, displaced relatively by  $2\pi/n$ ,  $4\pi/n$ , ..., and adding the corresponding ordinates. The result is a wave of frequency  $n$  times that of the harmonic sought (with the addition, however, of harmonics of orders  $kn$  where  $k$  is an integer). The method gives also the phase angle  $\alpha_n$ .

Figure 3.20 Graphical harmonic analysis

A semi-graphical method is shown in Figure 3.20. The base of a complete period  $2\pi$  is divided into  $m$  parts, the corresponding ordinates being  $y_0, y_1, y_2, \dots, y_m$ . Construct axes OA and OB; set out the radii  $y_0$  to  $y_m$  ( $= y_0$ ) at angles  $0, 2\pi/m, 4\pi/m, \dots$ , from the axis OA. Then project the extremities horizontally ( $p$ ) and vertically ( $q$ ), and take the sum of the two sets of projections with due regard to their sign. Then for the  $n$ th harmonic

$$a_n = \frac{2}{\pi} \sum_{p=0}^{m-1} p \quad \text{and} \quad b_n = \frac{2}{\pi} \sum_{q=0}^{m-1} q$$

The labour is reduced if  $2\pi/m$  is a simple fraction of  $2\pi$ , for then some groups of radii are coincident.

#### 3.2.10.3 Power

The r.m.s. value of a current

$$i = I_0 + i_1 \sin(\omega t + \alpha_1) + i_2 \sin(2\omega t + \alpha_2) + \dots \Leftarrow$$

is obtained from the square root of the average squared value, resulting in

$$I = \sqrt{(I_0^2 + \frac{1}{2} i_1^2 + \frac{1}{2} i_2^2 + \dots)} = \sqrt{(I_0^2 + I_1^2 + I_2^2 + \dots)} \Leftarrow$$

where  $I_1 = i_1/\sqrt{2}$ ,  $I_2 = i_2/\sqrt{2}$ , etc., are the r.m.s. values of the individual harmonic components. The r.m.s. voltage is obtained in a similar way.

**Power** The instantaneous power  $p$  in a circuit with an applied voltage

$$v = v_1 \sin(\omega t + \alpha_1) + v_2 \sin(2\omega t + \alpha_2) + \dots \Leftarrow$$

producing a current

$$i = i_1 \sin(\omega t + \alpha_1 - \phi_1) + i_2 \sin(2\omega t + \alpha_2 - \phi_2) + \dots \Leftarrow$$

is the product  $vi$ : this includes (i) a series of the form

$$v_n i_n \sin(n\omega t + \alpha_n) \sin(n\omega t + \alpha_n - \phi_n) \Leftarrow$$

all terms of which have a fundamental-period average  $\frac{1}{2} v_n i_n \cos \phi_n$ ; and (ii) a series of the form

$$v_p i_q \sin(p\omega t + \alpha_p) \sin(q\omega t + \alpha_q - \phi_q) \Leftarrow$$

which, over a fundamental period, averages zero. Power is circulated by a voltage and a current of different frequencies, but the circulation averages zero. The mean (active) power is therefore

$$\begin{aligned} P &= \frac{1}{2} v_1 i_1 \cos \phi_1 + \frac{1}{2} v_2 i_2 \cos \phi_2 + \dots + \frac{1}{2} v_n i_n \cos \phi_n + \dots \Leftarrow \\ &= V_1 I_1 \cos \phi_1 + V_2 I_2 \cos \phi_2 + \dots + V_n I_n \cos \phi_n + \dots \Leftarrow \end{aligned}$$

where the capital letters denote component r.m.s. values. Thus the harmonics contribute power separately.

**Power factor** The ratio of the active power  $P$  to the apparent power  $S$  is

$$P/S = (V_1 I_1 \cos \phi_1 + \dots + V_n I_n \cos \phi_n + \dots) / VI$$

This may be less than unity even with all phase angles zero if the ratio  $V_n/I_n$  is not the same for each component. Where the applied voltage is a *pure sinusoid* of fundamental frequency there can be no harmonic powers; the active power is  $P = V_1 I_1 \cos \phi_1$ . Then

$$P/S = (V_1 I_1 \cos \phi_1) / V_1 I = (I_1/I) \cos \phi_1$$

where  $I_1/I = I_1/\sqrt{(I_1^2 + I_2^2 + \dots + I_n^2)} = \delta$ , the *distortion factor*. The overall power factor is consequently  $\delta \cos \phi_1$ . This is typical of circuits containing non-linear elements.

### 3.2.11 Three-phase systems

A symmetrical  $m$ -phase system has  $m$  source e.m.f.s, all of the same waveform and frequency, and displaced  $2\pi/m$  rad or  $1/m$  period in time;  $m$  is most commonly 3, but is occasionally 6, 12 or 24.

**Symmetric three-phase system** In Figure 3.21(a) the symmetric sinusoidal three-phase system has source e.m.f.s in phases A, B and C given by

$$e_a = e_m \sin \omega t; \quad e_b = e_m \sin(\omega t - 2\pi/3); \quad e_c = e_m \sin(\omega t - 4\pi/3) \Leftarrow$$

The instantaneous sum of the phase e.m.f.s (and also the phasor sum of the corresponding r.m.s. phasors  $E_a$ ,  $E_b$  and  $E_c$ ) is zero.

**Asymmetric three-phase system** The asymmetric system in Figure 3.21(b) has, in general, unequal phase voltages and phase displacements. Such asymmetry may occur in machines with unbalanced phase windings and in power supply systems when faults occur; the usual method of dealing with asymmetry is described in Section 3.2.12. Attention here is confined to the basic symmetric cases.

Figure 3.21 Three-phase systems

#### 3.2.11.1 Phase interlinkage

While individual phase sources can be used separately, they are generated in the same machine and are normally interlinked. Using r.m.s. phasors, let the e.m.f. in a generator winding XY be such as to drive positive current out at X: then X is positive to Y and its e.m.f.  $E_{XY}$  is represented by an arrow with its point at X. The e.m.f.  $E_{YX}$  between terminals Y and X is therefore  $-E_{XY}$ . Further, when two windings XN and YN have a common terminal N, the e.m.f.s are

$$X \text{ to } Y: E_{XY} = E_{XN} - E_{YN}$$

$$Y \text{ to } X: E_{YX} = E_{YN} - E_{XN} = -E_{XY}$$

Common phase interconnections are shown in Figure 3.22.

#### 3.2.11.2 Star

Let the phase e.m.f.s be  $E_{an}$ ,  $E_{bn}$  and  $E_{cn}$  with an arbitrary positive direction outward from the star-point N. Then the line e.m.f.s are

$$E_{ab} = E_{an} - E_{bn}; \quad E_{bc} = E_{bn} - E_{cn}; \quad E_{ca} = E_{cn} - E_{an}$$

These are of magnitude  $\sqrt{3}$  times that of a phase e.m.f., and provide a symmetric three-phase system of line e.m.f.s, with  $E_{ab}$  leading  $E_{an}$  by  $30^\circ$ . Thus  $E_l = \sqrt{3} E_{ph}$  and  $I_l = I_{ph}$ , the subscripts l and ph referring to line and phase quantities respectively.

Figure 3.22 Three-phase interconnections

## 3.2.11.3 Delta

The line-to-line e.m.f. is that of the phase across which the lines are connected. The line current is the difference of the currents in the phases forming the line junction, so that the relations for symmetric loading are  $E_l = E_{ph}$  and  $I_l = \sqrt{3} I_{ph}$ .

## 3.2.11.4 Interconnected star

A line-to-neutral e.m.f. comprises contributions from successive half-phases and sums to  $\frac{1}{\sqrt{3}}$  of a complete phase e.m.f. The line-to-line e.m.f. is  $\sqrt{3}$  times the magnitude of a complete phase e.m.f. and the line current is numerically equal to the phase current.

## 3.2.11.5 Power

The total power delivered to or absorbed by a polyphase system, be it symmetric and balanced or not, is the algebraic sum of the individual phase powers. Consider an  $m$ -phase system with instantaneous line currents  $i_1, i_2, \dots, i_m$ , the algebraic sum of which is zero by the Kirchhoff node law. Let the voltages of the input (or output) terminals, with reference to a common point X, be  $v_1 - v_X, v_2 - v_X, \dots, v_m - v_X$ ; then the instantaneous powers will be  $(v_1 - v_X)i_1, (v_2 - v_X)i_2, \dots, (v_m - v_X)i_m$ , which together sum to the total instantaneous power  $p$ . There is no restriction on the choice of X; it can be any of the terminals, say M. In this case  $v_m - v_X = v_m - v_m = 0$ , and the power summation has only  $m-1$  terms. The average power over a full period  $T$  is, therefore,

$$P = (1/T) \int_0^T [(v_1 - v_m)i_1 + \dots + (v_{m-1} - v_m)i_{m-1}] dt$$

The first term of the sum in brackets represents the indication of a wattmeter with  $i_1$  in its current circuit and  $v_1 - v_m$  across its volt circuit, i.e. connected between terminals 1 and M. It follows that three wattmeters can measure the power in a three-phase four-wire system, and two in a three-phase three-wire system. Some of the common cases are listed below.

- (1) *Three-phase, four-wire, load unbalanced*—The connections are shown in Figure 3.23(a). Wattmeters  $W_1, W_2$

Figure 3.23 Three-phase power measurement

and  $W_3$  measure the phase powers separately. The total power is the sum of the indications:

$$P = P_1 + P_2 + P_3$$

- (2) *Three-phase, four-wire, load balanced*—with the connections shown in Figure 3.23(a), all the meters read the same. Two of the wattmeters can be omitted and the reading of the remaining instrument multiplied by 3.
- (3) *Three-phase, three-wire, load unbalanced*—two wattmeters are connected with their current circuits in any pair of lines, as in Figure 3.23(b). The total power is the algebraic sum of the readings, regardless of waveform. A two-element wattmeter summates the power automatically; with separate instruments, one will tend to read reversed under certain conditions, given below.
- (4) *Three-phase, three-wire, load balanced*—with sinusoidal voltage and current the conditions in Figure 3.23(c) obtain. Wattmeters  $W_1$  and  $W_2$  indicate powers  $P_1$  and  $P_2$  where

$$P_1 = V_{ab}I_a \cos(30^\circ + \phi) = V_1 I_1 \cos(30^\circ + \phi)$$

$$P_2 = V_{cb}I_c \cos(30^\circ - \phi) = V_1 I_1 \cos(30^\circ - \phi)$$

The total active power  $P = P_1 + P_2$  is therefore

$$P = V_1 I_1 [\cos(30^\circ + \phi) + \cos(30^\circ - \phi)] = \sqrt{3} V_1 I_1 \cos \phi$$

where  $\cos \phi$  is the phase power factor. The algebraic difference is  $P_1 - P_2 = V_1 I_1 \sin \phi$ , whence the reactive power is given by

$$Q = \sqrt{3} V_1 I_1 \sin \phi = \sqrt{3} (P_1 - P_2)$$

and the phase angle can be obtained from  $\phi = \arctan(Q/P)$ . For  $\phi = 0$  (unity power factor) both wattmeters read alike; for  $\phi = 60^\circ$  (power factor 0.5 lag)  $W_1$  reads zero; and for lower lagging power factors  $W_1$  tends to read backwards.

The active power of a single phase has a double-frequency pulsation (Figure 3.18). For the asymmetric two-phase system under balanced conditions and a phase displacement of  $90^\circ$ , and for all symmetric systems with  $m = 3$  or more, the total power is constant.

## 3.2.11.6 Harmonics

Considering a symmetrical balanced system of three-phase non-sinusoidal voltages, and omitting phase displacements (which are in the context not significant), let the voltage of phase A be

$$v_a = v_1 \sin \omega t + v_2 \sin 2\omega t + v_3 \sin 3\omega t + \dots$$

Writing  $\omega t - \frac{2}{3}\pi$  and  $\omega t - \frac{4}{3}\pi$ , respectively, for phases B and C, and simplifying, we obtain

$$v_a = v_1 \sin \omega t + v_2 \sin 2\omega t + v_3 \sin 3\omega t + \dots$$

$$v_b = v_1 \sin(\omega t - \frac{2}{3}\pi) + v_2 \sin 2(\omega t - \frac{4}{3}\pi) + v_3 \sin 3\omega t + \dots$$

$$v_c = v_1 \sin(\omega t - \frac{4}{3}\pi) + v_2 \sin 2(\omega t - \frac{2}{3}\pi) + v_3 \sin 3\omega t + \dots$$

The fundamentals have a normal  $2\pi/3$  rad ( $120^\circ$ ) phase relation in the sequence ABC, as also do the 4th, 7th, 10th, ..., harmonics. The 2nd (and 5th, 8th, 11th, ...) harmonics have the  $2\pi/3$  rad phase relation but of reversed sequence ACB. The triplen harmonics (those of the order of a multiple of 3) are, however, co-phased and form a zero-sequence set.

The relation  $V_l = \sqrt{3} V_{ph}$  in a three-phase star-connected system is applicable only for sine waveforms. If harmonics are present, the line- and phase-voltage waveforms differ because of the effective phase angle and sequence of the harmonic components. The  $n$ th harmonic voltages to neutral in two successive phases AB are  $v_n \sin n\omega t$  and  $v_n \sin n(\omega t - \frac{2}{3}\pi)$ ,

and between the corresponding line terminals the  $n$ th harmonic voltage is  $2v_n \sin n(\frac{1}{3}\pi)$ . For triplen harmonics this is zero; hence no triplens are present in balanced line voltages because, in the associated phases, their components are equal and in opposition. In a balanced delta connection, again no triplens are present between lines: the delta forms a closed circuit to triplen circulating currents, the impedance drop of which absorbs the harmonic e.m.f.s.

### 3.2.12 Symmetrical components

Figure 3.21(a) shows the sine waves and phasors of a balanced symmetric three-phase system of e.m.f.s of sequence ABC. The magnitudes are equal and the phase displacements are  $2\pi/3$  rad. In Figure 3.21(b), the asymmetric sine waveforms have also the sequence ABC, but they are of different magnitudes and have the phase displacements  $\alpha$ ,  $\beta$  and  $\gamma$ . Problems of asymmetry occur in the unbalanced loading of a.c. machines and in fault conditions on power networks. While a solution is possible by the Kirchhoff laws, the method of *symmetrical components* greatly simplifies analysis.

Any set of asymmetric three-phase e.m.f.s or currents can be resolved into a summation of three sets of symmetrical components, respectively of positive phase-sequence (p.p.s.) ABC, negative phase-sequence (n.p.s.) ACB, and zero phase-sequence (z.p.s.). Use is made of the operator  $\alpha$ , resembling the  $90^\circ$  operator  $j$  (Section 3.2.9.1) but implying a counter-clockwise rotation of  $2\pi/3$  rad ( $120^\circ$ ). Thus

$$\alpha^2 = 1 \angle 120^\circ = \frac{1}{2}(-1 + j\sqrt{3})$$

$$\alpha^3 = 1 \angle 240^\circ = \frac{1}{2}(-1 - j\sqrt{3})$$

$$\alpha^4 = 1 \angle 360^\circ = 1 + j0$$

$$1 + \alpha + \alpha^2 = 0$$

A symmetric three-phase system has only p.p.s. components

$$E_a = E_{a+}; \quad E_b = \alpha^2 E_{a+}; \quad E_c = \alpha E_{a+}$$

whereas an asymmetric system (Figure 3.24) comprises the three sets

$$\text{z.p.s. } \psi \quad E_{a0}; \quad E_{b0} = E_{a0}; \quad E_{c0} = E_{a0}$$

$$\text{p.p.s. } \psi \quad E_{a+}; \quad E_{b+} = \alpha^2 E_{a+}; \quad E_{c+} = \alpha E_{a+}$$

$$\text{n.p.s. } \psi \quad E_{a-}; \quad E_{b-} = \alpha E_{a-}; \quad E_{c-} = \alpha^2 E_{a-}$$

where the subscripts 0, + and - designate the z.p.s., p.p.s. and n.p.s. components, respectively. The p.p.s. and the n.p.s. components sum individually to zero. Therefore, if the originating phasors  $E_a$ ,  $E_b$ ,  $E_c$  also sum to zero there are no z.p.s. components; if they do not, their residual is the sum of the three z.p.s. components.

The asymmetrical phasors have now been reduced to the sum of three sets of symmetrical components:

$$E_a = E_{a0} + E_{a+} + E_{a-}$$

$$E_b = E_{b0} + E_{b+} + E_{b-}$$

$$E_c = E_{c0} + E_{c+} + E_{c-}$$

The components are evaluated from the arbitrary identities

$$E_a = Z + P + N$$

$$E_b = Z + \alpha^2 P + \alpha N$$

$$E_c = Z + \alpha P + \alpha^2 N$$

where

$$Z = (E_a + E_b + E_c)/3$$

Figure 3.24 Symmetrical components

$$P = (E_a + \alpha E_b + \alpha^2 E_c)/3$$

$$N = (E_a + \alpha^2 E_b + \alpha E_c)/3$$

Figure 3.24 is drawn for an asymmetric system with voltages  $E_a = 200$ ,  $E_b = 100$  and  $E_c = 400$  V, and phase-displacement angles  $\delta = 90^\circ$ ,  $\beta = 120^\circ$  and  $\gamma = 150^\circ$ . In phasor terms,

$$E_a = 200 \angle 0^\circ = 200 + j0 \text{ V}$$

$$E_b = 100 \angle (-90^\circ) = 0 - j100 \text{ V}$$

$$E_c = 400 \angle 150^\circ = -346 + j200 \text{ V}$$

Then

$$Z = (200 - j100 - 346 + j200)/3 = -49 + j33 = E_{a0}$$

$$P = (200 + 87 + j50 + 347 + j200)/3 = 211 + j83 = E_{a+}$$

$$N = (200 - 87 + j50 - j400)/3 = 38 - j117 = E_{a-}$$

The summation  $E_{a0} + E_{a+} + E_{a-} = 200 + j0 = E_a$ . The p.p.s. and n.p.s. components of  $E_b$  and  $E_c$  are readily obtained.

#### 3.2.12.1 Power

In linear networks there is no interference between currents of different sequences. Thus p.p.s. voltages produce only p.p.s. currents, etc. The total power is therefore

$$P = P_a + P_b + P_c$$

$$= 3(V_0 I_0 \cos \phi_0 + V_+ I_+ \cos \phi_+ + V_- I_- \cos \phi_-)$$

This is equivalent to the more obvious summation of phase powers

$$P = V_a I_a \cos \phi_a + V_b I_b \cos \phi_b + V_c I_c \cos \phi_c$$

Symmetrical-component techniques are useful in the analysis of power-system networks with faults or unbalanced

loads: an example is given in Section 3.3.4. Machine performance is also affected when the machine is supplied from an asymmetric voltage system: thus in a three-phase induction motor the n.p.s. components set up a torque in opposition to that of the (normal) p.p.s. voltages.

### 3.2.13 Line transmission

Networks of small physical dimensions and operated at low frequency are usually considered to have a zero propagation time; a current started in a closed circuit appears at every point in the circuit simultaneously. In extended circuits, such as long transmission lines, the propagation time is significant and cannot properly be ignored.

The basics of energy propagation on an ideal loss-free line are discussed in another section. Propagation takes place as a voltage wave  $v$  accompanied by a current wave  $i$  such that  $v/i = z_0$  (the surge impedance) travelling at speed  $u$ . Both  $z_0$  and  $u$  are functions of the line configuration, the electric and magnetic space constants  $\epsilon_0$  and  $\mu_0$ , and the relative permittivity and permeability of the medium surrounding the line conductors. At the receiving end of a line of finite length, an abrupt change of the electromagnetic-field pattern (and therefore of the ratio  $v/i$ ) is imposed by the discontinuity unless the receiving-end load is  $z_0$ , a termination called the *natural load* in a power line and a *matching impedance* in a telecommunication line. For a non-matching termination, wave reflection takes place with an electromagnetic wave running back towards the sending end. After many successive reflections of rapidly diminishing amplitude, the system settles down to a steady state determined by the sending-end voltage, the receiving-end load impedance and the line parameters.

#### 3.2.13.1 A.c. power transmission

The steady-state condition considered is the transfer of a constant balanced apparent power per phase from a generator at the sending end (s) to a load at the receiving end (r) by a sinusoidal voltage and current at a frequency  $f = \omega/2\pi$ . The line has uniformly distributed parameters: a conductor resistance  $r$  and a loop inductance  $L$  effectively in series, and an insulation conductance  $g$  and capacitance  $C$  in shunt, all per phase and per unit length. The series impedance, shunt admittance and propagation coefficient per unit length are  $z = r + j\omega L$ ,  $y = g + j\omega C$  and  $\gamma = \sqrt{yz}$ , respectively. For a line of length  $l$  the overall parameters are  $zl = Z$ ,  $yl = Y$  and  $l\sqrt{yz} = \sqrt{YZ} = \gamma l$ . The solution for the receiving-end terminal conditions is in terms of  $\sqrt{YZ}$  and its hyperbolic functions as a two-port:

$$V_s = V_r A + I_r B = V_r \cosh(\sqrt{YZ}) + I_r z_0 \sinh(\sqrt{YZ}) \Leftarrow$$

$$I_s = V_r C + I_r D = V_r (1/z_0) \sinh(\sqrt{YZ}) + I_r \cosh(\sqrt{YZ}) \Leftarrow$$

Using the hyperbolic series (Section 1.2.2) and writing  $z_0 = \sqrt{Z/Y}$ , we obtain for a symmetrical line

$$A = 1 + YZ/2 + (YZ)^2/24 + \dots = D$$

$$B = Z[1 + YZ/6 + (YZ)^2/120 + \dots] \Leftarrow$$

$$C = Y[1 + YZ/6 + (YZ)^2/120 + \dots] \Leftarrow$$

The significance of the higher powers of  $YZ$  depends on: (i) the line configuration, (ii) the properties of the ambient medium, and (iii) the physical length of the line in terms of the wavelength  $\lambda = u/f$ . For air-insulated overhead lines the inductance is large and the capacitance small: the propagation velocity approximates to  $u = 3 \times 10^5$  km/s (corresponding to a wavelength  $\lambda = 6000$  km at 50 Hz), with a natural load  $z_0$

Figure 3.25 Transmission-line phasor diagram

of the order of 400–500  $\Omega$ . Cable lines have a low inductance and a large capacitance: the permittivity of the dielectric material and the presence of armouring and sheathing result in a propagation velocity around 200 km/s, a surge impedance below 100  $\Omega$ , and the possibility (in high-voltage cables) that the charging current may be comparable with the load current if the cable length exceeds 25–30 km.

For balanced three-phase power transmission, the general equations are applied for the line-to-neutral voltage, line current and phase power factor. Phasor diagrams for the load and no-load ( $I_r = 0$ ) receiving-end conditions for an overhead-line transmission are shown in Figure 3.25, with  $V_r$  as datum. On no load,  $V_s = V_r A$ , and as  $A$  has a magnitude less than unity and a small positive angle  $\alpha$ , the phasor  $V_r A$  is smaller than  $V_r$  and leads it by angle  $\alpha$ : thus  $V_r > V_s$ , the *Ferranti effect*. For the loaded condition,  $I_r B$  is added to  $V_r A$  to give  $V_s$ . Similarly  $V_r C$  is added to  $I_r D$  to obtain  $I_s$ .

The product  $V_r I_r = I_r (V_s - V_r A)$  is the receiving-end complex apparent power  $S_r$ . Let  $V_s$  lead  $V_r$  by angle  $\theta$ ; then the receiving-end load has the active and reactive powers  $P_r$  and  $Q_r$  given by

$$P_r = (V_s V_r / B) \cos(\theta - \beta) - (V_r^2 A / B) \cos(\beta\psi - \alpha) \Leftarrow$$

$$Q_r = (V_s V_r / B) \sin(\theta - \beta) + (V_r^2 A / B) \sin(\beta\psi - \alpha) \Leftarrow$$

where  $\alpha$  and  $\beta\psi$  are the angles in the complexors  $A$  and  $B$ . The importance of  $B$  (roughly the overall series impedance) is clear.

**Line chart** Operating charts for a transmission circuit can be drawn to relate graphically  $V_s$ ,  $V_r$ ,  $P_r$  and  $Q_r$ , using the appropriate overall  $ABCD$  parameters (e.g. with terminal transformers included).

**Receiving-end chart** A receiving-end chart gives active and reactive power at the receiving end for  $V_r$  constant (Figure 3.26(a)). The co-ordinates ( $x$ ,  $y$ ) and the radius ( $r$ ) of the constant-voltage circles are

$$x = -V_r^2 (A/B) \cos(\beta\psi - \alpha) \Leftarrow$$

$$y = -V_r^2 (A/B) \sin(\beta\psi - \alpha) \Leftarrow$$

$$r = V_s V_r / B$$

where  $A$  and  $B$  are scalar magnitudes, and  $\alpha$  and  $\beta\psi$  the angles in  $A$  and  $B$ . For a given  $V_r$  the chart comprises a family of concentric circles, each corresponding to a particular  $V_s$ . If a given receiving-end load is located by its active and reactive power components,  $V_s$  is obtained from the corresponding  $V_s$  circle.

Figure 3.26 Line charts

**Sending-end chart** For a given  $V_s$  the sending-end chart comprises a family of circles as shown in Figure 3.26(b), each circle corresponding to a particular  $V_r$ . Load points outside the envelope of these circles cannot be supplied at the  $V_s$  for which the chart is drawn.

### 3.2.13.2 Short line

For an overhead interconnector line the capacitive shunt admittance is neglected, reducing the general parameters to  $A=D=1$ ,  $B=Z=R+jX$  and  $C=0$ . The operating conditions are those in Figure 3.27, with a receiving-end voltage  $V_r$  (taken as reference phasor), a sending-end voltage  $V_s$  and a load current  $I$  at a lagging phase angle  $\phi$  with respect to  $V_r$  and having active and reactive components respectively  $I_p$  and  $I_q$ . Then

$$\begin{aligned} V_s &= V_r + (I_p - jI_q)(R + jX) \\ &= V_r + (I_p R + I_q X) + j(I_p X - I_q R) = V_r + v + ju \end{aligned}$$

To a close approximation,  $v$  is the difference of the voltages  $V_s$  and  $V_r$ , while  $u$  determines their phase difference (or transmission angle). The regulation and angle are therefore  $v/V_s$  p.u. and  $\theta = \arctan(u/V_s)$  rad.

Suppose that  $V_r = V_s$ ; then  $v=0$  giving  $I_q = -I_p(R/X)$ , and  $u = I_p X [1 + (R/X)^2]$  giving  $\theta = \arctan(I_p/V_s) [1 + (R/X)^2]$ . The consequences are that (i) for a receiving-end active power  $P$  the load must be able to absorb a leading

Figure 3.27 Operating conditions for a short transmission line

reactive power  $Q = P(R/X)$ , and (ii) the transmission angle is determined largely by  $X$ . If  $R/X = 0.5$ , typical of an overhead line, then  $Q = 0.5P$  and  $\theta = \arctan[1.25 X(I_p/V_s)]$ . With interconnector cables the  $R/X$  ratio is usually greater than unity and shunt capacitance current is no longer negligible.

Independent adjustment of  $V_s$  and  $V_r$  is not feasible, and effective load control requires adjustment of  $v$  (e.g. by transformer taps) and of  $u$  (e.g. by quadrature boosting).

### 3.2.14 Network transients

Energy cannot be instantaneously converted from one form to another, although the time needed for conversion can be very short and the conversion rate (i.e. the power) high. Change between states occurs in a period of *transience* during which the system energies are redistributed in accordance with the energy-conservation principle (Section 1.3.1). For example, in a simple series circuit of resistance  $R$ , inductance  $L$  and capacitance  $C$  connected to a source of instantaneous voltage  $v$ , the corresponding rates of energy input, dissipation (in  $R$ ) and storage (in  $L$  and  $C$ ) are related by

$$p = vi = Ri + [L(di/dt)i + (q/C)i] \Leftarrow$$

Dividing by the common current  $i$  and writing the capacitor charge  $q$  as the time-integral of the current gives the voltage equation

$$v = Ri + L(di/dt) + (1/C) \int i dt$$

and any changes in the parameters or in the applied voltage demand changes in the distribution of the circuit energy. The integro-differential equation can be solved to yield both steady-state and transient conditions.

In practical circuits the system may be too complex for such a direct solution; the following methods may then be attempted:

- (1) formal mathematics for simple cases with linear parameters;
- (2) simplification, e.g. by linearising parameters or by neglecting second-order terms;
- (3) writing a possible solution based on the known physical behaviour of the system, with a check by differentiation;
- (4) setting up a model system on an analogue computer; or
- (5) programming a digital computer to give a solution by iteration.

#### 3.2.14.1 Classification

Where the system has only one energy-storage component, *single-energy* transients occur. Where two (or more) different

storages are concerned, the transient has a *double-* (or *multiple-*) *energy* form. Transients may occur in the following circumstances.

- (1) *Initiation*—a system, initially dead, is energised.
- (2) *Subsidence*—an initially energised system is reduced to a zero-energy condition.
- (3) *Transition*—a change from one state to another, where both states are energetic.
- (4) *Complex*—the superposition of more than one disturbance.
- (5) *Relaxation*—transition between states that, when reached, are themselves unstable.

Further distinctions can be made, e.g. between linear and non-linear parameters, neglect or otherwise of propagation time within the system, etc. Attention here is mainly confined to simple electric networks with constant parameters and, by analogy (Section 1.3.1), to corresponding mechanical systems.

### 3.2.14.2 Transient forms

During transience, the current  $i$  for an impressed voltage stimulus  $v(t)$  is considered to be the superposition of a transient component  $i_t$  and a final steady-state current  $i_s$ , so that at any instant  $i = i_s + i_t$ . Alternatively, the voltage  $v$  for an impressed current stimulus  $i(t)$  is the summation  $v = v_s + v_t$ . The quantities  $i_s$  or  $v_s$  are readily derived by applying the appropriate steady-state technique. The form of  $i_t$  or  $v_t$  is characteristic of the system itself, is independent of the stimulus and comprises exponential terms  $k \exp(\lambda t)$  where  $k$  depends on the boundary conditions. This is the case because of the fixed proportionality between the stored energy  $\frac{1}{2} Li^2$  and the rate of energy dissipation  $Ri^2$  in an  $RL$  circuit; and similarly for  $\frac{1}{2} Cv^2$  and  $v^2/R$  in an  $RC$  circuit. Hence the transient form can be obtained from a case in which the final steady state is of zero energy, i.e. a subsidence transient.

The subsidence transient in a *single-energy* (first-order) system having the general equation  $dy/dt + ay = 0$  can be found by substituting  $\lambda y$  for  $dy/dt$  to give  $\lambda y + ay = 0$ , whence  $\lambda = -a$ . Then the solution is

$$y = k \exp(\lambda t) = k \exp(-at)$$

a simple exponential decay as in Figure 1.2 of Section 1.2.2. For a *double-energy* (second-order) system the basic equation is

$$d^2y/dt^2 + a(dy/dt) + by = 0 \quad \text{or} \quad \lambda^2 + a\lambda + b = 0$$

The quadratic in  $\lambda$  has two roots,  $\lambda_1$  and  $\lambda_2$ , and the solution has a pair of exponential terms that depend on the relation between  $a$  and  $b$ . For a *multiple-energy* ( $n$ th-order) system there will be  $n$  roots. From Section 1.2.2 it will be seen that exponential terms can represent oscillatory as well as decay forms of response.

**Single-energy system** Consider the  $RL$  circuit shown in Figure 3.28, subsequent to closure of the switch at  $t = 0$ . The transient current form is obtained from  $L(di/dt) + Ri = 0$ , or  $L\lambda i + Ri = 0$ , giving  $\lambda = -R/L$ . Then

$$i_t = k \exp[-t(R/L)] = k \exp(-t/T)$$

where  $T = L/R$  is the *time-constant*. The final steady-state current depends on the source voltage  $v$ . In Figure 3.28(a), with  $v = V$ , a constant direct voltage,  $i_s = V/R$ . Immediately after switching, with  $t = 0+$ , the current  $i$  is still zero because the inductance prevents any instantaneous rise. Hence

$$i = i_s + i_t = V/R + k \exp(-0) = V/R + k$$

so that  $k = -(V/R)$ . From  $t = 0$  the current is, therefore,

$$i = i_s + i_t = (V/R)[1 - \exp(-t/T)]$$

Figure 3.28 Transients in an inductive-resistive circuit

The two terms and their summation are shown in Figure 3.28(a).

If, as in Figure 3.28(b), the source voltage is sinusoidal expressed by  $v = v_m \sin(\omega t - \alpha)$  and again switching occurs at  $t = 0$ , the form of the transient current is unchanged, but the final steady-state current is

$$i_s = (v_m/Z) \sin(\omega t - \alpha - \phi)$$

where  $Z = \sqrt{R^2 + \omega^2 L^2}$  and  $\phi = \arctan(\omega L/R)$ . At  $t = 0+$

$$i = i_s + i_t = (v_m/Z) \sin(-\alpha - \phi) + k$$

which gives  $k = -(v_m/Z) \sin(-\alpha - \phi)$ . The final steady-state and transient current components are shown in Figure 3.28(b) with their resultant. Initially the current is asymmetric, but subsequently the decay of  $i_t$  allows the current to approach the steady-state condition.

If  $\omega L \gg R$ , then approximately  $\phi \approx \frac{1}{2}\pi$ . Let the switch be closed at  $v = 0$  for which  $\alpha = 0$ . Then the current is

$$i = (v_m/\omega L) [\sin(\omega t - \frac{1}{2}\pi) + 1]$$

which raises  $i$  to twice the normal steady-state peak when  $t$  reaches a half-period: this is the *doubling effect*. However, if the switch is closed at a source-voltage maximum, the current assumes its steady-state value immediately, with no transient component.

**Summary for an  $RL$  circuit** The transient current has a decaying exponential form, with a value of  $k$  such that, when it is added to the final steady-state current, the initial current flowing in the circuit at  $t = 0$  is obtained. (In both of the cases in Figure 3.28 the initial current is zero.) Thus if the initial circuit current is 10 A and the final current is 25 A, the value of  $k$  is  $-15$  A.

For the  $CR$  circuit in Figure 3.29, the form of the transient is found from  $Ri + q/C = 0$ ; differentiating, we obtain

$$R(di/dt) + (1/C)i = 0 \quad \text{or} \quad R\lambda i + 1/C = 0$$

from which  $\lambda = -1/CR = -1/T$ , where  $T = CR$  is the *time-constant*. Thus  $i_t = k \exp(-t/T)$ . With the capacitor initially uncharged and a source direct voltage  $V$  switched on at  $t = 0$ ,

$$i = i_s + i_t = 0 + k \exp(-t/T)$$

Figure 3.29 Transients in a capacitive-resistive circuit

As this must be  $V/R$  at  $t=0+$ , then  $k = V/R$ , as shown in Figure 3.29(a). In Figure 3.29(b) the initiation of a CR circuit with a sine voltage is shown.

**Summary for an RC circuit** The transient current is a decaying exponential  $k \exp(-t/T)$ . The initial current is determined by the voltage difference between the voltage applied by the source and that of the capacitor. (In Figure 3.29 the capacitor is in each case uncharged.) If this p.d. is  $V_0$ , then the initial current is  $V_0/R$ .

**Double-energy system** A typical case is that of a series RLC circuit. The transient form is obtained from  $L(di/dt) + Ri + q/C = 0$ , differentiated to

$$d^2i/dt^2 + (R/L)(di/dt) + (1/LC)i = 0$$

Thus  $\lambda^2 + (R/L)\lambda + 1/LC = 0$  is the required equation, with the roots

$$\lambda_1, \lambda_2 = -\frac{R}{2L} \pm \left( \frac{R^2}{4L^2} - \frac{1}{LC} \right)^{1/2}$$

The resulting transient depends on the sign of the quantity in parentheses, i.e. on whether  $R/2L$  is greater or less than  $1/\sqrt{LC}$ . Four waveforms are shown in Figure 3.30.

(1) **Roots real:**  $R > 2\sqrt{LC}$ . The transient current is unidirectional and results from two simple exponential curves with different rates of decay.

Figure 3.30 Double-energy transient forms

- (2) **Roots equal:**  $R = 2\sqrt{LC}$ . This has more mathematical than physical interest, but it marks the boundary between unidirectional and oscillatory transient current.
- (3) **Roots complex:**  $R < 2\sqrt{LC}$ . The roots take the form  $-\alpha \pm j\omega_n$ , and the transient current oscillates with the interchange of magnetic and electric energies respectively in  $L$  and  $C$ ; but the oscillation amplitude decays by reason of dissipation in  $R$ . With  $R = 0$  the oscillation persists without decay at the undamped natural frequency  $\omega_n = 1/\sqrt{LC}$ .

**Pulse drive** The response of networks to single pulses (or to trains of such pulses) is an important aspect of data transmission. An ideal pulse has a rectangular waveform of duration ('width')  $t_p$ . It can be considered as the resultant of two opposing step functions displaced in time by  $t_p$  as in Figure 3.31(a).

In practice a pulse cannot rise and fall instantaneously, and often the amplitude is not constant (Figure 3.31(b)). Ambiguity in the precise position of the peak value  $V_p$  makes it necessary to define the *rise time* as the interval between the levels  $0.1 V_p$  and  $0.9 V_p$ . The *tilt* is the difference between  $V_p$  and the value at the start of the trailing edge, expressed as a fraction of  $V_p$ .

The response of the output network to a voltage pulse depends on the network characteristics (in particular its time-constant  $T$ ) and the pulse width  $t_p$ . Consider an ideal input

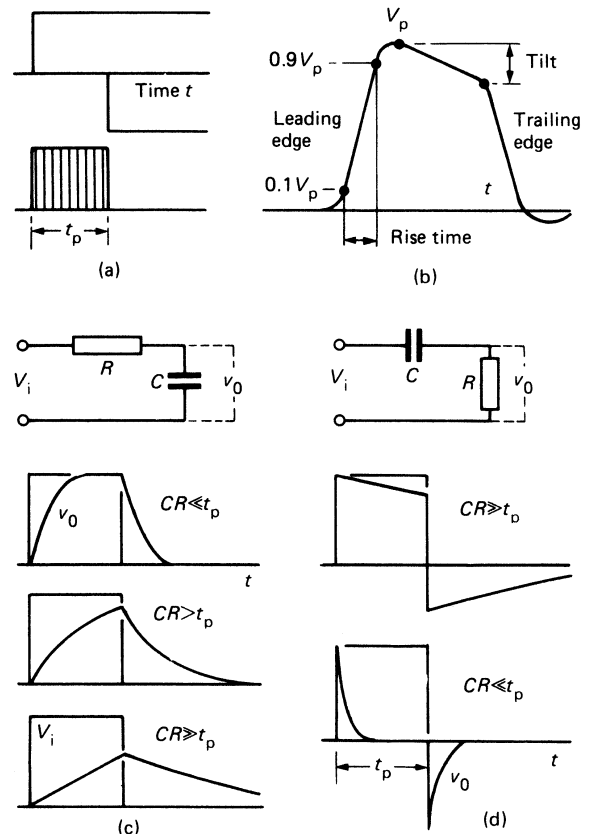

Figure 3.31 Pulse drive

voltage  $V_i$  of rectangular waveform applied to an ideal low-pass series network (Figure 3.31(c)), the output being the voltage  $v_0$  across the capacitor  $C$ . Writing  $p$  for  $d/dt$ , then

$$\frac{v_0}{V_i} = \frac{1/pC}{R + 1/pC} = \frac{1}{1 + pCR} = \frac{1}{1 + pT}$$

where  $T = CR$  is the network time-constant. This represents an exponential growth  $v_0 = V_i[1 - \exp(-t/T)]$  over the interval  $t_p$ . The trailing edge is an exponential decay, with  $t$  reckoned from the start of the trailing edge. Three typical responses are shown. For  $CR \ll t_p$  the output voltage reaches  $V_i$ ; for  $CR > t_p$  the rise is slow and does not reach  $V_i$ ; for  $CR \gg t_p$  the rise is almost linear, the final value is small and the response is a measure of the time-integral of  $V_i$ .

With  $C$  and  $R$  interchanged as in Figure 3.31(d) to give a high-pass network, the whole of  $V_i$  appears across  $R$  at the leading edge, falling as  $C$  charges. Following the input pulse there is a reversed  $v_0$  during the discharge of the capacitor. The output/input voltage relation is given by

$$\frac{v_0}{V_i} = \frac{R}{R + 1/pC} = \frac{pCR}{1 + pCR} = \frac{pT}{1 + pT}$$

For  $CR \gg t_p$  the response shows a tilt; for  $CR \ll t_p$  the capacitor charges rapidly and the output  $v_0$  comprises positive- and negative-going spikes that give a measure of the time-differential of  $V_i$ .

### 3.2.14.3 Laplace transform method

Application of the Laplace transforms is the most usual method of solving transient problems. The basic features of the Laplace transform are set out in Section 1.2.7 and Table 3.4, which gives transform pairs. The advantages of the method are that: (1) any stimulus, including discontinuous and pulse forms, can be handled, (2) the solution is complete with both steady-state and transient components, (3) the initial conditions are introduced at the start, and (4) formal mathematical processes are avoided.

Consider the system in Figure 3.28(a). The applied direct voltage  $V$  has the Laplace transform  $V(s) = V/s$ ; the operational impedance of the circuit is  $Z(s) = R + Ls$ . Then the Laplace transform of the current is

$$I(s) = \frac{V(s)}{Z(s)} = \frac{V}{s(R + Ls)} = \frac{V}{L} \frac{1}{s(s + R/L)} = \frac{V}{L} \frac{1}{s(s + a)}$$

The term  $V/L$  is a constant unaffected by transformation. The term in  $s$  is almost of the form  $a/(s + a)$ . So, if we write

$$I(s) = \frac{V}{aL} \frac{a}{s(s + a)}$$

where  $a = R/L = 1/T$ , the inverse Laplace transform gives

$$i(t) = (V/aL)[1 - \exp(-at)] = (V/R)[1 - \exp(-t/T)]$$

which is the complete solution. More complex problems require the development of partial fractions to derive recognisable transforms which are then individually inverse-transformed to give the terms in the solution of  $i(t)$ .

### 3.2.15 System functions

It is characteristic of linear constant-coefficient systems that their operational solution involves three parts: (i) the excitation or stimulus, (ii) the output or response and (iii) the system function. Thus in the relation  $I(s) = V(s)/Z(s)$  for the current in  $Z$  resulting from the application of  $V$ ,  $1/Z(s)$  is the *system function* relating voltage to current. For the simple

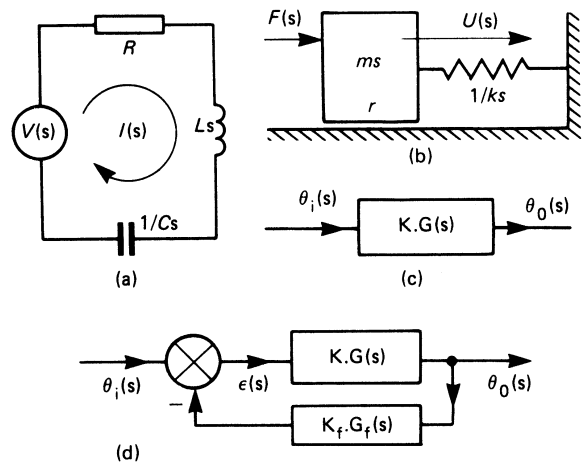

Figure 3.32 System functions

electrical system shown in Figure 3.32(a) the system function  $Y(s)$  relating  $V(s)$  to  $I(s)$  in  $I(s) = V(s)Y(s)$  is  $Y(s) = 1/(R + Ls + 1/Cs)$ . Different functions could relate the capacitor charge or the magnetic linkage in the inductor to the transform  $V(s)$  of the stimulus  $v(t)$ .

The mechanical analogue (Figure 3.32(b)) of this electrical system, as indicated in Section 1.3.1, has a system transfer function to relate force  $f(t)$  to velocity  $u(t)$  of the mass  $m$  and one end of the spring of compliance  $k$  in the presence of viscous friction of coefficient  $r$ . Then  $F(s)$  and  $U(s)$  are the transforms of  $f(t)$  and  $u(t)$ , and the operational 'mechanical impedance' has the terms  $ms$ ,  $1/ks$  and  $r$ . In general, an input  $\theta_i(s)$  and an output  $\theta_o(s)$  are related by a system transfer function  $KG(s)$  (Figure 3.32(c)), where  $K$  is a numerical or a dimensional quantity to include amplification or the value of some physical quantity (such as admittance). The transform of the integro-differential equation of variation with time is expressed by the term  $G(s)$ . The system is then represented by the block diagram in Figure 3.32(c); i.e.  $\theta_o(s)/\theta_i(s) = KG(s)$ .

A number of typical system transfer functions for relatively simple systems are given in Table 3.4.

The output of one system may be used as the input to another. Provided that the two do not interact (i.e. the individual transfer functions are not modified by the connection) the overall system function is the product  $[K_1G_1(s)] \times [K_2G_2(s)]$  of the individual functions. If the systems are paralleled and their outputs are additively combined, the overall function is their sum.

#### 3.2.15.1 Closed-loop systems

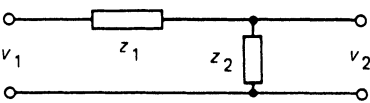

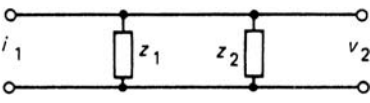

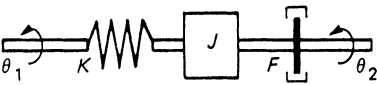

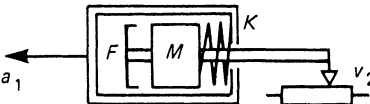

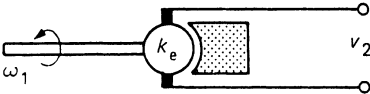

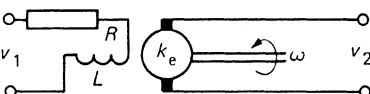

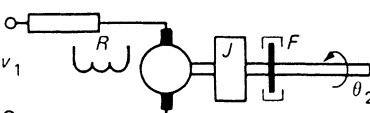

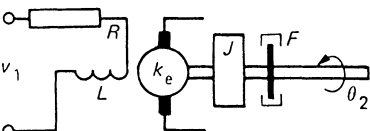

In Figure 3.32, parts (a), (b) and (c) are *open-loop* systems. However, the output can be made to modify the input by feedback through a network  $K_fG_f(s)$  as in (d). The signal

$$\theta_f(s) = [K_fG_f(s)]\theta_o(s)$$

is combined with  $\theta_i(s)$  to give the modified input.

For *positive feedback*, the resultant input is  $\sigma(s) = \theta_i(s) + \theta_f(s)$ , and the effect is usually to produce instability and oscillation.

**Table 3.4** System transfer functions [the relation  $f_2(t)/f_1(t)$  of output to input quantity in terms of the Laplace transform  $F_2(s)/F_1(s)$ ]

System	Transfer function
1 Electrical network	 $\frac{V_2(s)}{V_1(s)} = \frac{Z_2(s)}{Z_1(s) + Z_2(s)}$
2 Electrical network	 $\frac{V_2(s)}{I_1(s)} = \frac{Z_1(s)Z_2(s)}{Z_1(s) + Z_2(s)}$
3 Feedback amplifier	 $\frac{V_2(s)}{V_1(s)} = \frac{Z_2(s)}{Z_1(s)}$
4 Second-order system	 $\frac{\theta_2(s)}{\theta_1(s)} = \frac{1}{1 + 2\zeta sT + s^2T^2}$ $T = \sqrt{J/K}$ $\zeta = F/2\sqrt{JK}$
5 Accelerometer	 $\frac{V_2(s)}{A_1(s)} = \frac{k_a}{1 + 2\zeta sT + s^2T^2}$ $T = \sqrt{M/K}$ $\zeta = F/2\sqrt{MK}$
6 Permanent-magnet generator	 $\frac{V_2(s)}{\omega_1(s)} = k_e$
7 Separately excited generator	 $\frac{V_2(s)}{V_1(s)} = \frac{k_e \omega}{R(1 + sT)}$ $T = L/R$
8 Motor: armature control	 $\frac{\theta_2(s)}{V_1(s)} = \frac{K_e}{s(1 + sT)}$ $K_e = F_e/(FR + F_e^2)$ $T = FR/(FR + F_e^2)$
9 Motor: field control	 $\frac{\theta_2(s)}{V_1(s)} = \frac{k_e}{s(1 + sT_1)(1 + sT_2)}$ $T_1 = L/F,$ $T_2 = L/R$

$v$  voltage  
 $i$  current  
 $Z$  impedance  
 $R, r$  resistance

$L$  inductance  
 $k_e$  e.m.f. coefficient  
 $c$  damping coefficient  
 $T$  time-constant

$\theta/\psi$  angular displacement  
 $\omega/\dot{\psi}$  angular velocity  
 $a$  acceleration  
 $k_a$  acceleration coefficient

$M$  mass  
 $J$  inertia  
 $F$  viscous friction coefficient  
 $K$  stiffness

For *negative feedback*, the resultant input is the difference  $e(s) = \theta_i(s) - \theta_o(s)$ , an 'error' signal. With the main system  $KG(s)$  now relating  $e$  and  $\theta_o$ , the output/input relation is

$$\frac{\theta_o(s)}{\theta_i(s)} = \frac{KG(s)}{1 + [KG(s)][K_f G_f(s)]}$$

Suppose that there is unity feedback  $K_f G_f(s) = 1$ , then if  $KG(s)$  is large

$$\theta_o(s)/\theta_i(s) \approx KG(s)/[1 + KG(s)] \approx 1$$

and the output closely follows the input in magnitude and wave shape, a condition sought in servo-mechanisms and feedback controls.

### 3.2.15.2 System performance

In general, a system function takes the form numerator/denominator, each a polynomial in  $s$ , relating response to input stimulus. Two forms are

$$KG(s) = \frac{b_m s^m + b_{m-1} s^{m-1} + \dots + b_0}{a_n s^n + a_{n-1} s^{n-1} + \dots + a_0} \quad (3.1) \Leftarrow$$

$$= \frac{b_m (s - z_1)(s - z_2) \dots (s - z_m)}{a_n (s - p_1)(s - p_2) \dots (s - p_n)} \quad (3.2) \Leftarrow$$

The response depends both on the system and on the stimulus. Performance can be studied if simple formalised stimuli (e.g. step, ramp or sinusoidal) are assumed; an exponential stimulus is even more direct because (in a linear system) the transient and steady-state responses are then both exponential. With the system function expressed in terms of the complex frequency  $s = \sigma + j\omega$  it is necessary to express the stimulus in similar terms and to evaluate the response as a function of time by inverse Laplace transformation. The response in the *frequency domain* (i.e. the output/input relation for sustained sinusoidal stimuli over a frequency range) is obtained by taking  $s = j\omega$  and solving the complexor  $KG(j\omega)$ . Another alternative is to derive the poles ( $p$ ) and zeroes ( $z$ ) in equation (3.2) above.

Thus there are several techniques for evaluating system functions. Some are graphical and give a concise representation of the response to specified stimuli.

### 3.2.15.3 Poles and zeros

In equation (3.2), the numbers  $z$  are the values of  $s$  for which  $KG(s) = 0$ ; for, if  $s$  is set equal to  $z_1$  or  $z_2, \dots$ , the numerator has a zero term as a factor. Similarly, if  $s$  is set equal to  $p_1$  or  $p_2, \dots$ , there is a zero factor in the denominator and  $KG(s)$  is infinite. Then the  $z$  terms are the *zeros* and the  $p$  terms are the *poles* of the system function. Except for the term  $b_m/a_n$ , the system function is completely specified by its poles and zeros.

Consider the network of Figure 3.33, the system function required being the output voltage  $v_o$  in terms of the input voltage  $v_i$ . This is the ratio of the parallel branches  $R_2 L_2 C$  to the whole impedance across the input terminals. Algebra gives

$$KG(s) = \frac{8(s+1)}{(s^3 + 3s^2 + 14s + 16)} \Leftarrow$$

$$= \frac{8}{(s+1.36)[s + (0.82 + j3.33)][s + (0.82 - j3.33)]} \Leftarrow$$

by factorising numerator and denominator. Thus there is one zero for  $s = -1$ . There are three poles, with  $s = -1.36$ , and  $-0.82 \pm j3.33$ . These are plotted on the complex  $s$ -plane in Figure 3.33. Poles on the real axis correspond to simple exponential variations with time, decaying for negative and increasing indefinitely for positive values. Poles in conjugate pairs on the  $j\omega$  axis correspond to sustained sinusoidal

Figure 3.33 Poles and zeros

oscillations. If the poles occur displaced from the origin and not on either axis, they refer to sinusoids with a decay or a growth factor, depending on whether the term  $\sigma$  is negative or positive.

### 3.2.15.4 Harmonic response

This is the steady-state response to a sinusoidal input at angular frequency  $\omega$ . When a sine signal input is applied to a linear system, the steady-state response is also sinusoidal and is related to the input by a relative magnitude  $M$  and a phase angle  $\alpha$ . The system function is  $KG(j\omega)$ .

Consider again the network of Figure 3.33. Writing  $s = j\omega$  and simplifying gives the phasor expression for  $V_o/V_i$  as

$$KG(j\omega) = \frac{8(j\omega + 1)}{(16 - 3\omega^2) + j\omega(14 - \omega^2)} = |M| \angle \alpha$$

Plots of  $|M|$  and  $\angle \alpha$  are shown in Figure 3.34(a). For  $\omega = 0$  the network is a simple voltage divider with  $V_o/V_i = 0.5$  and a phase angle  $\alpha = 0$ . For  $\omega = \infty$ , the terminal capacitor effectively

Figure 3.34 Harmonic response

short circuits the output terminals so that  $V_o/V_i=0$ . At intermediate frequencies the gain  $|M|$  rises to a peak at  $\omega=3.3$  rad/s and thereafter falls toward zero. The phase angle  $\alpha$  is small and positive below  $\omega=1$ , being always negative thereafter, to become  $-180^\circ$  at infinite frequency.

**Nyquist diagram** The Nyquist diagram is a polar plot of  $|M|$  over the frequency range (Figure 3.34(b)), for an input  $V_i=1+j0$ . The plot is particularly useful for feedback systems. If the open-loop transfer function is plotted, and in the direction of increasing  $\omega$  it encloses the point  $(-1+j0)$ , then when the loop is closed the system will be unstable as the output is more than enough to supply a feedback input even when  $V_i=0$ . The Nyquist criterion for stability is therefore that the point  $(-1+j0)$  shall not be enclosed by the plot.

**Bode diagram** The Bode diagram for the system shown in Figure 3.33 is Figure 3.34(a) redrawn with logarithmic ordinates of  $|M|$  and a logarithmic scale of  $\omega$ . Normally the ordinates are expressed as a gain  $20 \log |M|$  in decibels. For the example being considered,  $M=0.5$  for very low frequencies, so that  $20 \log |M| = -6$  dB; for  $\omega=3.3$  the amplitude of  $M$  is 1.4 and the corresponding gain is  $+2.9$  dB; and at the two frequencies when the output and input magnitudes are the same,  $M=1$  and  $20 \log (1)=0$  dB. All these are shown in the Bode diagram (Figure 3.34(c)). On the logarithmic frequency scale, equal ratios of  $\omega$  are separated by equal distances along the horizontal axis. If successive values 0.5, 1, 2, 4, ..., are marked in equidistantly, their successive ratios  $1/0.5$ ,  $2/1$ , ..., are all equal to 2, so that each interval is a *frequency octave*. Correspondingly the equispaced frequencies 0.1, 1, 10, ..., express a *frequency decade*.

The phase-angle plot is drawn in degrees to the same logarithmic scale of frequency.

An advantage of the Bode plot is the ease with which system functions can be built up term by term. The product of complex operators is reduced to the addition of the logarithms of their moduli and phase angles; similarly the quotient is reduced to subtraction. If the system function can adequately be expressed in *simple* terms, the Bode diagram can be rapidly assembled. Such terms are listed below.

- (1)  $j\omega$ : represented by a line through  $\omega=1$  and rising with frequency at 6 dB per octave or 20 dB per decade, and with a constant phase angle  $\alpha=90^\circ$ .
- (2)  $1/j\omega$ : as for  $j\omega$ , but falling with frequency, and with  $\alpha=-90^\circ$ .
- (3)  $1+j\omega T$ : a straight line of zero gain for frequencies up to that for which  $\omega T=1$ , and thereafter a second straight line rising at 6 dB per octave; the change of direction occurs at the *break point* (Figure 3.35(a)).
- (4)  $1/(1+j\omega T)$ : as for  $1+j\omega T$ , except that after the break point the gain drops with frequency at 6 dB per octave.

**Table 3.5** Gain and phase angle for  $1+j\omega T$

$\omega T$	Gain (dB)		Angle ( $^\circ$ )	$\omega T$	Gain (dB)		Angle ( $^\circ$ )
	Approx.	True			Approx.	True	
0	0	0.0	0	2	6	7.0	63.5
0.01	0	0.00	0.5	4	12	12.3	76
0.1	0	0.04	5.7	8	18	18.1	83
0.25	0	0.26	14	10	20	20.0	84
0.5	0	1.0	26.5	16	24	24.0	86.5
1.0	0	3.0	45	100	40	40.0	89.5

**Figure 3.35** Bode diagrams

In Figure 3.35(a) the true gain shown by the broken curve is approximated by the two straight lines meeting at the break point. The approximate and true gains, and the phase angles, are given in Table 3.5 for the term  $1+j\omega T$ . The error in the gain is 3 dB at the break point, and 1 dB at one-half and twice the break-point frequency, making correction very simple.

The uncorrected Bode plot for the system function

$$KG(j\omega) = K \frac{(1+j\omega 0.5)}{j\omega(1+j\omega 0.25)^2} = \frac{[1]}{[2][3]}$$

is shown in Figure 3.35(b). Term [1] is the same as in Figure 3.35(a). Term [2] is a straight line running downward

through  $\omega = 1$  with a slope of 6 dB per octave. Term [3] has a break point at  $\omega = 4$ , but as it is a squared term its slope for  $\omega > 4$  is 12 dB per octave. The full-time plot of gain is obtained by direct superposition. The effect of the constant  $K$  is to lift the whole plot upward by  $20 \log(K)$ . The summed phase angles approach  $-90^\circ$  at zero frequency and  $-180^\circ$  at infinite frequency.

**Nichols diagram** The Nichols diagram resembles the Nyquist diagram in construction, but instead of phasor values the magnitudes are the log moduli. The point  $(-1 + j0)$  of the Nyquist diagram becomes the point  $(0 \text{ dB}, \angle -180^\circ)$ . The Nichols diagram is used for determining the closed-loop response of systems.

### 3.2.16 Non-linearity

A truly linear system, in which *effect* is in all circumstances precisely proportional to *cause*, is a rarity in nature. Yet engineering analyses are most usually based on a linear assumption because it is mathematically much simplified, permits of superposition and can sometimes yield results near enough to reality to be useful. If, however, the non-linearity is a significant property (such as magnetic saturation) or is introduced deliberately for a required effect (as in rectification), a non-linear analysis is essential. Such analyses are mathematically cumbersome. No general method exists, so that *ad hoc* techniques have been applied to deal with specific forms of non-linearity. The treatment depends on whether a steady-state or a transient condition is to be evaluated.

#### 3.2.16.1 Techniques

Some of the techniques used are: (i) step-by-step solution, graphical or by computation; (ii) linearising over finite intervals; (iii) fitting an explicit mathematical function to the non-linear characteristic; and (iv) expressing the non-linear characteristic as a power series.

**Step-by-step solution** Consider, as an example, the growth of the flux in a ferromagnetic-cored inductor in which the inductance  $L$  is a function of the current  $i$  in its  $N$  turns. Given the flux magnetomotive-force (m.m.f.) characteristic, and the (constant) resistance  $r$ , the conditions for the sudden application of a constant voltage  $V$  are given by

$$V = \frac{d}{dt}(Li) \simeq \frac{dL}{dt}i + N(\Delta\Phi/\Delta\tau)\leftarrow$$

which is solved in suitable steps of  $\Delta t$ , successive currents  $i$  being evaluated for use with the magnetic characteristic to start the next time-interval.

**Linearising** A non-linear characteristic may be approximated by a succession of straight lines, so that a piecemeal set of linear equations can be applied, 'matching' the conditions at each discontinuity.

For 'small-signal' perturbations about a fixed quiescent condition, the mean slope of the non-linear characteristic around the point is taken and the corresponding parameters derived therefrom. Oscillation about the quiescent point can then be handled as for a linear system.

**Explicit function** For the resistance material in a surge diverter the voltage-current relationship  $v = ki^x$  has been employed, with  $x$  taking a value typically between 0.2 and 0.3.

The resistance-temperature relationship of a thermistor, in terms of the resistance values  $R_1$  and  $R_2$  at corresponding absolute temperatures  $T_1$  and  $T_2$  takes the form

$$R_2 = R_1 \exp(k/T_2 - k/T_1)\leftarrow$$

Several functions, such as  $y = a \sinh(bx)$ , have been used as approximations to magnetic saturation excluding hysteresis. A static-friction effect, of interest at zero speed in a control system, has been expressed as  $y = k(\text{sgn } x)$ , i.e. a constant that acts against the driving torque.

**Series** A typical form is  $y = a_0 + a_1 x + a_2 x^2 + \dots + a_n x^n$ , where the coefficients  $a$  are independent of  $x$ . Such a series may have a restricted range, and the powers limited to even orders if the required characteristic has the same shape for both negative and positive  $y$ . A second-degree series  $y = a_0 + a_1 x + a_2 x^2$  can be fitted through any three points on a given function of  $y$ , and a third-degree expression through any four points. However, the prototype characteristic must not have any discontinuities.

Rational-fraction expressions have also been developed. The open-circuit voltage of a small synchronous machine in terms of the field current might take the form  $v = (27 + 0.006i)/(1 + 0.03i)$ . Similarly, the magnetisation curve of an electrical sheet steel might have the  $B$ - $H$  relationship

$$H = B(426 - 760B + 440B^2)/(1 - 0.80B + 0.17B^2)\leftarrow$$

with hysteresis neglected. An exponential series

$$B = \frac{1}{\mu_0} [1 - \exp(-bH)] + c[1 - \exp(-dH)] + \dots + \mu_0 H$$

has been suggested to represent the magnetisation characteristic of a machine, the final term being related to the air gap line.

**Non-linear characteristics** Figure 3.36 shows some of the typical relations  $y = f(x)$  that may occur in non-linear systems. Not all are analytic, and some may require step-by-step methods.

The *simple* relations shown are: (a) response depending on direction, as in rectification; (b) skew symmetry, showing the effect of saturation; and (c) negative-slope region, but with  $y$  univalued.

The *complex* relations are: (d) negative-slope region, with  $y$  multivalued; (e) build-up of system with hysteresis, unsaturated; (f) toggle characteristic, typical of idealised saturated hysteresis; and (g) backlash, with  $y$  taking any value between the characteristic limit-lines.

Figure 3.36 Typical non-linear characteristics

### 3.2.16.2 Examples

A few examples of non-linear parameters and techniques are given here to illustrate their very wide range of interest.

**Resistors** Thermally sensitive resistors (thermistors) may have positive or negative resistance-temperature coefficients. The latter have a relation between resistance  $R$  and absolute temperature  $T$  given by  $R_2 = R_1 \exp [b (1/T_2 - 1/T_1)]$ . They are made from oxides of the iron group of metals with the addition of small amounts of ions of different valency, and are applied to temperature measurement and control. Thermistors with a positive resistance-temperature coefficient made from monocrystalline barium titanate have a resistance that, for example, increases 100-fold over the range 50–100°C; they are used in the protection of machine windings against excessive temperature rise.

Voltage-sensitive resistors, made in disc form from silicon carbide, have a voltage-current relationship approximating to  $v = ki^\beta$ , where  $\beta$  ranges from 0.15 to 0.25. For  $\beta = 0.2$  the power dissipated is proportional to  $v^6$ , the current doubling for a 12% rise in voltage.

**Inductors** The current in a load fed from a constant sinusoidal voltage supply can be varied over a wide range economically by use of a series inductor carrying an additional d.c.-excited winding to vary the saturation level and hence the effective inductance. The core material should have a flux-m.m.f. relationship like that in Figure 3.36(f). Grain-oriented nickel and silicon irons are suitable for the inductor core. A related phenomenon accounts for the in-rush current in transformers.

**Describing function** In a non-linear system a sinusoidal drive does not produce a sinusoidal response. The describing-function technique is devised to obtain the *fundamental-frequency* effect of non-linearity under steady-state (but not transient) conditions.

Consider a stimulus  $x = h \cos \omega t$  to give a response  $y = f(i)$ . As non-linearity inevitably introduces harmonic distortion,  $y$  can be expanded as a Fourier series (Section 1.2.5) to give

$$y = a_0 + a_1 \cos \omega t + a_2 \cos 2\omega t + \dots + b_1 \sin \omega t + b_2 \sin 2\omega t + \dots$$

The components  $a_1 \cos \omega t$  and  $b_1 \sin \omega t$  are regarded as the 'true' response, with a gain factor  $(a_1 + jb_1)/h$ , the other terms being the distortion. The gain factor is the describing function. Let  $y = ax + bx^2$  with  $x = h \cos \omega t$ ; applying the expansion gives the fundamental-frequency term  $y = (a + \frac{3}{4}bh^2)h \cos \omega t$ . The describing function is therefore  $a + \frac{3}{4}bh^2$ , which is clearly dependent on the magnitude  $h$  of the input. Thus the technique consists in evaluating the Fourier series for the output waveform for a sinusoidal input, and finding therefrom the magnitude and phase angle of the fundamental-frequency response.

**Ferroresonance** The individual r.m.s. current-voltage characteristics of a pure capacitor  $C$  and a ferromagnetic-cored (but loss-free) inductor  $L$  for a constant-frequency sinusoidal r.m.s. voltage  $V$  are shown in Figure 3.37. With  $L$  and  $C$  in series and carrying a common r.m.s. current  $I$ , the applied voltage is  $V = V_L - V_C$ . At low voltage  $V_L$  predominates, and the  $I-V$  relationship is the line  $OP$ , with  $I$  lagging  $V$  by 90°. At  $P$ , with  $V = V_0$  and  $I = I_0$ , the system is at a limit of stability, for an increase in  $V$  results in a reduction in  $V_L - V_C$ . At a current level  $Q$  the difference is zero. The current therefore 'jumps' from  $I_0$  to a higher level  $I_1$  (point  $R$ ),

Figure 3.37 Ferroresonance

still with  $V = V_0$ . During the rapid rise there is an interchange of stored energy, and for  $V > V_0$  the circuit is capacitive. When  $V$  is reduced from above to below  $V_0$ , a sudden current jump from  $I_1$  to  $I_0$  occurs. A comparable jump phenomenon takes place for a parallel connection of  $C$  and  $L$ .

**Phase-plane technique** 'Phase' here means 'state' (as in the solid, liquid and vapour 'phases' of water). The phase-plane technique can be used to elucidate non-linear system behaviour graphically. Figure 3.38 shows a circuit of series  $R$ ,  $L$  and  $C$  with a drive having the voltage-current relationship  $v = -ri + ai^3$ . Then, with constant circuit parameters,

$$L(di/dt) + (R - r + ai^2)i + q/C = 0$$

where  $q$  is the time-integral of  $i$ . The presence of  $L$  and  $C$  indicates the possibility of oscillation. The middle ('damping') term can be negative for small currents (increasing the oscillation amplitude) but positive for larger currents (reducing the amplitude). Hence the system seeks a constant amplitude irrespective of the starting condition. The  $q-i$  phase-plane loci show the stable condition as related to the degree of drive non-linearity (indicated by the broken curves). With suitable scales the locus for minor non-linearity is circular, indicating near-sinusoidal oscillation; for major drive non-linearity, however, the locus shows abrupt changes and an approach to a 'relaxation' type of waveform.

**Isoclines** A non-linear second-order system described by

$$d^2y/dt^2 + f(y, dy/dt) + g(y, dy/dt)y = 0$$

can be represented at any point in the phase plane having the co-ordinates  $y$  and  $dy/dt$ , representing, for example, position

Figure 3.38 Phase-plane trajectories for an oscillatory circuit

and velocity, or charge and current. By writing  $dy/dt = z$  and eliminating time by division, we obtain a first-order equation relating  $z$  and  $y$ :

$$dz/dy = -[f(y, z)z + g(y, z)y]/z$$

Integration gives phase-plane trajectories that everywhere satisfy this equation, starting from any initial condition. If  $dz/dy$  cannot be directly integrated, it is possible to draw the trajectories with the aid of *isoclines*, i.e. lines along which the *slope* of the trajectory is constant. Make  $dz/dy = m$ , a constant; then  $-mz = f(y, z)z + g(y, z)y$ . Since for  $z = 0$  the slope  $m$  is infinite (i.e. at right angles to the  $y$  axis) the trajectories intersect the horizontal  $y$  axis normally, except at singular points.

Consider a linear system with an undamped natural frequency  $\omega_n = 1$  and a damping coefficient  $c = 0.5$ . For zero drive

$$d^2y/dt^2 + dy/dt + y = 0 \quad \text{or} \quad dz/dt = -(z + y) \Leftarrow$$

if  $z$  is written for  $dy/dt$ . Dividing the second equation by  $z$  and equating it to a constant  $m$  gives

$$m = dz/dy = -(z + y)/z \quad \text{or} \quad z/y = -1/(1 + m) \Leftarrow$$

representing a family of straight lines with the associated values

$m$	-4	-2	-1	0	1	2	4	$\infty \Leftarrow$
$z/y$	$\frac{1}{3}$	1	$\infty$	-1	$-\frac{1}{2}$	$-\frac{1}{3}$	$-\frac{1}{5}$	0

Draw the  $z/y$  axes on the phase plane (Figure 3.39) marked with short lines of the appropriate slope  $m$ . Then, starting at any arbitrary point, a trajectory is drawn to cross each axis at the indicated slope. With no drive, all trajectories approach, and finally reach, the origin after oscillations in a counter-clockwise direction; for a steady drive  $V$ , the only difference is to shift the vortex to  $V$  on the  $y$ -axis. The approach to O or V represents the decaying oscillation of the system and its final steady state. Because  $dt = dy/z$ , the finite difference  $\Delta t = \Delta y/z$  gives the time interval between successive points on a trajectory.

Figure 3.39 Phase-plane trajectories

### 3.3 Power-system network analysis

#### 3.3.1 Conventions

Modern power-system analyses are based mainly on nodal equations scaled to a per-unit basis, with a particular convention for the sign of reactive power.

##### 3.3.1.1 Per-unit basis

The total apparent power in a three-phase circuit ABC with phase voltages  $V_a, V_b, V_c$ , currents  $I_a, I_b, I_c$  and phase angles between the associated voltage and current phasors of  $\theta_a, \theta_b, \theta_c$  is

$$S = (P_a + P_b + P_c) + j(Q_a + Q_b + Q_c) = P + jQ$$

where for phase A the active power is  $P_a = V_a I_a \cos \theta_a$  and the reactive power is  $Q_a = V_a I_a \sin \theta_a$ . Corresponding expressions apply for phases B and C.

If the phases are balanced, all three have the same scalar voltage  $V$  and current  $I$ , and all phase angles are  $\theta$ . Then  $S = 3(VI \cos \theta + jVI \sin \theta)$ . This can be written in the form

$$\frac{S}{k} = \left( \frac{3}{a} \frac{V}{b} \frac{I}{c} \frac{\cos \theta}{d} \right) + j \left( \frac{3}{a} \frac{V}{b} \frac{I}{c} \frac{\sin \theta}{d} \right)$$

where  $k, a, b, c$  and  $d$  are scaling factors. It is customary to choose  $a = 3$  and  $d = 1$ , leaving  $c$  and  $b$ , one of which is assigned an independent value while the other takes a value depending on the overall scaling relation  $k = abcd$ .

In normal operating conditions the scalar voltage  $V$  approximates to the rated phase voltage  $V_R$ ; hence  $b$  is taken as  $V_R$  so that  $V/b$  is the voltage in per unit of  $V_R$ . Defining the scaled variables as  $S_{pu}, V_{pu}$  and  $I_{pu}$ , the *total* apparent power is

$$S_{pu} = (V_{pu} I_{pu} \cos \theta) + j(V_{pu} I_{pu} \sin \theta) \Leftarrow$$

which is an equation in one-phase form, justifying the use of single-line schematic diagrams to represent three-phase power circuits.

The scaling factors are termed *base* values; i.e.  $k$  is the base apparent power,  $b$  is the base phase voltage and  $c$  is the base current. These definitions imply further base values for impedance and admittance, namely  $Z_{base} = b/c$  and  $Y_{base} = c/b$ .

If the line-to-line voltage  $V_l$  is used, then in the foregoing scaling equation  $3/a$  and  $V/b$  becomes  $\sqrt{3}/d'$  and  $V_l/b' \Leftarrow$ . Choosing  $d' = \sqrt{3}$  and  $b' \Leftarrow$  as rated line voltage leaves  $S/k$  unchanged. Note, however that: (i)  $\theta_l$  remains as the angle between *phase* voltage and current; and (ii) in the per-unit equation  $S = VI^*$  the voltage  $V$  is the per-unit *phase* voltage, not the line-to-line voltage (although numerically both have the same per-unit value).

##### 3.3.1.2 Reactive power convention

Reactive power may be lagging or leading. The common convention is to consider lagging reactive power flow to be positive, as calculated from the product of the voltage and current-conjugate phasors; thus  $S = VI^* = P + jQ$ , with  $Q$  a positive number for a lagging power factor condition. For a leading power factor,  $Q$  has the same flow direction but is numerically negative. As a consequence, an inductor *absorbs*, but a capacitor *generates*, lagging reactive power, as shown in Figure 3.40.

*Note:* system engineers refer, for brevity, to the flow of 'power' and 'vars', meaning active power and reactive power, respectively.

Figure 3.40 Power taken by resistive, inductive and capacitive loads

Figure 3.41 Sample network

### 3.3.1.3 Nodal-admittance equations

The nodal-admittance equations derive from the node-voltage method of analysis in Section 3.2.3. For the network in Figure 3.41, currents  $I_1$ ,  $I_2$  and  $I_3$  are injected respectively into nodes 1, 2 and 3. The loads are linked by branches of admittance  $y_{12}$ ,  $y_{23}$  and  $y_{31}$ , and to the earth or external reference node  $r$  by branches of admittance  $y_{10}$  and  $y_{30}$ . Assuming that the node voltages  $V_1$ ,  $V_2$  and  $V_3$  are expressed with reference to  $r$  and that  $V_r = 0$ , then writing the Kirchhoff current equations and simplifying gives

$$\begin{aligned} (y_{10} + y_{12} + y_{13})V_1 - y_{12}V_2 - y_{13}V_3 &= I_1 \\ -y_{21}V_1 + (y_{21} + y_{23})V_2 - y_{23}V_3 &= I_2 \\ -y_{31}V_1 - y_{32}V_2 + (y_{30} + y_{31} + y_{32})V_3 &= I_3 \end{aligned}$$

Cast into matrix form, these equations become

$$\begin{pmatrix} y_{10} + y_{12} + y_{13} & -y_{12} & -y_{13} \\ -y_{21} & y_{21} + y_{23} & -y_{23} \\ -y_{31} & -y_{32} & y_{30} + y_{31} + y_{32} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \\ V_3 \end{pmatrix} = \begin{pmatrix} I_1 \\ I_2 \\ I_3 \end{pmatrix}$$

This can be abbreviated to the nodal-admittance matrix equation  $YV = I$ , matrix  $Y$  being known as the nodal-admittance matrix. The relationship between the branch elements and the corresponding matrix elements can be seen by inspection.

For some purposes the alternative impedance matrix equations are used: viz.  $ZI = V$ , where  $Z = Y^{-1}$  is the

nodal-impedance matrix. However, evaluating the inverse of  $Y$  is more complicated than finding  $Y$ , and the admittance form may be considered as the primary (or given) form.

### 3.3.2 Load-flow analysis

Load-flow analysis is the solution of the nodal equations, subject to various constraints, to establish the node voltages. At the same time generator power outputs, transformer tap settings, branch power flows and powers taken by voltage-sensitive loads (including reactive power compensators) are determined.

#### 3.3.2.1 Problem description

As indicated in Figure 3.41, the elements of a power system can be represented either as equivalent branches with appropriate admittance incorporated into the matrix  $Y$ , or as equivalent current sources added to the matrix  $I$ .

**Transmission lines and cables** These are represented by their series admittance and shunt (charging) susceptance. These parameters are actually distributed quantities, but are taken into account by  $\Pi$  (or, occasionally,  $T$ ) equivalent networks (Section 3.2.5).

**Transformers** These are modelled by equivalent circuits with an ideal transformer in series with a leakage admittance (Figure 3.42(a)). With two terminals connected to a common reference point (earth) the circuit reduces to that in Figure 3.42(b): the ideal transformer with a turns ratio  $(1+t)/1$  is replaced by an equivalent  $\Pi$ . The tap setting  $t$  represents the per-unit of nominal turns ratio: e.g.  $t = \pm 0.05$  for  $\pm 5\%$  taps.

**Loads** These can be represented either as equivalent admittances  $Y_{k0}$  connected between bus-bars and earth, or as current sources. If the load demand at bus-bar  $k$  is  $S_k = P_k + jQ_k$ , then the equivalent admittance at voltage  $V_k$  is found from

$$S_k = V_k I_k^* = |V_k|^2 Y_{k0}^* \quad \text{or} \quad Y_{k0} = S_k^* / |V_k|^2$$

where  $|V_k|$  is assumed to be 1.0 p.u. (i.e. rated voltage). The equivalent admittance is incorporated into the corresponding diagonal element of the nodal-admittance matrix. In the current-source representation, the current  $I_k$  is substituted into the current column-matrix  $I$  by a fixed power requirement  $S_k$  and the (unknown) voltage  $V_k$ , where  $I_k = S_k^* / V_k^*$ .

**Generator units** or stations can likewise be represented by current sources, but usually the bus-bar to which a generator is connected has a controlled voltage. At a bus-bar  $m$  the requirement would be for specified values of active power  $P_m$  and voltage  $|V_m|$ , with the reactive power  $Q_m$  to be determined.

Figure 3.42 Transformer equivalent circuit

**Slack bus-bar** In a load-flow study, the total active power supplied cannot be specified in advance because the loss in the supply network will not be known. Further, in an  $n$ -bus-bar network, there are  $n$  complexor equations involving  $2n$  real-number equations. However, there are  $2n+2$  unknowns. To reduce this number to  $2n$  it is the practice to specify the voltage of one bus-bar in both magnitude and phase angle. This is termed the *slack bus-bar*, to which the chosen *slack generator* is connected. The slack-bus-bar equation can now be removed from the solution process and, when all other voltages have been determined, the slack-bus-bar generation can be found. For a slack bus-bar  $k$ , for example, the generation  $S_k$  is found from

$$S_k = V_k \sum_m (Y_{km}^* V_m^*) \leftarrow$$

### 3.3.2.2 Network solution process

Solution of the matrix equation is now sought. As it embodies several simultaneous equations, the solution has to be iterative. The two main procedures are the Gauss–Seidel and the Newton–Raphson methods. An important consideration in the computation process is the rate of convergence.

### 3.3.2.3 Gauss–Seidel procedure

This early (and still effective) technique resembles the over-relaxation method used in linear algebra. Consider a four bus-bar network described by the equations

$$Y_{11}V_1 + Y_{12}V_2 + Y_{13}V_3 + Y_{14}V_4 = S_1^*/V_1^*$$

$$Y_{21}V_1 + Y_{22}V_2 + Y_{23}V_3 + Y_{24}V_4 = S_2^*/V_2^*$$

$$Y_{31}V_1 + Y_{32}V_2 + Y_{33}V_3 + Y_{34}V_4 = S_3^*/V_3^*$$

$$Y_{41}V_1 + Y_{42}V_2 + Y_{43}V_3 + Y_{44}V_4 = S_4^*/V_4^*$$

where  $Y_{12} = -y_{12}$ , etc. Let bus-bar 1 be chosen as the slack bus-bar, and let  $V_1$  be  $1+j0$ . Then the remaining three equations are to be solved for  $V_2$ ,  $V_3$  and  $V_4$ . The method adopted is one of successive estimation.

First, the equations are rearranged by extracting the diagonal terms  $Y_{11}V_1, Y_{22}V_2, \dots$ , and transferring all other terms to the right-hand side. Each equation is then divided by the diagonal admittance element ( $Y_{11}, Y_{22}, \dots$ ).

If  $V_k^{(p)}$  denotes the  $p$ th estimate of  $V_k$  and the equations are solved in the sequence 2–3–4–2–3– $\dots$ , then an iterative process is the following:

$$V_2^{(p+1)} \leftarrow - (Y_{21}/Y_{22})V_1 + 0 - (Y_{23}/Y_{22})V_3^{(p)} \leftarrow \\ - (Y_{24}/Y_{22})V_4^{(p)} + S_2^*/Y_{22}V_2^*(p)$$

$$V_3^{(p+1)} \leftarrow - (Y_{31}/Y_{33})V_1 - (Y_{32}/Y_{33})V_2^{(p+1)} + 0 \\ - (Y_{34}/Y_{33})V_4^{(p)} + S_3^*/Y_{33}V_3^*(p) \leftarrow$$

$$V_4^{(p+1)} \leftarrow - (Y_{41}/Y_{44})V_1 - (Y_{42}/Y_{44})V_2^{(p+1)} \leftarrow \\ - (Y_{43}/Y_{44})V_3^{(p+1)} + 0 + S_4^*/Y_{44}V_4^*(p) \leftarrow$$

Note that as each new estimate becomes available, it is used in the succeeding equations. Being iterative, the process of convergence can usually be assisted by the use of ‘acceleration’. If  $\Delta V_k^{(p)} = V_k^{(p+1)} - V_k^{(p)}$ , then a new estimate can be obtained from  $V_k^{(p+1)} = V_k^{(p)} + \omega \Delta V_k^{(p)}$ ; here  $\omega$  is an accelerating factor, optimally a complex number but usually taken as real, with typical values in the range 1.0–1.6.

To terminate the successive-estimation process, various convergence tests are applied. The simplest is to examine the difference between successive voltage estimates and to stop

when the maximum of  $|V_k^{(p+1)} - V_k^{(p)}|$  for  $k=1, 2, \dots, n$  is less than  $\epsilon$ , a suitable small number such as 0.000 01 p.u. However, the preferred test is

$$V_k^{(p)} \sum_m Y_{km}^* V_m^*(p) - S_k < \gamma \psi$$

where  $\gamma$  is a measure of the maximum allowable apparent-power mismatch at any bus-bar, with a value typically 0.01 p.u.

During iteration, other calculations (e.g. voltage magnitude corrections at generator bus-bars and changes in transformer tap settings) can be included. If bus-bar 2 in the example above is a generator bus-bar, then the reactive power  $Q_2$  can be assigned an initial value, say  $Q_2^{(0)} = 0$ , and  $V_2^{(1)}$  obtained therefrom. The voltage estimate can then be scaled to agree with the specified magnitude  $|V_2|$ , and  $Q_2^{(1)}$  immediately calculated, prior to proceeding to the next equation.

The Gauss–Seidel procedure is well suited to implementation on a microcomputer, in which core space is limited. However, matrix-inversion techniques (as required in the Newton–Raphson procedure following) for large networks demand too much core space.

### 3.3.2.4 Newton–Raphson procedure

The Newton–Raphson procedure is at present the most generally adopted method. It has strong convergence characteristics and suits a wide range of problems. The method employs the preliminary terms in the Taylor series expansion (Section 1.2.4) of a set of functions of variables  $V$ . The  $k$ th function is defined as

$$\mathbf{f}(V) = \mathbf{f}[V^{(p)} + \mathbf{J}(V^{(p)})(V - V^{(p)})]$$

The true set of values  $V$  is taken as given by  $V = V^{(p)} + \gamma^{(p)}$ , i.e. by the sum of an approximate set  $V^{(p)}$  and a set of error terms  $\gamma^{(p)}$ . Then, taking the first two terms of the Taylor expansion,

$$\mathbf{f}(V) = \mathbf{f}[V^{(p)} + \mathbf{J}(V^{(p)})(V - V^{(p)})] \leftarrow$$

whence

$$\mathbf{J}(V^{(p)})\gamma^{(p)} = -\mathbf{f}(V^{(p)}) \leftarrow$$

Matrix  $\mathbf{J}(V^{(p)})$  is the Jacobian matrix of first derivatives of the functions  $\mathbf{f}(V)$ . Voltage estimates  $V^{(p)}$  are used to evaluate specific matrix elements of  $\mathbf{J}$ ; and  $\gamma^{(p)}$  is the column matrix of voltage differences  $\Delta V^{(p)}$  to be evaluated, these being the difference between the true and approximate values of the voltages  $V$ . Likewise, the term  $-\mathbf{f}(V^{(p)})$  is the set of per-unit apparent-power differences  $\Delta S^{(p)}$  between specified and calculated values, where

$$\Delta S_k^{(p)} = S_k - V_k^{(p)} \sum_m Y_{km}^* V_m^*(p) \leftarrow$$

The load-flow equation to be solved becomes

$$\mathbf{J}(V^{(p)})\Delta V^{(p)} = \Delta S^{(p)}$$

When  $\Delta V^{(p)}$  is determined, the voltages are updated to  $V^{(p+1)} = V^{(p)} + \Delta V^{(p)}$ .

The polar form of the equations is most usually employed, so with  $V_k = |V_k| \angle \delta_k$  and  $Y_{km} = |Y_{km}| \angle \angle_{km}$  the function  $\mathbf{f}_i = 0$  becomes

$$(V_i Y_{i1} V_1 \cos \beta_{i1} + V_i Y_{i2} V_2 \cos \beta_{i2} + \dots - P_i) \leftarrow$$

$$+ j(V_i Y_{i1} V_1 \sin \beta_{i1} + V_i Y_{i2} V_2 \sin \beta_{i2} + \dots - Q_i) = 0 + j0$$

where  $\beta_{i1} = \delta_i - \delta_1 - \angle_{i1}$  and similarly for  $\beta_{i2}, \dots$ . Partial differentiation to form the terms of the Jacobian matrix, and then separation of the real and imaginary parts, gives the matrix equations to be solved. For generator bus-bars the voltage magnitudes are fixed, so that only equations in reals are needed to evaluate  $\angle \delta$ .

Generator bus-bars are often termed ' $P$ ,  $V$ ' and load bus-bars referred to as ' $P$ ,  $Q$ ' bus-bars, reflecting the values specified.

The Jacobian equations for the Newton–Raphson method are thus of the form

$$\begin{pmatrix} \partial \mathbf{f}_1 / \partial \delta_1 & \partial \mathbf{f}_1 / \partial \delta_2 & \cdots & \partial \mathbf{f}_1 / \partial V_1 & \partial \mathbf{f}_1 / \partial V_2 & \cdots \\ \partial \mathbf{f}_2 / \partial \delta_1 & \partial \mathbf{f}_2 / \partial \delta_2 & \cdots & \partial \mathbf{f}_2 / \partial V_1 & \partial \mathbf{f}_2 / \partial V_2 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \partial \mathbf{f}_1 / \partial \delta_1 & \partial \mathbf{f}_1 / \partial \delta_2 & \cdots & \partial \mathbf{f}_1 / \partial V_1 & \partial \mathbf{f}_1 / \partial V_2 & \cdots \\ \partial \mathbf{f}_2 / \partial \delta_1 & \partial \mathbf{f}_2 / \partial \delta_2 & \cdots & \partial \mathbf{f}_2 / \partial V_1 & \partial \mathbf{f}_2 / \partial V_2 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \end{pmatrix} \begin{pmatrix} \Delta \delta_1 \\ \Delta \delta_2 \\ \vdots \\ \Delta V_1 \\ \Delta V_2 \\ \vdots \end{pmatrix} = \begin{pmatrix} \Delta P_1 \\ \Delta P_2 \\ \vdots \\ \Delta Q_1 \\ \Delta Q_2 \\ \vdots \end{pmatrix}$$

Written in abbreviated form, this is

$$\begin{pmatrix} \mathbf{J}_{11} & \mathbf{J}_{12} \\ \mathbf{J}_{21} & \mathbf{J}_{22} \end{pmatrix} \begin{pmatrix} \Delta \delta \\ \Delta V \end{pmatrix} = \begin{pmatrix} \Delta P \\ \Delta Q \end{pmatrix}$$

To save computer-memory space, it is usual to omit  $\mathbf{J}_{12}$  and  $\mathbf{J}_{21}$ , an approximation that leaves two *decoupled* sets of equations. This approach, called the 'fast decoupled Newton–Raphson loadflow', is in wide use.

For any set of estimates of the voltage, the elements of the Jacobian matrix are evaluated, and the set of equations solved (using space-saving sparse-matrix programming techniques) for  $\Delta \delta$  and  $\Delta V$ ; the values of  $V$ ,  $\Delta P$  and  $\Delta Q$  are updated, and so on. Convergence is achieved for most networks in a few iterations.

A further development is to extend the Taylor series to the second-derivative term, when the series will terminate if Cartesian co-ordinates are employed. Iteration is more lengthy, but the convergence characteristics are more powerful. This 'second-order Newton–Raphson procedure' is gaining popularity.

### 3.3.3 Fault-level analysis

The calculation of three-phase fault levels in large power networks again involves solution of the nodal-admittance equations  $\mathbf{YV} = \mathbf{I}$  subject to constraints.

#### 3.3.3.1 System representation

Representation of generators and loads by fixed  $P$ ,  $|V|$  and  $P$ ,  $Q$  requirements is not valid because of the large and sudden departure of the bus-bar voltages from their nominal values.

*Passive loads* are usually represented by a constant admittance, implying that the load power is proportional to the square of the bus-bar voltage. Relations  $P \propto |V|^{1.2}$  and  $Q \propto |V|^{1.6}$  would be more likely, but the  $|V|^2$  proportionality affords a measure of demand variability and is more easily represented in the admittance matrix  $\mathbf{Y}$ .

*Synchronous machines* such as generators and motors are represented by a voltage source in series with an appropriate admittance. For example, at bus-bar  $k$  where the node voltage is  $V_k$ , the current could be represented by  $I_k = y_k''(E_k'' - V_k)$  using the subtransient e.m.f. and admittance. The term  $y_k'' V_k$  can be transferred to the other side of the nodal-admittance equation in such a way that  $y_k''$  joins any load-admittance term in the diagonal element  $Y_{kk}$ .

The network equations have now been modified to the form

$$\mathbf{Y}'' \mathbf{V} = \begin{pmatrix} \mathbf{y}'' \mathbf{E}'' \\ \mathbf{0} \end{pmatrix}$$

where  $\mathbf{Y}''$  is the admittance matrix  $\mathbf{Y}$  with diagonal elements supplemented by equivalent load admittances and machine subtransient admittances, and the right-hand-side elements are either of the type  $y_k'' E_k''$  or zero.

#### 3.3.3.2 Method of solution

In three-phase short-circuit conditions the voltages  $V$  will differ from the steady-state load values, but the right-hand-side elements will, with the exception of the element corresponding to the faulted bus-bar, remain constant. Let bus-bar  $m$  be short circuited; then  $V_m = 0$ . Solving the remaining equations for the voltages  $V_i$  (with  $i = 1, 2, \dots, n$ ,  $i \neq m$ ) by the Gauss–Seidel procedure and then substituting the voltage values obtained in the  $m$ th equation yields a new right-hand-side value of one or other of the forms

$$y_m'' E_m'' + I_{msc} \quad \text{or} \quad 0 + I_{msc}$$

Here  $I_{msc}$  is the three-phase per-unit short-circuit current injected into bus-bar  $m$  to make  $V_m = 0$ . The fault level (in megavolt-amperes (MV-A)) is then

$$V_{m(\text{prefault})} \times I_{msc} \times \sqrt{3} \times \text{MV-A}(\text{base})$$

A preferred alternative uses the superposition theorem (Section 3.2.2.1). The injection of  $I_{msc}$ , when acting alone, superposes a change  $\Delta V_m (= -V_{m(\text{prefault})})$  at bus-bar  $m$ . The equations to be solved become

$$\begin{pmatrix} \Delta V_1 \\ \vdots \\ \Delta V_m \\ \vdots \\ \Delta V_n \end{pmatrix} = \begin{pmatrix} 0 \\ \vdots \\ I_{msc} \\ \vdots \\ 0 \end{pmatrix} \quad \text{or} \quad \mathbf{Y}'' \Delta \mathbf{V} = \mathbf{I}_{sc}$$

Inversion of  $\mathbf{Y}''$  gives  $\mathbf{V} = \mathbf{Z}'' \mathbf{I}_{sc}$ , in which the  $m$ th equation is known to be  $-V_m = Z_{mm}'' I_{msc}$ . If we assume nominal prefault voltage, i.e.  $V_m = 1 + j0$  p.u., then the value of the three-phase short-circuit current at bus-bar  $m$  is  $I_{msc} = -1/Z_{mm}''$ . The voltage at any other bus-bar  $k$  can then be found from

$$V_k = V_{k(\text{prefault})} + \Delta V_k = V_{k(\text{prefault})} + Z_{km}'' I_{msc}$$

By shifting the short circuit from bus-bar to bus-bar, the fault level for each can be found from the inverses of the appropriate diagonal elements of matrix  $\mathbf{Z}''$ .

### 3.3.4 System-fault analysis

The analysis of *unbalanced* faults in three-phase power networks is an important application of the *symmetrical-component* method (Section 3.2.12). The procedure for given fault conditions is as follows.

- (1) Obtain the sequence impedance values for all items of the plant, equipment and transmission links concerned.
- (2) Reduce all ohmic impedances to a common line-to-neutral base and a common voltage.
- (3) Draw a single-line connection diagram for each of the sequence components, simplifying where possible (e.g. by star–delta conversion, see Section 3.2.4.5).
- (4) Calculate the z.p.s., p.p.s. and n.p.s. currents, tracing them through the network to obtain their distribution with reference to the particular values sought.

Impedance in the neutral connection to earth, and in the earth path itself, must be multiplied by 3 for z.p.s. currents when the z.p.s. connection diagram is being set up in (3)

because the three z.p.s. component currents are co-phasal and flow together in the z.p.s. path.

In general, a network offers differing impedances  $Z_+$ ,  $Z_-$  and  $Z_0$  to the sequence components. In static plant (e.g. transformers and transmission lines)  $Z_-$  may be the same as  $Z_+$ , but  $Z_0$  is always significantly different from either of the other impedances. The presence of z.p.s. currents implies that a neutral connection is involved.

### 3.3.4.1 Sequence networks

As an example, Figure 3.43 shows transmission lines 4 and 5–6 linking a generating station with generators 1 (isolated neutral) and 2 (solid-earthed neutral) to a second station with generator 3 (neutral earthed through resistor  $R_n$ ). The numerals are used to indicate position: e.g.  $Z_{1+}$  is the p.p.s. impedance per phase of generator 1, and  $Z_{60}$  is the z.p.s. impedance of line 6 between generator 3 and a fault at F.

The p.p.s. network is identical with the physical set-up of the original network (which operates with p.p.s. conditions when normally balanced and unfaulted). Each generator is a source of p.p.s. voltages only. It is here assumed that all the generators develop the same e.m.f.  $E_a$ .

The n.p.s. network is similar in configuration (but not usually in impedance values) to the p.p.s. system. There are, however, no source e.m.f.s: the n.p.s. voltages are 'fictitious' ones developed by the fault.

The z.p.s. network is radically different from the other two, being concerned with neutral connections and earth faults. The effective line impedance is that of three conductors sharing equally the total n.p.s. current. To this must be added the earth-connection and earth-path impedances multiplied by 3, to give the z.p.s. impedance  $Z_0$ .

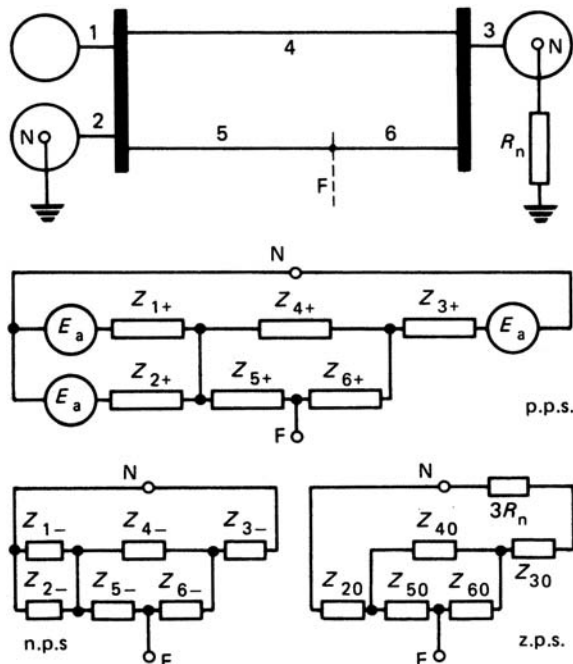

Figure 3.43 Phase-sequence networks

Typical values of  $Z_-$  and  $Z_0$  in terms of  $Z_+$  are

Ratio	Generator	Transformer	Transmission link	
			Overhead	Cable
$Z_-/Z_+$	0.6–0.7	1.0	1.0	1.0
$Z_0/Z_+$	0.1–0.8	1.0 or $\infty$	3–5	1–3

The value of  $Z_0$  for a synchronous generator depends on the arrangement of the stator winding.

To evaluate the system when faulted, it is necessary to determine the fault currents and the voltage of the sound line(s) to earth. If the voltages and currents at the fault are  $V_a$ ,  $V_b$ ,  $V_c$  and  $I_a$ ,  $I_b$ ,  $I_c$ , respectively, the following expressions always apply:

$$V_a = E_a - I_+ Z_+ - I_- Z_- - I_0 Z_0; \quad I_a = I_+ - I_- + I_0$$

$$V_b = \alpha^2 E_a - \alpha^2 I_+ Z_+ - \alpha I_- Z_- - I_0 Z_0; \quad I_b = \alpha^2 I_+ + \alpha I_- + I_0$$

$$V_c = \alpha E_a - \alpha I_+ Z_+ - \alpha^2 I_- Z_- - I_0 Z_0; \quad I_c = \alpha I_+ + \alpha^2 I_- + I_0$$

where  $\alpha$  is the 120° rotation operator (see Section 3.2.12). From the boundary conditions at the fault concerned it is possible to write three equations and to solve them for the symmetrical components  $I_+$ ,  $I_-$  and  $I_0$ .

Sequence networks for some of the many transformer connections are shown in Figure 3.44. Further sequence networks are given in reference 1.

### 3.3.4.2 Boundary conditions

Three simple cases are shown in Figure 3.45. It is assumed that only fault currents are concerned, and that in-feed to the fault is from one direction.

- (a) *Earth fault of resistance  $R_f$  on line A*—at the fault,  $V_a = I_a R_f$  and  $I_b = I_c = 0$ . This leads to  $I_{a0} = I_{a+} = I_{a-}$ , so that the three sequence currents in phase A are identical. It follows that  $I_b$  and  $I_c$  are zero, as required. From the basic equations

$$I_{a+} = I_{a-} = I_{a0} = \frac{1}{3} I_a = E_a / (Z_+ + Z_- + Z_0 + 3R_f) = E_a / Z$$

and the fault current is  $I_a = 3E_a/Z$ . The three sequence networks are, in effect, connected in series. The component currents, and the voltages  $V_b$  and  $V_c$ , are obtained from those in phase A by application of the basic relations in Section 3.3.4.1. Each sequence current divides in the branches of its network in accordance with the configuration and impedance values.

- (b) *Short circuit between lines B and C*—the boundary conditions are  $I_a = 0$ ,  $I_b = -I_c$  and  $V_b = V_c$ . As there is no connection to earth at the fault, the z.p.s. network is omitted. The p.p.s. and fault currents are

$$I_{a+} = E_a / (Z_+ + Z_-) = E_a / Z$$

$$I_b = -I_c = -j\sqrt{3}E_a/Z$$

where  $Z = Z_+ + Z_-$  is the impedance of the p.p.s. and n.p.s. networks in series. The voltages to neutral at the fault are

$$V_a = E_a - I_+ Z_+ - I_- Z_- = 2E_a(Z_-/Z)$$

$$V_b = V_c = E_a(Z_-/Z)$$

- (c) *Double line-earth fault on lines B and C*—here the boundary conditions are  $I_a = 0$ , and  $V_b = V_c = 0$ . The sequence components of the fault current are

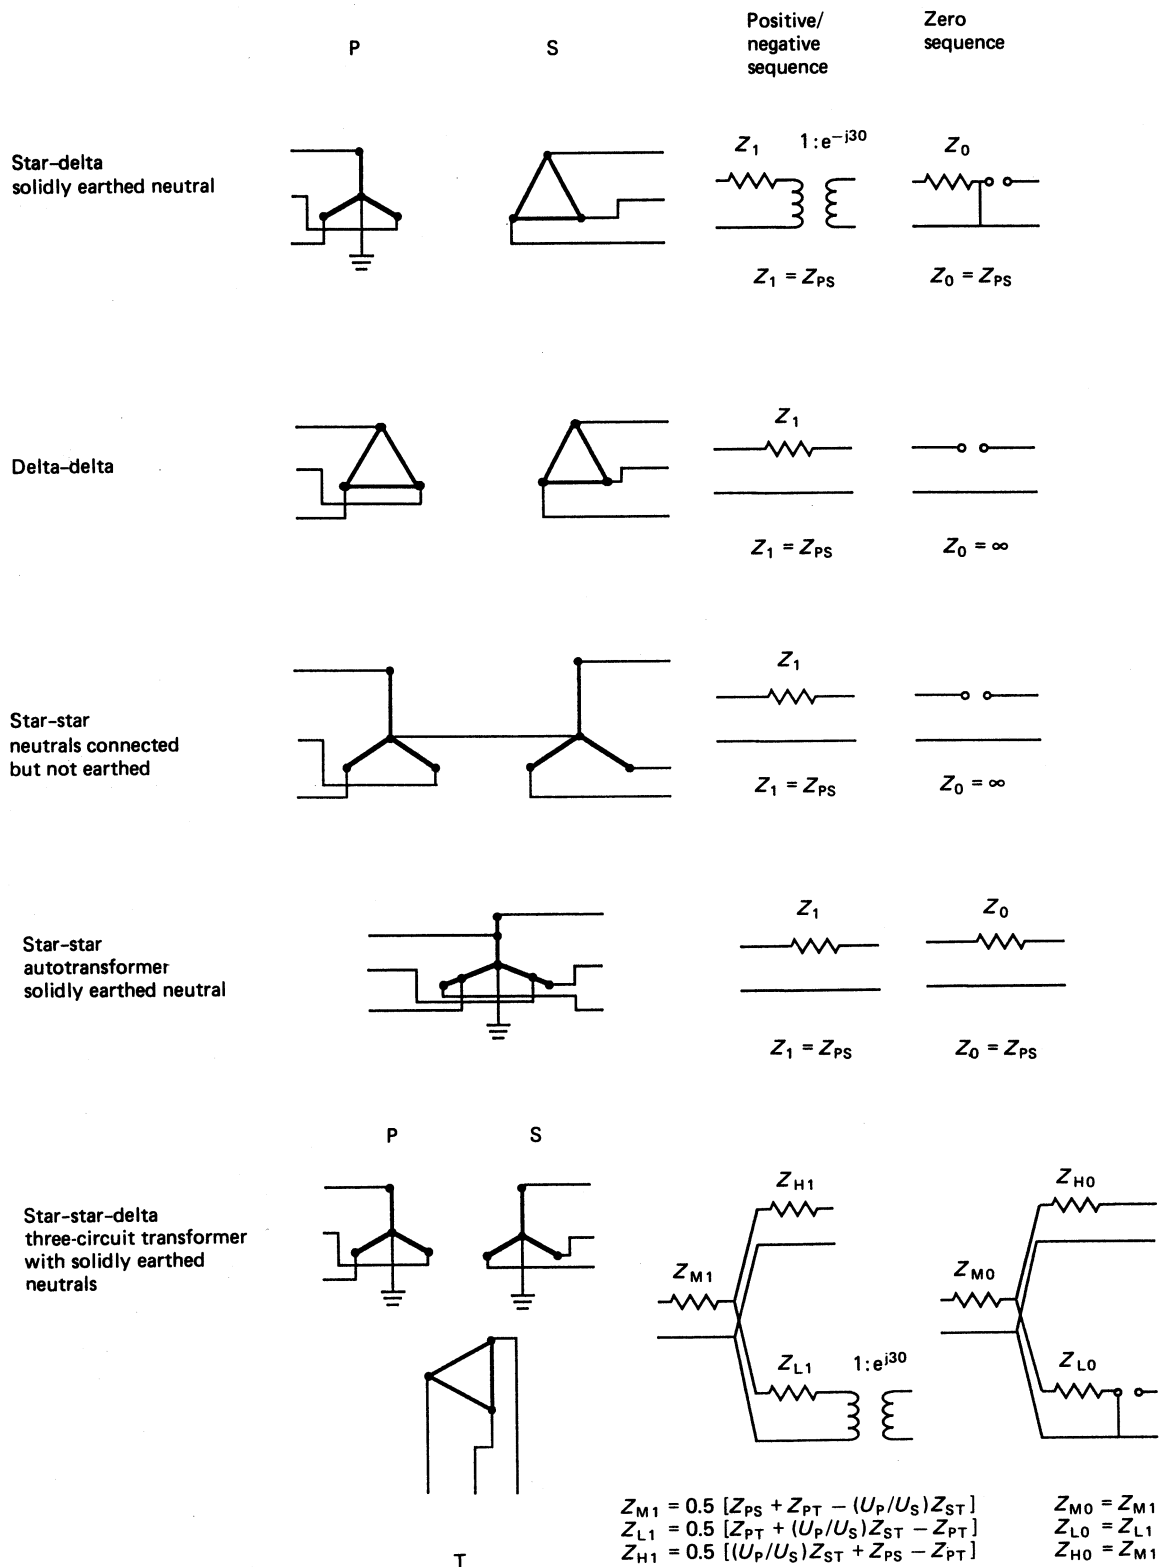

Figure 3.44 Transformer equivalent sequence networks.  $U_P$  and  $U_S$  and the 3-phase MVA ratings of winding P and S respectively

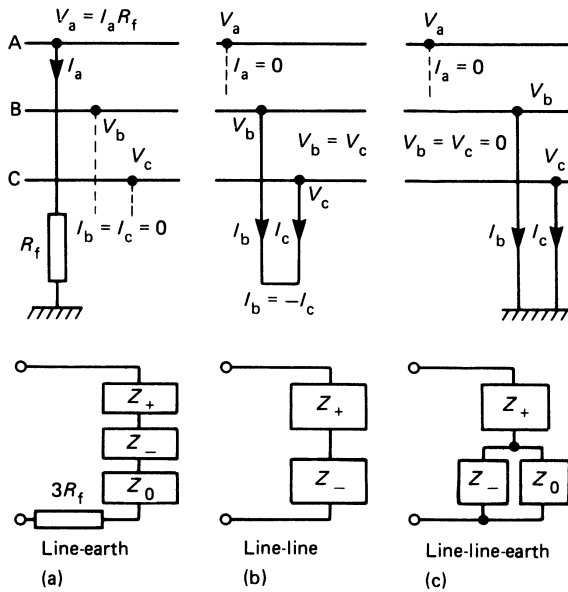

Figure 3.45 Boundary conditions at line faults

$$I_{a+} = E_a / [Z_+ + Z_- Z_0 / (Z_- + Z_0)] \Leftarrow$$

$$I_{a-} = -I_{a+} [Z_0 / (Z_- + Z_0)] \Leftarrow$$

$$I_{a0} = -I_{a+} [Z_- / (Z_- + Z_0)] \Leftarrow$$

The sequence networks are connected in series-parallel.

Figure 3.46 shows the interlinked phase-sequence networks where both ends feed the fault  $F$ . Conditions in (a), (b) and (c) correspond to those in Figure 3.45. Networks for a broken-conductor condition are shown in (d) and (e); the former is for a case in which both ends at the break remain insulated, while the latter applies where the conductor on side 2 falls to earth, the additional constraint involving ideal 1/1 transformers in side 2 of the combined sequence network. In more complicated cases, ideal transformers with phase-shift or with ratios other than 1/1 may be required. Evaluation of these, and of conditions involving simultaneous faults at different points and/or phases, requires matrix analysis and computer programs.

### 3.3.5 Phase co-ordinate analysis

The same techniques developed for the analysis of balanced networks, i.e. load-flow and three-phase fault-level analysis, can be used to develop the analysis of unbalanced faults or loads on either balanced or unbalanced networks using a phase representation of the system. The symmetrical component theory, which has formed the basis of unbalanced power system network analysis, was developed by several authors between 1912 and 1918. Although forming the basis of most modern computer-aided fault analyses, the method is limited by both balanced network assumptions and the difficulties associated with finding equivalent network models in the space described by the set of (transformed) 0, 1, 2 variables, e.g. for simultaneous faults.

The phase co-ordinate method described here uses only the primary phase  $a$ ,  $b$ ,  $c$  variables and computer-based

Figure 3.46 Interconnected phase-sequence networks

matrix computational methods to solve the resulting equations subject to the necessary constraints imposed by load-flow or fault analyses.<sup>2-6</sup>

#### 3.3.5.1 Element representation

For brevity, when referring to the sequence frame of reference, only the zero-, positive- and negative-sequence components usually associated with Fortescue will be discussed.

**General element** The general network element of the power system shown in Figure 3.47 for a three-phase system may be described in matrix form by

Figure 3.47 General three-phase system element

$$V_{abc} = E_{abc} + Z_{abc} I_{abc}$$

where  $V_{abc}$  represents the per-phase series voltage drops ( $V_1 - V_4$ ), ( $V_2 - V_5$ ) and ( $V_3 - V_6$ ),  $E_{abc}$  is the matrix of the equivalent voltage sources per phase,  $I_{abc}$  is the matrix of currents flowing per phase between nodes 1 and 4, 2 and 5, and 3 and 6, respectively, and  $Z_{abc}$  represents the passive three-phase mutually coupled network.

Defining the transformation relating the phase to the sequence components by

$$V_{abc} = TV_{012}$$

where  $\alpha = 1 \angle 120^\circ$  and, for the usual Fortescue components  $V_0$ ,  $V_1$  and  $V_2$ , will be used instead of the rather cumbersome notation  $V_0$ ,  $V_+$  and  $V_-$ ; thus

$$T = \begin{pmatrix} 1 & 1 & 1 \\ 1 & \alpha^2 & \alpha \\ 1 & \alpha & \alpha^2 \end{pmatrix}$$

Noting that  $T^{-1} = \frac{1}{3}T^*$ , upon transformation the equivalent sequence relationship becomes

$$TV_{012} = TE_{012} + Z_{abc}TI_{012}$$

or

$$V_{012} = E_{012} + Z_{012}I_{012}$$

where

$$Z_{012} = \frac{1}{3}T^*Z_{abc}T \quad (3.3)$$

and likewise

$$Y_{012} = \frac{1}{3}T^*Y_{abc}T$$

For the customary linear device  $Z_{abc}$  is symmetric, but without further assumptions  $Z_{012}$  is unsymmetric.

**Transmission lines** The series relationships along a transmission line may be represented by the partitioned equations

$$\begin{pmatrix} V_1 \\ V_2 \\ 0 \end{pmatrix} = \begin{pmatrix} Z_{11} & Z_{12} & Z_{13} \\ Z_{21} & Z_{22} & Z_{23} \\ Z_{31} & Z_{32} & Z_{33} \end{pmatrix} \begin{pmatrix} I_1 \\ I_2 \\ I_3 \end{pmatrix}$$

where  $V_1$  and  $V_2$  are column submatrices representing the series voltages along conductors and subconductors, respectively, carrying the currents in the submatrices  $I_1$  and  $I_2$ .  $I_3$  is a submatrix representing the currents in any earth wires present, which are assumed to be solidly earthed at each end. This latter assumption is normal, but unnecessary, for the solution of the system equations, because extra equations representing earth wires can be included for solution.

A matrix reduction (completion of bundling process and earth-wire removal) will then yield the equations of the equivalent phase conductors, thus giving

$$V_{abc} = Z_{abc}I_{abc}$$

The  $3 \times 3$  matrix  $Z_{abc}$  represents the series impedance of the transmission line, including all the effects due to unbalanced configuration and the use of bundled conductors and earth wires. In a three-phase representation of the network this matrix may be treated in the same way as the single series impedance of the more usual one-line diagram.

By similar reasoning, the potential coefficients of the transmission line (phase and earth wires) per unit of length may be computed for any configuration. From these coefficients a shunt-reactance matrix is found, and then, by reduction, the

$3 \times 3$  matrix  $Z_{shunt}$  representing the total distributed capacitive reactance over the length of the line. Inverting this matrix gives  $Y_{shunt}$  from which the Maxwell coefficients, and hence capacitances, can be determined if necessary.

Three-phase transmission-line models follow as extensions of the nominal or distributed  $\pi$  and  $T$  representations. In the  $\pi$  representation one-half of the transmission-line equivalent capacitance is connected to each end of the line.

The nodal voltages and currents injected into the busbars at each end of the transmission line are then related by

$$\begin{pmatrix} I_1 \\ I_2 \\ I_3 \\ I_4 \\ I_5 \\ I_6 \end{pmatrix} = \begin{pmatrix} Y_{abc} + \frac{1}{2}Y_{shunt} & -Y_{abc} \\ -Y_{abc} & Y_{abc} + \frac{1}{2}Y_{shunt} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_4 \\ V_5 \\ V_6 \end{pmatrix}$$

The similarity between the three-phase and single-phase admittance matrices is evident—each element in the single-phase matrix is replaced by the appropriate  $3 \times 3$  admittance sub-matrix.

**Machine representation** The general element shown in Figure 3.47 may be taken to represent any synchronous or induction machine with a star-connected stator winding when nodes 1, 2 and 3 are short circuited. For a balanced design the voltage sources would be displaced  $120^\circ$  from each other and be equal in magnitude.

The phase-impedance matrix  $Z_{abc}$  can be found by simple transformation of the normally available sequence impedance matrix, as indicated in equations (3.3) and (3.4). The sequence impedance matrix here reflects the structure of the machine and the purpose of the study in the selection of the positive sequence reactance. A typical salient-pole diesel generator, for example, with segmented dampers, 14 poles and 90.7% winding pitch rated at 1340 kV-A, 3.3 kV, 50 Hz has negative and zero reactances of  $X_2 = 0.274$  p.u. and  $X_0 = 0.067$  p.u., respectively. In a fault-level study the machine is represented in the positive-sequence circuit by the subtransient reactance  $X_d' = 0.227$  p.u. =  $X_1$ . The phase-impedance matrix would then be

$$Z_{abc} = \frac{1}{3}TZ_{012}T^* = \begin{pmatrix} 0+j0.1893 & 0.0138-j0.0612 & -0.0138-j0.0612 \\ -0.0138-j0.0612 & 0+j0.1893 & 0.0138-j0.0612 \\ 0.0138-j0.0612 & -0.0138-j0.0612 & 0+j0.1893 \end{pmatrix} \quad (3.4)$$

Note that, with  $X_1 \neq X_2$ , the phase-impedance matrix elements contain both positive and negative real parts, although no resistances were included in the sequence impedances.

Such a representation neglects the effective winding capacitances. These capacitances could be added, if necessary, in the same manner as the transmission-line capacitances in the three-phase representation in delta and shunt connections (a four-terminal lattice network with one terminal earthed). Neglected also is any representation of a machine neutral node. Instead of adding an appropriate row or column to  $Z_{abc}$ , the effect of any earthing reactance  $X_g$  can be included in the value of  $X_0$ , i.e.  $X_0 + 3X_g$ .

**Figure 3.48** Per-unit schematic representation of a single-phase transformer

**Transformer representation** The third type of network element is the transformer in one-, two- and three-phase circuits with all the associated possible variations of construction and connection.

(a) *Derivation of equivalent-circuit model.* A single-phase representation of a transformer in per-unit form illustrated schematically in *Figure 3.48* by an ideal transformer of turns ratio  $(1+t):1$  with an equivalent leakage admittance of  $y$  per unit.

From the relationships across the ideal transformer an equivalent circuit model is as shown in *Figure 3.49* and thus represents a single-phase tapped transformer.

If nodes  $k$  and  $q$  are earthed as in the one-line diagram representation of a balanced three-phase system, the lattice circuit reduces to the equivalent  $\pi$  representation, as shown in *Figure 3.50*.

**Figure 3.49** Symmetrical lattice equivalent circuit of a single-phase transformer with a variable turns ratio

**Figure 3.50** Single-phase equivalent  $\pi$  representation when nodes  $k$  and  $q$  are earthed

The lattice equivalent of *Figure 3.49* provides an adequate model for single-phase variable-turns-ratio transformers and in combinations for three-phase star-star banks with tapped windings, but can only be used with care in banks containing delta-connected windings. In a star-delta bank of single-phase transformer units, for example, with normal turns ratio, a value of 1.0 p.u. voltage on each leg of the star winding produces under balanced conditions 1.732 p.u. voltage on each leg of the delta winding (rated line to neutral voltage as base). The structure of the bank requires in the per-unit representation an effective tapping at  $\sqrt{3}$  times nominal turns ratio on the delta side, i.e.  $1+t=4.732$  or  $t=3.732$ .

For a delta-delta or star-delta transformer with taps on the star winding, the equivalent circuit of *Figure 3.49* would have to be modified to allow for effective taps to be represented on each side. This, the general symmetrical lattice equivalent circuit of a single-phase transformer where both primary and secondary windings may have either actual or equivalent variable turns ratios  $\alpha$  and  $\beta$  or both is shown in *Figure 3.51*. This single-phase transformer model can be used to assemble equivalent circuits of polyphase transformer banks, some of which are shown below

(b) *Star-star transformer.* For a two-circuit three-phase transformer or autotransformer connected in a star-star arrangement, the equivalent circuit is as shown in linear-graph form in *Figure 3.52*. Parallel transformer windings are taken to represent equivalent single-phase transformers. The circuit is constructed from the simple connection of three of the general circuits shown in *Figure 3.51* with taps on both windings. In practice, of course, either  $\alpha$  or  $\beta$ , or both, would be 1.0 p.u.

**Figure 3.51** General transformer symmetrical lattice equivalent circuit with primary and secondary equivalent turns  $\alpha$  and  $\beta$  per unit

**Figure 3.52** A three-phase equivalent circuit of a star-star connected transformer

**Table 3.6** Connection table for the star–star transformer equivalent circuit shown in Figure 3.52 ( $\alpha = 1 + t_\alpha$  p.u.;  $\beta = 1 + t_\beta$  p.u.)

Admittance	Between nodes
$y/\alpha^2\psi$	N–A, N–B, N–C
$y/\beta^2\psi$	n–a, n–b, n–c
$y/\alpha\beta\psi$	A–a, B–b, C–c
$-y/\alpha\beta\psi$	n–A, n–B, n–C; N–a, N–b, N–c
$3y/\alpha\beta\psi$	N–n

In a more concise form, the equivalent circuit of Figure 3.52 may be described by the connection table given in Table 3.6 where, for example, an admittance of value  $y/\alpha^2\psi$  is connected between N and A, also N and B, etc. If the neutrals are earthed or connected together either solidly or through an impedance, the appropriate additions or deletions can be made to the circuit and corresponding terms changed in the connection table. From inspection of the circuit, the corresponding admittance matrix can be assembled with or without rows and columns for the neutral nodes, depending on the earthing arrangements.

(c) *Delta–delta transformer.* With the same convention (that parallel windings may be considered to represent single-phase transformers) the equivalent circuit of a delta–delta transformer may be constructed by the same principles, as shown in Figure 3.53. The corresponding connection table is shown in Table 3.7, where both windings have variable ratios. With taps on one winding only either  $\alpha\psi$  or  $\beta\psi$  would have the value  $\sqrt{3}$ , the tap value  $t_{\alpha\psi}$  or  $t_{\beta\psi}$  being zero accordingly.

**Figure 3.53** A three-phase equivalent circuit of a delta–delta connected transformer**Table 3.7** Connection table for the delta–delta transformer in the equivalent circuit shown in Figure 3.53 ( $\alpha = \sqrt{3}(1 + t_\alpha)$  p.u.;  $\beta = \sqrt{3}(1 + t_\beta)$  p.u.)

Admittance	Between nodes
$y/\alpha^2\psi$	A–B, B–C, C–A
$y/\beta^2\psi$	a–b, b–c, c–a
$2y/\alpha\beta\psi$	A–A, B–b, C–c
$-y/\alpha\beta\psi$	A–b, B–c, C–a; a–B, b–C, c–A

**Figure 3.54** A three-phase equivalent circuit of a star–delta connected transformer

(d) *Star–delta transformer.* Using the same techniques, the three-phase equivalent circuit model of a star–delta transformer may be assembled and is shown in Figure 3.54. The convention used for numbering nodes and thus identifying opposite sides of the symmetrical lattice networks is as follows:

$$A-N/c-b; \quad B-N/a-c; \quad C-N/b-a.\psi$$

The connection table for Figure 3.54 is given in Table 3.8. Again, for taps on one side of the transformer only, either  $t_{\alpha\psi}$  or  $t_{\beta\psi}$  is zero. The neutral node N in the table can be identified with the reference earth node if solidly earthed or extra terms can be added to the table or not, according to the earthing arrangements.

(e) *Three-winding transformers.* With the same assumptions the analysis can be extended to three-circuit transformers and autotransformers and to any multiwinding transformer regardless of the number of circuits. Consider, for example, a star–star–delta transformer with solidly earthed neutrals. Let the star primary and secondary winding (P and S) terminals be labelled A, B, C, N and A'↔B', C'↔N', respectively, with the delta tertiary winding (T) terminals labelled a, b, c, as shown in Figure 3.55.

If  $y_{PS}$ ,  $y_{PT}$  and  $y_{ST}$  are the short-circuit per-unit admittances of the two windings indicated by the subscripts with the third winding open, a three-phase equivalent circuit can be assembled from paralleling one star–star and two star–delta equivalent circuits in turn. The circuit line diagram is too complex to illustrate conveniently, but with the same convention concerning the matching of parallel sides in the identification of the single-phase units, A–N with A'–N'↔, A–N with c–b and A'–N'↔ with c–b, etc., the connection

**Table 3.8** Connection table for the star–delta transformer in the equivalent circuit shown in Figure 3.54 ( $\alpha = 1 + t_\alpha$  p.u.;  $\beta = \sqrt{3}(1 + t_\beta)$  p.u.)

Admittance	Between nodes
$y/\alpha^2\psi$	A–N, B–N, C–N
$y/\beta^2\psi$	a–b, b–c, c–a
$y/\alpha\beta\psi$	A–c, B–a, C–b
$-y/\alpha\beta\psi$	A–b, B–c, C–a

Figure 3.55 A star-star-delta transformer showing terminal markings

table will be as in Table 3.9, where  $\alpha/\beta$  represents the turns ratio of winding P,  $\beta/\gamma$  of winding S, and  $\gamma/\psi$  of winding T. Neutrals N and N' are solidly earthed.

Note that, because two symmetrical lattice networks are connected to any two nodes on the same winding, a and b for example, the total admittance between these nodes is the sum of the corresponding admittances belonging to each of the two lattices between these nodes, e.g.

$$y_{PT}/\gamma\psi + y_{ST}/\gamma\psi = (y_{PT} + y_{ST})/\gamma\psi$$

(f) *Open-delta transformer.* The validity of the equivalent-network model in representing unbalanced transformer designs is demonstrated in the analysis of the open-delta transformer. Figure 3.56 shows a schematic circuit diagram

Figure 3.56 Equivalent circuit of an open-delta transformer

Table 3.9 Connection table for a three-winding star-star-delta transformer ( $\alpha = 1 + t_p$  p.u.;  $\beta = 1 + t_s$  p.u.;  $\gamma = \sqrt{3(1 + t_T)}$  p.u.)

Admittance	Between nodes
$(y_{PS} + y_{PT})/\alpha\psi$	N-A, N-B, N-C
$(y_{PS} + y_{ST})/\beta\psi$	N'-A', N'-B', N'-C'
$y_{PS}/\alpha\beta\psi$	A-A', B-B', C-C'
$-y_{PS}/\alpha\beta\psi$	N'-A, N'-B, N'-C; N-A', N-B', N-C'
$(y_{PT} + y_{ST})/\gamma\psi$	a-b, b-c, c-a
$y_{PT}/\alpha\gamma\psi$	A-c, B-a, C-b
$y_{ST}/\beta\gamma\psi$	A'-c, B'-a, C'-b
$-y_{PT}/\alpha\gamma\psi$	A-b, B-c, C-a
$-y_{ST}/\beta\gamma\psi$	A'-b, B'-c, C'-a

of the transformer with each delta open opposite nodes A and a, respectively. Connecting parallel branches of the windings by symmetrical-lattice equivalent circuits yields the connection table shown in Table 3.10.

Equivalent circuits for other unbalanced transformers and for transformers with different numbers of primary and secondary phases, i.e. *m-to-n* transformers such as Scott, Zig-zag, Vee transformers, etc., can be found in reference 5.

(g) *Effects of magnetising impedances.* The preceding transformer models do not account for the effects of core structure and saturation. In particular, it is noted that the phase circuits give the same representation as transformer sequence impedance circuits with a series impedance of equal value in each of the positive-, negative-, and zero-sequence circuits. More accurate representations include the transformer magnetising impedances in three-phase transformers.

**Table 3.10** Connection table for the open-delta transformer with each winding open opposite nodes A and a respectively ( $\alpha = \sqrt{3(1+t_s)}$  p.u.;  $\beta = \sqrt{3(1+t_\beta)}$  p.u.)

Admittance	Between nodes
$y/\alpha^2\psi$	A–B, C–A
$y/\beta^2\psi$	a–b, c–a
$y/\alpha\beta\psi$	B–b, C–c
$-y/\alpha\beta\psi$	A–b, A–c, B–a, C–a
$2y/\alpha\beta\psi$	A–a

In terms of the sequence quantities, these impedances are of particular importance in the zero-sequence networks. High values of zero-sequence voltage in shell-type transformers, and the effects of the tank walls and out-of-core return paths for zero-sequence fluxes in three-legged core-type transformers, give magnetising impedances of the same order of magnitude as the system impedances.

The transformer equivalent sequence networks can be modified to become T networks, with the magnetising impedance sequence components in the legs of the Ts. In phase coordinates the shunt impedance branch can be added likewise to the transformer single-phase model, as indicated in Figure 3.57. The dotted line indicates the part of the transformer short-circuit impedance placed in the lattice networks; the other part could be incorporated into a lattice network if equivalent taps are required on both sides. The equality of the series admittances has no significance.

Starting from the usual measures of these magnetising admittances in sequence terms, the three-phase equivalent circuit can be developed as follows where, for a balanced design,

$$Y_{abc} = \frac{1}{3} TY_{012} T^*$$

$$= \frac{1}{3} \begin{bmatrix} Y_0 + Y_1 + Y_2 & Y_0 + \alpha Y_1 + \alpha^2 Y_2 & Y_0 + \alpha^2 Y_1 + \alpha Y_2 \\ Y_0 + \alpha^2 Y_1 + \alpha Y_2 & Y_0 + Y_1 + Y_2 & Y_0 + \alpha Y_1 + \alpha^2 Y_2 \\ Y_0 + \alpha Y_1 + \alpha^2 Y_2 & Y_0 + \alpha^2 Y_1 + \alpha Y_2 & Y_0 + Y_1 + Y_2 \end{bmatrix}$$

This phase-admittance matrix represents an equivalent delta network with connections to earth at each node where  $y_1 = y_2$  as shown in Figure 3.58.

(h) *Phase-shifting transformers.* Phase-shifting transformers may be represented in a similar manner from an assembly of single-phase elements, but here the single-phase elements have to be derived.

- (1) *Single-phase equivalent-circuit model*—following the method described in Section 3.3.5.2, the single-phase representation may be illustrated approximately as in Figure 3.59, where the ideal transformer now represents

**Figure 3.57** Per-unit schematic representation of a single-phase transformer with core representation

**Figure 3.58** Phase representation of core branch impedances

**Figure 3.59** Per-unit schematic representation of a single-phase phase-shifting transformer

an ideal phase-shifting transformer. The invariance of the product  $V_1^*$  across the ideal transformer requires a distinction to be made between the turns ratios for current and voltage; thus

$$V_s = (1 + t_v) V'^{\leftarrow}$$

$$i_r = -(1 + t_1) i_s$$

where  $1 + t_v = 1 + t + jq$  and  $1 + t_1 = 1 + t - jq$ .

Following the same procedure as before yields the  $4 \times 4$  phase admittance matrix  $Y$  of the equivalent phase-shifting transformer. For a phase-shifting transformer, however, although an equivalent lattice network corresponding to the admittance matrix  $Y$  can be constructed, it is no longer a bilinear network because of asymmetry in  $Y$ . The equivalent circuit of a single-phase phase-shifting transformer is thus of limited value, and the transformer is best represented algebraically by its admittance matrix.

- (2) *Three-phase phase-shifting transformers*—For both non-phase-shifting and phase-shifting transformers the phase-admittance matrix for any polyphase bank can be built up from the single-phase admittance matrices by identification of the nodes of each single-phase unit with the three-phase terminations, A, B, C and a, b, c according to the winding connection.

The three-phase admittance matrix of the star-delta phase-shifting transformer is:

$$Y_{3\text{phase}} = \begin{matrix} & \begin{matrix} A & B & C & N & a & b & c \end{matrix} \\ \begin{matrix} A \\ B \\ C \\ N \\ a \\ b \\ c \end{matrix} & \begin{pmatrix} \frac{y}{\alpha_I \alpha_V} & 0 & 0 & \frac{-y}{\alpha_I \alpha_V} & 0 & \frac{y}{\alpha_I \beta} & \frac{-y}{\alpha_I \beta \psi} \\ 0 & \frac{y}{\alpha_I \alpha_V} & 0 & \frac{-y}{\alpha_I \alpha_V} & \frac{-y}{\alpha_I \beta} & 0 & \frac{y}{\alpha_I \beta} \\ 0 & 0 & \frac{y}{\alpha_I \alpha_V} & \frac{-y}{\alpha_I \alpha_V} & \frac{y}{\alpha_I \beta} & \frac{-y}{\alpha_I \beta \psi} & 0 \\ \frac{-y}{\alpha_I \alpha_V} & \frac{-y}{\alpha_I \alpha_V} & \frac{-y}{\alpha_I \alpha_V} & \frac{3y}{\alpha_I \alpha_V} & 0 & 0 & 0 \\ 0 & \frac{-y}{\alpha_V \beta} & \frac{y}{\alpha_V \beta \psi} & 0 & \frac{2y}{\beta^2} & \frac{-y}{\beta^2} & \frac{-y}{\beta^2} \\ \frac{y}{\alpha_V \beta} & 0 & \frac{-y}{\alpha_V \beta \psi} & 0 & \frac{-y}{\beta^2} & \frac{2y}{\beta^2} & \frac{-y}{\beta^2} \\ \frac{-y}{\alpha_V \beta} & \frac{y}{\alpha_V \beta} & 0 & 0 & \frac{-y}{\beta^2} & \frac{-y}{\beta^2} & \frac{2y}{\beta^2} \end{pmatrix} \end{matrix}$$

The neutral node N has been preserved in the matrix. If N was earthed through an earthing impedance, the appropriate admittance would appear in the element  $y_{NN}$  or, if earthed directly, the row and column corresponding to N would be removed.

### 3.3.5.2 Fault analysis

By representing polyphase network conditions in terms of their phase co-ordinates, i.e. phase voltages, currents and impedances, thereby preserving the physical identity of the system, instead of transforming the phase co-ordinates to symmetrical component co-ordinates, a generalised analysis of polyphase networks under all fault conditions can be developed.

**General form of prefault equations** It was shown in Section 3.3.3.3 that the general form of the nodal admittance equations  $YV = I$  may be used to describe the three-phase system where each bus-bar in the one-line diagram of the balanced system is replaced by three equivalent separate-phase bus-bars. Each voltage and current element in equations  $YV = I$  for the balanced system is replaced correspondingly by three phase-to-earth voltages and three currents, with each element of the nodal-admittance matrix being replaced by a three-phase element represented by a  $3 \times 3$  nodal admittance submatrix. The same principle used in the assembly of the single-phase admittance matrix underlies the assembly of the three-phase admittance matrix.

The phase relationships at each bus-bar are, then, at bus-bar  $k$ , for example,

$$I_k = S_k^* / V_k^*$$

where  $I_k$  is the phase current injected into bus-bar  $k$ ,  $V_k$  is the phase-to-earth voltage, and  $S_k$  is the phase power.

The network admittance matrix  $Y$  can be adjusted to the basic prefault form from which all calculations for the various faults commence by classifying the energy sources as active or passive, according to their behaviour during fault

conditions. Some loads, for example, may be characterised by passive admittances per phase; thus the equation for node  $j$  becomes

$$I_j = y_{j0}' V_j$$

The network nodal admittance equations can be modified accordingly by substituting for the load currents and then transferring the admittances across to supplement the diagonal elements of matrix  $Y$ . If the load has unequal positive-, and zero-sequence admittances, the admittance  $y_{j0}'$  may be replaced by an equivalent  $3 \times 3$  phase admittance matrix, which in turn is transferred to supplement the appropriate block diagonal  $3 \times 3$  submatrix of  $Y$ . In this case, the substitution for the three corresponding phase currents is made simultaneously.

With appropriate node connections, active sources such as machines may be represented by the general network element shown previously containing voltage sources in series with a passive network. The equations  $YV = I$  governing the current injected into the network from a star-connected machine connected to the three-phase bus-bars  $p$ ,  $q$ , and  $r$  with a neutral earthed through an impedance  $y_{N0}$ , are:

$$\begin{pmatrix} Y_{pp} & Y_{pq} & Y_{pr} & -y_0 \\ Y_{qp} & Y_{qq} & Y_{qr} & -y_0 \\ Y_{rp} & Y_{rq} & Y_{rr} & -y_0 \\ -y_0 & -y_0 & -y_0 & Y_{NN} \end{pmatrix} \begin{pmatrix} V_1 \\ V_2 \\ V_3 \\ V_N \end{pmatrix} = \begin{pmatrix} y_1 & E_p \\ y_1 & E_q \\ y_1 & E_r \\ -y_0 & E_N \end{pmatrix}$$

where  $I_N$  is the current injected into the neutral node N, and is usually zero,  $E_N$  is the sum of the phase e.m.f.s, and is also usually zero ( $E_p + E_q + E_r = 0$ ),  $y_0$  is the machine zero sequence admittance,  $y_1$  is the positive-sequence admittance, and  $Y_{NN} = 3y_0 + y_{N0}$ . The values of the voltage sources  $E_p$ ,  $E_q$  and  $E_r$  are the appropriate phase-displaced transient or subtransient values according to the purpose of the study.

Substituting again for the respective currents in equation  $YV = I$  and transferring the product terms  $y_{ij} V_j$  to the left-hand side, the modified network admittance equations become

$$Y'V = [y_g E] = I' \quad (3.5) \Leftarrow$$

where  $Y'$  is the supplemented phase admittance matrix and  $[y_g E]$  or  $I'$  is a column matrix the elements of which are of the form  $y_1 E$ , or zero. The similarity is evident between the three-phase prefault equations and the familiar equivalent one-line diagram or single-phase prefault equations established for three-phase fault studies of balanced systems described in Section 3.3.3.

**Solution of equations for various types of fault condition** All the various types of fault condition can be analysed by means of simple modifications to, and the solution of, these equations.

(a) *Single phase-to-earth fault.* If a single phase-to-earth short circuit occurs at bus-bar  $k$ , the bus-bar voltage  $V_k$  will be constrained to be zero, the value of the earth reference voltage. To obtain the extra degree of freedom for this constraint to be valid within a consistent set of equations, the current on the right-hand side of the  $k$ th equation in equation (3.5) must be unspecified, and allowed to take its value according to the solution of the remaining set of  $(n-1)$  equations in the  $(n-1)$  unknown voltages,  $V_j$ ,  $i = 1, 2, \dots, n$ , ( $i \neq k$ ), with  $V_k = 0$ .

Letting the value of this  $k$ th current be  $I_k''$ , where

$$I_k'' = \sum_{m=1}^n Y_{km}' V_m \\ = \mathcal{A}_k' + \mathcal{I}_{SC}$$

$I_k''$  is the prefault value and  $Y_{km}' (m=1, 2, \dots, n)$  are the elements of the  $k$ th row of the matrix  $Y'$ , then  $\mathcal{I}_{SC}$  is the current in the short-circuit connection to earth.

This calculation is exactly the same as that for a three-phase fault in existing computer programs based on a one-line diagram and three-phase apparent-power base.

The numerical methods of solution are the standard methods developed for such problems in linear algebra, namely matrix-inversion methods or, for large systems, iterative methods such as the Gauss-Seidel technique, and can be found in the usual numerical-analysis textbooks.

(b) *Multiphase faults.* These are described in (1)–(4) below.

- (1) *Phase-to-phase short circuits*—for bus-bars short-circuited together (zero-impedance connection) either the modified admittance equations can be solved subject to a number of additional constraints, or the admittance matrix  $Y'$  can be modified, and the number of equations reduced for solution without constraints.

In the first approach, where the number of nodes remains constant, the appropriate bus-bar voltages are constrained to be equal. To obtain the extra degrees of freedom for these constraints to be valid within a consistent set of equations, the currents on the right-hand sides of the corresponding equations must be unspecified and allowed to take their values accordingly. These currents are, at bus-bar  $k$ , for example,

$$I_k'' = \mathcal{A}_k' + \sum \mathcal{I}_{SC}$$

where  $\sum \mathcal{I}_{SC}$  is the total short-circuit current injected into bus-bar  $k$  from all other bus-bars short circuited to bus-bar  $k$ .

For a phase-to-phase short circuit occurring between bus-bars  $j$  and  $k$ , for example, the equations are solved with voltages  $V_j = V_k$  and currents  $I_j''$  and  $I_k''$  being unknown where

$$I_j'' = \mathcal{A}_j' + \mathcal{A}_{jk}'$$

and

$$I_k'' = \mathcal{A}_k' + \mathcal{A}_{jk}'$$

$I_{kj} (= -I_{jk})$  is the short-circuit current passing between bus-bars  $j$  and  $k$ ,  $I_{kj}$  that being injected into bus-bar  $j$ , and  $I_{jk}$  being that injected into bus-bar  $k$ .

- (2) *Phase-to-phase faults via impedances*—if the faults between phases occur through impedances the equations are solved for the voltages  $V$  with matrix  $Y'$  supplemented by the appropriate admittances.
- (3) *Phase-to-phase-to-earth faults*—earthed multiphase faults follow as extensions of the previous sections. If several phases are short circuited to earth simultaneously, the equations are solved with all the respective voltages having a value of zero. The total fault current to earth follows from the appropriate sums of the respective fault currents. If impedances are present in the fault, the corresponding admittances are included in the matrix  $Y'$  and the fault currents are evaluated depending on the fault impedance configuration.
- (4) *Simultaneous faults*—using phase co-ordinates, any two- or three-phase fault may be considered to be a multiple fault, in the sense that more than one represented bus-bar is involved. The techniques of solution above may be applied, therefore, without restriction, to any number of simultaneous faults, regardless of their

type or geographical location. As noted previously, the solution involves the solving of a set of simultaneous linear algebraic equations with or without constraints on the appropriate voltages, depending on the modifications made to the original network connection table.

(c) *Open conductors.* Open conductors present no difficulty other than that of introducing an extra bus-bar or bus-bars into the network, depending on the number of open circuits. The appropriate changes are made in the connection table, and the admittance or impedance matrices are modified accordingly.

*The source transformation method of solution* The above methods of solution may be referred to as 'distributed source methods', in which the various equivalent-current sources retain their identity and are generalisations of the existing methods of solution in the standard three-phase fault-level analysis described in Section 3.3.3.2.

An alternative approach would be to use Norton's theorem, or superposition methods, commencing from the supplemented nodal impedance matrix  $Z'^{-1} (= \mathcal{A}'^{-1})$ . The method depends on knowing the voltage drop caused by the fault current, and hence determines this current for an equivalent current source acting alone at the point of fault. The fault conditions are then obtained by superposition.<sup>3</sup>

### 3.3.5.3 Polyphase loadflow analysis

For polyphase load flow, several questions are raised which are not encountered in balanced one-line diagram analysis. If the phase voltages are unbalanced then the characteristics of the loads under such conditions should be known. An admittance matrix representation may well be better than a specified  $P + jQ$  demand. A further problem is the lack of knowledge of the active and reactive power distribution between the phases of the generators.

A synchronous generator model avoiding this latter difficulty and using only the total output power of the machine is, for a machine connected to the three-phase bus-bars  $p, q$  and  $r$ :

$$\begin{pmatrix} Y_{abc} & -y_1 & -y_0 \\ & -\alpha^2 y_1 & -y_0 \\ & -\alpha y_1 & -y_0 \\ y_1 & -\alpha y_1 & -\alpha^2 y_1 & 3y_1 & 0 \\ y_0 & -y_0 & -y_0 & 0 & (3y_0 + \mathcal{A}_{N0}) \end{pmatrix} \begin{pmatrix} V_p \\ V_q \\ V_r \\ E_a \\ V_N \end{pmatrix} = \begin{pmatrix} I_p \\ I_q \\ I_r \\ \sum S^*/E^*_a + \mathcal{A}_{N0}|V_N|^2/E^*_a \\ 0 \end{pmatrix}$$

To a first approximation the term  $y_{N0}|V_N|^2/E^*_a$  can be neglected in comparison with the magnitude of the term  $\sum S^*/E^*_a$ .

For each generator the machine admittance matrix  $Y_{abc}$  can be added to the polyphase admittance matrix representing the network of lines, transformers and admittance loads. By any of the usual load-flow techniques these equations can then be solved iteratively. At generator bus-bars where a  $P|V|$  specification is given, the value of  $P$  is the total active power output of the machine and  $|V|$  can be either  $E_a$  or  $V_p$  or any other

controlled bus-bar voltage. Several existing conventional (one-line diagram) load-flow programs already allow the generator terminal voltage magnitude to be unknown and to be adjusted according to the voltage value of a remote-controlled bus-bar. In principle, the same situation and adjustments characterise the phase co-ordinate load-flow analysis

### 3.3.6 Network power limits and stability

Steady-state a.c. power transfer over transmission links has limitations imposed by terminal voltages and link impedance. Transient conditions for stable operation are dynamic, and more complicated.

#### 3.3.6.1 Steady-state conditions

Two typical cases concern a link transferring power from a sending-end generator at bus-bar voltage  $V_s$  to a receiving end of voltage  $V_r$  where there is either (1) a static load only or (2) a generator. Case (2) is the more important, as loss of synchronism is possible.

(1) *Load stability* The power taken by a static load of constant power factor is proportional to the square of the voltage. As the load power is increased the voltage falls, at first slightly but subsequently more rapidly until maximum power is attained. Thereafter both load voltage and power decrease, but the system is still stable, though overloaded. The condition could occur following the clearance of a system fault.

The load is rarely purely static: it usually contains motors. With induction motors the reactive-power requirements increase as the voltage falls, and beyond the maximum-power conditions the machines will stall, and will draw heavy 'pick-up' currents after a restoration of the voltage.

(2) *Synchronous stability* The receiving-end active and reactive powers in terms of  $V_s$  and  $V_r$ , and the parameters *ABCD*, are given for a transmission link in Section 3.2.13.1. For a short line,  $A = 1 \angle 0^\circ$  and  $B = Z \angle \beta$ , where  $Z = R + jX$  and  $\beta = \arctan(X/R)$ , conditions shown in Figure 3.27.

If the resistance  $R$  can be neglected (as is often the case, especially where the link includes terminal transformers), the receiving-end active power  $P_r$  and its maximum  $P_{rm}$  become

$$P_r = (V_s V_r / X) \sin \theta\psi$$

$$P_{rm} = V_s V_r / X$$

To attain maximum active power, the receiving end must also accept a leading reactive power  $Q_r = V_r^2 / X$ .

Interpreting the angle  $\theta\psi$  between  $V_s$  and  $V_r$  as that between the generator rotor (indicated by the e.m.f.  $E_t$ ) and  $V_r$ , and including the appropriate generator reactance in  $X$ , the angle is now the *load angle*  $\delta$ , and maximum active power transfer will occur for a load angle  $\delta = \pi/2$  rad ( $90^\circ$  electric). The relation for normal conditions is marked N in Figure 3.60.

Although a system does not operate under continuous steady-state conditions with a system fault, the power-angle relation is important in the assessment of transient stability. The network for which the curve is calculated is obtained by connecting a 'fault shunt'  $Z_f$  at the point of fault. The value of  $Z_f$  is in terms of  $Z_-$  and  $Z_0$ , respectively, the total impedance to n.p.s. and z.p.s. currents up to the point of fault. These values are given below for line-line (LL), single-earth (LE), double-earth (LLE) and three-phase (3P) faults, while the corresponding power-angle relations are shown in Figure 3.60.

Figure 3.60 Power-angle relationships

Fault:	LL	LE	LLE	3P
$Z_f$	$Z_- \leftarrow$	$Z_- + Z_0$	$Z_- Z_0 / (Z_- + Z_0)$	Zero

#### 3.3.6.2 Transient conditions

If a system in a steady state is subjected to a sudden disturbance (e.g. short circuit, load change, switching out of a loaded circuit) the power demand will not immediately be balanced by change in the prime-mover inputs. To restore balance the rotors of the synchronous machines must move to new relative angular positions; this movement sets up angular oscillations, with consequent oscillations of current and power that may be severe enough to cause loss of synchronism. The phenomenon is termed *transient instability*.

*Rotor angle* For a single machine connected over a transmission link to an infinite bus-bar, the simple system shown in Figure 3.61 applies. The mechanical input  $P_m$  is, in the steady state, balanced by the electrical output for the angle  $\delta_0$  on the full-time power-angle relationship. If an electrical disturbance occurs such that the power-angle relation is suddenly changed to that indicated by the broken curve, the angle cannot

Figure 3.61 A single-machine system

Figure 3.62 Swing curves

immediately change because of the inertia of the generator and prime-mover rotors. The electrical power drops, and a power difference  $\Delta P$  appears, accelerating the rotating members towards the new balancing angle  $\delta_1$ . Overshoot takes the rotor angle to  $\delta_2$ . If the disturbance is not severe, the rotor assumes the angle  $\delta_1$  after some rapidly decaying oscillations of frequency 1 or 2 Hz. The angle-time relationship is that shown as curve A in Figure 3.62. However, if  $\Delta P$  is large, the overshoot may cause loss of synchronism—the unstable curve B. A comprehensive investigation of stability thus involves the calculation of *swing curves* for the machines concerned.

**Equation of motion** The equation of motion for a *single machine* is

$$M(d^2\delta/dt^2) + K_1(d\delta/dt) + K_2 = \Delta P$$

where  $M$  is the angular momentum. If the damping coefficients  $K_1$  and  $K_2$  are ignored, the equation of motion reduces to  $d^2\delta/dt^2 = \Delta P/M$ .

A mass of inertia  $J$  rotating at angular speed  $\omega_1$  stores a kinetic energy  $W = \frac{1}{2}J\omega_1^2$ . The momentum  $M = J\omega_1$  can be usefully related to the machine rating  $S$  by the *inertia constant*

$$H = W/S = \frac{1}{2}M\omega_1/S = \frac{1}{2}J\omega_1^2/S \approx 20Jn_1^2/S$$

in which  $\omega_1$  is the synchronous angular speed (rad/s) and  $n_1 = \omega_1/2\pi = f/p$  is the corresponding rotational speed (revolutions per second) for a machine with  $2p$  poles operating at a frequency  $f$ . The magnitude of  $H$  (in joules/volt-ampere, or MJ/MV-A, or seconds) has the typical values given in Table 3.11.

A direct solution of the equation of motion is not normally possible, and a *step-by-step* process must be adopted. For this, a succession of time intervals (e.g. 50 ms) is selected and the

rotor acceleration ( $d^2\delta/dt^2$ ) is calculated at the beginning of each. Assuming the acceleration to be constant throughout a time interval, the angular velocity and the movement  $\delta\psi$  during the interval can be found. At the end of the first interval, the new  $\Delta P$  is obtained from the power-angle curve and used to calculate the acceleration during the second interval, and so on. The complete *swing curve* can thus be obtained. The method can be extended (if the relevant data are available) to include damping, changes in excitation, saliency, prime-mover governor action and other factors that affect the swing phenomenon.

**Multi-machine system** A *two-machine* system with a transmission link can be represented by a single machine feeding an infinite bus-bar and having an equivalent momentum  $M = M_1M_2/(M_1 + M_2)$ .

A *group* of machines 1, 2, ..., paralleled on the same bus-bar can be treated as a single machine of rating  $S = S_1 + S_2 + \dots$ , and of equivalent momentum  $M = (S_1/S)M_1 + (S_2/S)M_2 + \dots$ .

For a *multi-machine* network, a separate equation of motion must be set up for each generator and a step-by-step solution undertaken. Determination of  $\Delta P$  for each machine at the end of a time interval involves a comprehensive load-flow calculation by computer.

**Equal-area criterion** Neglecting damping, governor action and changes in excitation, the stability of a simple generator/link/infinite-bus-bar system can be checked graphically using power-angle relationships. Consider the system shown in Figure 3.63, with the generator operating at a load angle  $\delta_0$  on the power-angle curve  $P_2$  with a prime-mover input  $P_m$  and both transmission links intact. A fault occurs on one link, changing the power-angle relationship to  $P_f$  and giving a power difference  $\Delta P$  between  $P_m$  and the electrical output. As a result the rotor accelerates until the angle  $\delta_s$  is reached, when the faulted link is switched out. The kinetic energy acquired by the rotor during this period is represented by area A. At  $\delta_s$  the power-angle relationship becomes  $P_1$  corresponding to a single healthy link. This reverses  $\Delta P$  and the rotor decelerates. At the angle  $\delta_2$  such that area B

Figure 3.63 Equal-area stability criterion

Table 3.11 Inertia constants of 50 Hz synchronous machines

Machine	$n$ (rev/s)	$H$ (s)
Turbogenerators	50	3–7
	25	5–10
Compensators	—	1–1.25
Motors	—	2–2.25
Hydrogenerators	8.3	2–4
	5	2–3.5
	2.5	2–3
	1.7	15–2.5

(representing kinetic energy returned from the rotor) is equal to  $A$ , the rotor speed is again synchronous. However,  $\Delta P$  is now reversed and the rotor will begin to swing back. The range of rotor-angle excursions is stable, but there is a critical value of the fault-clearance angle  $\delta_s$  that, if exceeded, will result in instability. If all the power-angle relationships are true sinusoids, the critical angle can be found analytically.

Conditions other than that shown in *Figure 3.63* can be dealt with if the relevant power-angle relationships can be drawn. It is to be noted that a *swing* curve may be required to relate rotor angle to *time*, as it is the time of fault clearance (or other event)—a quantity based on the delay of switch opening—that is normally specified.

## 4.1 Introduction

The properties of materials relevant to electrical engineering applications are mechanical, thermal and electromagnetic in nature. The mechanical properties which are of interest relate to the strength and deformation of materials, the latter being either reversible and governed by three elastic moduli or irreversible because of plastic changes or fracture. The thermal properties relate to heat capacity, conduction and expansion. The interaction of mechanical and thermal properties with the electrical properties leads to electro-mechanical and thermoelectric properties.

Traditionally, the electromagnetic properties are describable in terms of three main parameters: the electrical conductivity ( $\sigma$ ), the magnetic permeability ( $\mu$ ), and the electric permittivity ( $\epsilon$ ). The relative magnitude of these parameters determines whether the material is, respectively, electrically conducting, magnetic or dielectric. The electromagnetic transmittance of the material (i.e. the optical transparency) is governed by the refractive index which may be complex in nature and thus lead to complicated electromagnetic behaviour.

## 4.2 Mechanical properties

The mechanical properties of materials relate to their strength, rigidity and ductility. Materials may be deformed elastically, by which it is meant that the deformation is reversible and that the stress (force per unit area) and resulting strain (fractional size change) are proportional (*Hooke's law*). The constant of proportionality is known as the elastic modulus of which there are three types:

- (1) *Young's modulus* ( $M$ ) relates tensile stress and strain;
- (2) *Shear modulus* ( $G$ ) relates shear stress and strain; and
- (3) *the bulk modulus* ( $K$ ) relates bulk stress and volume strain.

During elastic deformation, not only is there a longitudinal elongation but also a cross-sectional decrease. The ratio of longitudinal to transverse strain is *Poisson's ratio*,  $\gamma$ .

If the materials are polycrystalline, the mechanical properties may be regarded as isotropic so that the four elastic constants may be interrelated by

$$M = \frac{3}{2}K(1 - \frac{2}{3}\gamma) \quad (4.1) \Leftarrow$$

$$M = \frac{2}{3}G(1 + \frac{2}{3}\gamma) \quad (4.2) \Leftarrow$$

The inherent strength of a material is limited by plastic deformation or fracture. Plastic deformation is a permanent deformation caused by a shearing of a few crystal planes (slip). Such deformation is affected by various types of dislocations within the material structure.

The fracture of a material is the separation into two or more parts by an applied stress and may be classified as either brittle or ductile. The former occurs after little or no plastic deformation, whereas ductile fracture occurs after extensive plastic deformation.

Materials may be strengthened but usually only at the expense of their ductility which may cause fabrication problems. Methods of increasing mechanical strength include work hardening (progressive application and removal of increasing stress), solution hardening (addition of an alloying element to produce internal strains), precipitation hardening (which involves careful heating and solution treatment), and dispersion hardening (diffusion of gases into the solid to produce hard particles).

Figure 4.1 Creep behaviour under constant applied stress

The stress and strain do not necessarily occur simultaneously in real materials but rather the material continues to deform indefinitely under the influence of a constant applied stress (creep). Such creep behaviour consists of four main phases (*Figure 4.1*). An initial instantaneous strain (which may be partly elastic and partly plastic) is followed by a primary creep region having a decreasing creep rate, a secondary creep region of constant minimum flow rate and a final region of accelerating strain ultimately leading to fracture.

## 4.3 Thermal properties

The basic thermal properties of materials include thermal capacity, conduction and expansion. The thermal capacity (the thermal energy required to raise the temperature by one degree Kelvin) is due to the storage of energy in the motion and oscillation of atoms and electrons. Such energy may be conducted through atomic and electronic collisions between regions at different temperatures. The thermal stability of the material is governed by the magnitudes of the thermal conduction and capacity since these parameters govern the temperature rise experienced by the material on the dissipation of power within the material. Such temperature rises can lead to technical difficulties, not only because of the eventual destruction of the material, but also due to its expansion which results from the increased amplitude of oscillation of the atoms.

## 4.4 Electrically conducting materials

Electrically conducting materials may be identified from fundamental electromagnetic theory as those for which the conduction current density  $j_c$  is considerably greater than the displacement current density  $j_d$  where

$$j_c = \sigma E \quad (\text{Ohm's law}) \quad (4.3) \Leftarrow$$

$$j_d = \epsilon \frac{D}{\delta t} \quad (4.4) \Leftarrow$$

where  $D$  is the electric flux density.

For  $j_c$  to dominate the electrical conductivity  $\sigma$  needs to be large. Since the electrical conductivity is approximately given by classical theory as

$$\sigma = (e^2/m)n\tau_c = enp \quad (4.5) \Leftarrow$$

(where  $m$  and  $e$  are the electron mass and charge, respectively, and  $p$  is the mobility), a high concentration of conduction electrons ( $n$ ) or a long time between collisions of electrons and the lattice ions of the material ( $2\tau_c$ ) leads to the dominance of  $j_c$ .

Since both electrical and thermal conduction are due to the flow of electrons in metals, it should be anticipated that the electrical and thermal ( $K$ ) conductivities should be related. The relationship is given by the *Wiedemann–Franz law*

$$\frac{\sigma}{K} = LT \quad (4.6) \Leftarrow$$

where  $L$  is the Lorentz Number and  $T$  is the temperature.

This has implications for the removal of Joule heat (which depends upon  $\sigma$ ) by thermal conduction (which depends upon  $K$ ).

Furthermore, the conduction of heat may be accompanied by the flow of electric current. This flow ceases when opposed by the electric field created by the resulting charge migration. The electromotive force (e.m.f.) generated is characterised by the thermoelectric power  $s$  which is the potential difference ( $dV$ ) per degree temperature difference ( $dT$ )

$$s = dV/dT \quad (4.7) \Leftarrow$$

Thus the potential difference between the ends of a material with thermoelectric power  $S_1$  at different temperatures measured via junctions with a second material of thermoelectric power  $S_2$  is governed by  $(S_1 - S_2)$ . This, the *Seebeck effect*, forms the basis of thermocouple operation. If, alternatively, a current is made to flow along or against a temperature gradient, the need for the conduction electrons to be in equilibrium with the crystal lattice leads to the heating of the cold end or the cooling of the hot end (*Thompson effect*), respectively. The flow of current through the junction between two materials can produce heating or cooling known as the *Peltier effect*, which can be used for temperature control.

The electrical conductivity of semiconductor materials incorporates both electrons ( $n_-$ ) and holes ( $u_+$ ) as carriers so that

$$\sigma = en_-p_{n_-} + eu_+p_{u_+} \quad (4.8) \Leftarrow$$

In photoconductors the number of carriers  $n_-$ ,  $u_+$  is enhanced through the absorption of light energy to free the carriers for conduction.

For technical applications it is often preferred to use the reciprocal of conductivity, i.e. the resistivity,  $\rho$ . The resistivity of a pure, conventional conductor increases with temperature

$$\rho_T = \rho_0(1 + \alpha T \dots) \quad (4.9) \Leftarrow$$

where  $\alpha$  is the temperature coefficient of resistivity (in parts per million per degree Celsius). The temperature dependence of the resistivity of some conductors is shown in *Figure 4.2*.

The resistivity of an impure conductor is greater than that of the pure conductor (due to additional electron collisions with the impurity ions) according to *Matthiessen's rule*:

$$\rho = \rho_T + \rho_r \quad (4.10) \Leftarrow$$

In the case of a dilute alloy (*Nordheim's rule*)

$$\rho_r = ax(1 - x) \quad (4.11) \Leftarrow$$

where  $x$  is the impurity concentration.

**Figure 4.2** Temperature dependence of the resistivity of various types of conductors

However, for alloys of transition metals (e.g. nickel) the above rules do not apply. Instead the resistivity variation with temperature may possess a point of inflexion which has important implications for a temperature-independent resistivity over a limited range. Furthermore, some materials become superconducting below a critical temperature  $T_c$  whereby the resistivity decreases to zero. For such a superconducting state to be maintained the current density in the material needs to be kept below a critical value.

Under d.c. conditions the resistance of a bulk conductor depends on the cross-sectional area ( $A$ ) and length ( $l$ )

$$R = (l/A)\rho \quad (4.12) \Leftarrow$$

With a.c. at an angular frequency  $\omega$  the current conduction is confined to a peripheral annulus of effective width (*skin depth*)

$$S = \sqrt{2\rho/c\mu\omega} \quad (4.13) \Leftarrow$$

where  $\mu$  is the permeability, so that the effective cross-sectional area  $A$  is reduced and the resistance increases with signal frequency.

Electrical conduction in thin films is also governed by the proximity of the film surface contributing to the impedance of the electron flow

$$R = sl/w \quad (4.14) \Leftarrow$$

where  $w$  is the film width and  $s$  the sheet resistance.

## 4.5 Magnetic materials

The magnetic influence of materials is incorporated in electromagnetic theory via the relative permeability which relates the magnetic flux density,  $B$ , to the magnetic field strength,  $H$ , according to

$$B = \mu_0\mu_r H \quad (4.15) \Leftarrow$$

where  $\mu_0$  is the permeability of free space for which  $\mu_r = 1$ . A measure of the magnetic influence of a material is given by the magnetic susceptibility which is the difference between the relative permeability of the material and that of free space

$$\chi_B = \mu_r - 1 \quad (4.16) \Leftarrow$$

However, in material science the preference is for the material influence to be described additively rather than factorially according to

$$B = \mu_0 H + \mathcal{J}_m \quad (4.17) \Leftarrow$$

where  $\mathcal{J}_m$  is the magnetic moment per unit volume which is determined by the product of the magnetic moment of the elementary dipoles  $\bar{\mu}_H$  and their concentration  $N$  according to

$$\mathcal{J}_m \simeq N \bar{\mu}_H \quad (4.18) \Leftarrow$$

A number of physical processes may produce such elementary dipole moments and these determine the type of magnetism displayed by the material.

*Diamagnetism* occurs when the electron orbitals associated with the atoms of the material are distorted in the presence of an external magnetic field. The orbiting electrons may be regarded as forming circulating currents which, according to electromagnetic theory, have associated magnetic moments. On the application of a magnetic field the orbitals adjust to oppose the field. Diamagnetic susceptibility is temperature independent, of the order of  $10^{-4}$  and is negative, implying a dilution of the magnetic flux within the material.

*Paramagnetism* is due to an inherent magnetic moment arising from an orbiting electron, a spinning electron and a spinning nucleus. In the latter two cases the magnetic moment may be regarded as originating from the spinning charge of the electron or proton constituting an effective circulating current. The nuclear effect is less pronounced than the electronic effect. Paramagnetic susceptibility is greater than diamagnetic susceptibility (ca.  $10^{-3}$  to  $10^{-4}$ ), is positive and decreases with temperature ( $T$ ) according to the *Curie law*:

$$\chi_p = C/T \quad (4.19) \Leftarrow$$

where  $C$  is the Curie constant.

Both diamagnetism and paramagnetism originate from the individual effects of atomic processes. However, in some materials, mainly the transition metals, the magnetic effects arising from individual atoms may be strongly coupled to give more pronounced magnetic properties to the bulk material. Such strong interatomic coupling leads to ferromagnetic, antiferromagnetic and ferrimagnetic effects

*Ferromagnetism* occurs when the magnetic moments of neighbouring atoms are aligned because of the strong interatomic coupling so that

$$\mathcal{J}_m = N_A \mu_A + N_B \mu_B \quad (4.20) \Leftarrow$$

where the suffixes A and B designate the neighbouring atoms. To minimise the magnetic energy of the bulk material, regions of like-magnetic-moment alignments (*domains*) are formed with neighbouring regions having differently orientated magnetic moments.

*Antiferromagnetism* occurs when the magnetic moments of neighbouring atoms are misaligned so that for a pure material the bulk magnetic effects are zero:

$$\mathcal{J}_m = N_A \mu_A - N_B \mu_B = 0; \quad A = B \quad (4.21) \Leftarrow$$

*Ferrimagnetism* arises when the neighbouring atoms in the misalignment have different magnetic moments so that there is a remnant magnetic effect in the bulk material:

$$\mathcal{J}_m = N_A \mu_A - N_B \mu_B \neq 0; \quad A \neq B \quad (4.22) \Leftarrow$$

For both ferromagnetic and ferrimagnetic materials the magnetic susceptibility is enhanced and considerably greater than for both diamagnetic and paramagnetic materials. In all cases the magnetic susceptibility decreases with temperature according to

$$\chi = C/(T - T_c) \quad (4.23) \Leftarrow$$

where  $T_c$  is the *Curie point* for ferromagnetic materials and the *Neel temperature* for antiferromagnetic materials. The significance of  $T_c$  is that the material ceases to be strongly magnetic for temperatures above  $T_c$  and becomes instead paramagnetic in nature.

Incorporation of magnetic materials as part of devices in electrical networks (e.g. transformer cores), electronic circuits (e.g. magnetic pick-ups) or microwave systems (e.g. ferrite isolators) may produce power losses or waveform distortion. At power frequencies, the power losses are produced by hysteresis effects which arise from the inertia of the ferromagnetic domains in following changes in an applied magnetic field and which produces a hysteresis  $B$ - $H$  loop (Figure 4.3). The power losses are given by the product of the energy product, the volume and the power frequency (*energy product* =  $\frac{1}{2} B H_{\max}$ ). In addition, losses occur due to *eddy currents* flowing in the magnetic material. These depend on the resistivity of the material ( $\rho$ ), the shape of the material ( $\beta$ ), the dimension ( $d$ ) perpendicular to the magnetic flux ( $B$ ) and the power frequency ( $f$ ) according to

$$\text{Eddy loss} = [(\pi B_{\max} f d^2) / (\rho \beta)] \mathcal{V} \text{Volume} \quad (4.24) \Leftarrow$$

Waveform distortion is produced by the non-linear relationship between  $B$  and  $H$  due to the hysteresis  $B$ - $H$  loop because, according to Lenz's law, the output voltage from an inductive element is given by

$$V_{\text{out}} \propto \frac{dB}{dt} = \mu_0 \frac{d[F(H)]}{dt} \quad (4.25) \Leftarrow$$

At radio and microwave frequencies, losses may occur due to the absorption of power from the electromagnetic wave to increase the energy of the elementary atomic magnetic dipoles. Ferrite materials which are used in radio and microwave frequency devices are anisotropic in nature so that the relative permeability is replaced by a permeability tensor.

Materials which demonstrate superconductivity do so not only below a critical temperature,  $T_c$ , and critical current

Figure 4.3  $B$ - $H$  hysteresis and the energy product  $B \cdot H$

Figure 4.4  $B$ - $H$  curves for superconductors

density, but also below a critical magnetic field strength ( $H_c$ ) which varies with temperature  $T$  according to

$$H_c = H_{c0}[1 - (T/T_c)^2] \quad (4.26) \Leftarrow$$

where  $H_{c0}$  is the critical field at absolute zero of temperature.

For field strengths below  $H_c$ , superconductors become diamagnetic, implying a low magnetic flux density within the material (Figure 4.4). The transition to the diamagnetic state may occur abruptly at  $H_c$  (corresponding to type I superconductors which are pure materials) or more gradually (corresponding to type II superconductors which are more common and include impure materials).

The ratio of the field penetration into the material (the *London penetration depth*,  $\lambda$ ) to the growth in superconductivity (the *coherence length*,  $\xi$ ), which is known as the *Ginsburg-Landau constant*, determines whether a material is of type I ( $\lambda/\xi < 0.71$ ) or type II ( $\lambda/\xi > 0.71$ ). In type II superconductors, in particular, the growth in current density may lead to 'flux jumping' whereby flux lines are dislodged leading to power dissipation which causes heating and hence loss of superconduction.

## 4.6 Dielectric materials

In electromagnetism, dielectric properties are incorporated via the relative permittivity  $\epsilon_r$  which relates the electric flux density,  $D$ , to the electric field strength,  $E$ , according to

$$D = \epsilon_0 \epsilon_r E \quad (4.27) \Leftarrow$$

where  $\epsilon_0$  is the permittivity of free space against which the permittivity of a dielectric is normalised. Thus, since for free space  $\epsilon_r = 1$ , the magnitude of dielectric effects may be considered in terms of the dielectric susceptibility

$$\chi E = \epsilon_r - 1 \quad (4.28) \Leftarrow$$

Alternatively, a relationship between  $D$  and  $E$  which is often preferred in fundamental materials studies is

$$D = \epsilon_0 E + P \quad (4.29) \Leftarrow$$

where  $P$  is the polarisation per unit volume and

$$P = Np = N\alpha E_L \quad (4.30) \Leftarrow$$

where  $p$  is the dipole moment of each atomic/molecular dipole,  $N$  is their concentration,  $E_L$  is the local field within

the dielectric which results from the electrostatic fields between ions and electrons

$$E_L = E + P/(3\epsilon_0) \Leftarrow (4.31)$$

and  $\alpha$  is the polarisability which is produced by a number of atomic or molecular processes in the dielectric material.

*Electronic polarisation* ( $\alpha_e$ ) is produced when the electron orbital is distorted by the presence of an electric field (Figure 4.5(a)).

*Ionic polarisation* ( $\alpha_i$ ) is produced when the lattice structure of the material is distorted by the electric field (Figure 4.5(b)).

*Orientalional polarisation*  $\alpha_o$  arises when electric dipoles already exist in the dielectric and are re-aligned by an applied electric field (Figure 4.5(c)).

Other polarisation mechanisms which occur in some materials under special conditions are ion-jump polarisation and space charge polarisation ( $\alpha_s$ ).

Consequently, the total polarisation per unit volume is

$$P = E_L \Sigma N_a \alpha_a \quad (4.32) \Leftarrow$$

where  $a = e, i, o$  or  $s$ .

The electromagnetic and materials descriptions are inter-related via the Clausius-Mosotti equation:

$$\frac{\epsilon_r - 1}{\epsilon_r + 1} = \frac{1}{3\epsilon_0} \Sigma N_a \alpha_a \quad (4.33) \Leftarrow$$

For situations in which the electric field is time varying in a periodic manner the polarisation  $P$  may lag behind the field  $E$

Figure 4.5 (a) Electronic polarisation ( $\alpha_e$ ). (b) Ionic polarisation ( $\alpha_i$ ). (c) Orientalional polarisation ( $\alpha_o$ )

due to the inertia associated with the physical processes described above. As a result, the relative permittivity becomes dependent on the  $E$  field angular frequency  $\omega\varsigma$  and on the relaxation time ( $\tau$ ) governing the inertia of the polarisation. As a result, the permittivity is complex in nature

$$\epsilon_r = \epsilon_\infty + \frac{N_0\alpha_0(\epsilon_\infty + 2)^2}{9\epsilon_0(1 + \omega^2\tau^2)} - j \frac{N_0\alpha_0(\epsilon_\infty + 2)^2\omega\tau\varsigma}{9\epsilon_0(1 + \omega^2\tau^2)} \quad (4.34) \Leftarrow$$

$$= \epsilon'_\varsigma - j\epsilon''_\varsigma$$

Since the relaxation times of the space charge and orientational polarisations differ significantly, the effects lead to sequential changes in  $\epsilon'_\varsigma$  and  $\epsilon''_\varsigma$  as the  $E$  field frequency increases. Ionic and electronic polarisation are governed by resonant effects (see Section 4.8) which also produce frequency-dependent complex permittivities (Figure 4.6).

Since the velocity of propagation of an electromagnetic wave depends upon  $\epsilon'_\varsigma$

$$v_\varsigma = c(\sqrt{\epsilon'_\varsigma})^{-1} \quad (4.35) \Leftarrow$$

the frequency dependence can lead to dispersion and waveform distortion. The imaginary component of  $\epsilon_r$  leads to signal attenuation and power dissipation which accounts for the loss tangent of a capacitor

$$\tan \delta_\varsigma = \epsilon''_\varsigma / \epsilon'_\varsigma \quad (4.36) \Leftarrow$$

The permittivity of a dielectric composed of two components whose individual permittivities,  $\epsilon_1$  and  $\epsilon_2$ , are not excessively different is given by

$$\epsilon^m = \chi_1 \epsilon_1^m + (1 - \chi_1) \epsilon_2^m \quad (4.37) \Leftarrow$$

where  $\chi_1$  is the fractional volume concentration of the  $\epsilon_1$  component;  $m = 1$  or  $-1$  depending upon whether the components are in parallel or series, respectively. For a random distribution of components such as in ceramics

$$\ln \epsilon_\varsigma = \chi_i \ln \epsilon_1 + (1 - \chi_1) \ln \epsilon_2 \quad (4.38) \Leftarrow$$

The behaviour of anisotropic dielectrics requires the introduction of a susceptibility matrix to relate the polarisation to the electric field:

**Figure 4.6** Variation of real and imaginary parts of the permittivity. (IR – infra-red; r.f. – radiofrequency)

$$\begin{bmatrix} P_x \\ P_y \\ P_z \end{bmatrix} = \begin{bmatrix} \chi_{11} & \chi_{12} & \chi_{13} \\ \chi_{21} & \chi_{22} & \chi_{23} \\ \chi_{31} & \chi_{32} & \chi_{33} \end{bmatrix} \begin{bmatrix} E_x \\ E_y \\ E_z \end{bmatrix} \quad (4.39) \Leftarrow$$

which is simplified for uniaxial crystals by the relationship

$$\chi_{11} = \chi_{22} \neq \chi_{33} \quad (4.40) \Leftarrow$$

Dielectrics which have an inherently asymmetric crystalline structure may be piezoelectric in nature whereby electrical polarisation is produced in response to a mechanical stress, and *vice versa*. (The effect is to be distinguished from electrostriction, whereby the mechanical strain direction is independent of field polarity.) Some piezoelectric materials are pyroelectric (spontaneously polarised in the absence of an  $E$  field and dependent upon heating), whilst some pyroelectric materials are ferroelectric (spontaneously polarised in the absence of an  $E$  field and polarisation switched in direction by  $E$ ). The behaviour of piezoelectric materials is governed by

$$D = \epsilon_0 \epsilon_r E + qT \quad (4.41) \Leftarrow$$

$$s = M^{-1}T + qE \quad (4.42) \Leftarrow$$

where  $s$  is the mechanical strain,  $T$  is the stress,  $M$  is Young's modulus and  $q$  the piezoelectric modulus. Such materials have important implications for electromechanical transduction which, in addition to their electronic applications, have power-orientated uses for spark ignition and vibration generation.

The electrical resistance of dielectrics is extremely high so that their insulating properties are enhanced. The equivalent resistance is composed of three components which are the bulk dielectric resistivity, the surface resistivity and an effective resistivity representing the imaginary part of the complex permittivity. The currents which flow in dielectrics are two-fold (equations (4.3) and (4.4))—the conduction current,  $j_c$ , being less than the displacement current,  $j_d$ . The insulating nature of dielectrics may be destroyed if the voltage across the dielectric exceeds a critical value. Such failure may occur via three processes: (1) thermal breakdown occurs when the Joule heating of the dielectric exceeds the thermal conduction; (2) dielectric breakdown occurs due to avalanche ionisation in the dielectric; and (3) gas breakdown occurs via voids in solid dielectrics producing chemical degradation of the dielectric. Since the breakdown voltage of the latter is less than that of the dielectric, gas occlusion into solid dielectrics leads to significant degradation of the electrical insulation properties.

## 4.7 Optical materials

The basic interaction which produces the optical properties of materials is that between the electromagnetic field of light and the electrical charges within the material.

Propagation of light through a transparent dielectric is governed by the refractive index  $n_\varsigma$  which is related to the relative permittivity according to

$$n_\varsigma = \sqrt{\epsilon_r} \quad (4.43) \Leftarrow$$

The signal frequency dependence of  $\epsilon_r$  (equation (4.34)) produces dispersion which leads to signal distortion.

For transparent dielectrics which are anisotropic, the refractive index depends upon the plane of polarisation of the light and the material is *birefringent*. The implication is that the propagation velocity thus depends on the plane of polarisation of the light.

Birefringence may be induced in certain dielectrics through the application of either an external electric field (*electro-optics*) or mechanical stress (*photoelasticity*). Electro-optical effects occur due to the  $E$  field dependence of the susceptibility

$$P = \epsilon_0 \chi (1 + aE + bE^2)E \quad (4.44) \Leftarrow$$

Since  $1 \gg a \gg b$ , high electric fields (e.g. high-power lasers) comparable to interatomic cohesive forces are needed for the effects to be observable. The quadratic dependence of the polarisation upon the  $E$  field corresponds to the *Kerr effect* and leads to the science of non-linear optics. Situations where the quadratic term is negligible correspond to the *Pockel effect*. Both effects may be utilised for power system voltage monitoring using optical fibre sensing systems.

Photoelastic effects arise through the dependence of the polarisation on mechanical stress which follows from the piezoelectric equations (equation (4.41)).

Some transparent materials also exhibit the *Faraday effect*, whereby the plane of polarisation of the optical signal is rotated through an angle  $\theta_\zeta$  in proportion to an applied magnetic flux  $B$  according to

$$\theta_\zeta = VBl = \frac{2\pi\zeta}{\lambda_\zeta}(\eta_1 - \eta_2)l \quad (4.45) \Leftarrow$$

where  $V$  is the Verdet constant,  $l$  the path length,  $\lambda_\zeta$  the optical wavelength, and  $\eta_1$  and  $\eta_2$  are the refractive indices.

Unlike the electro-optical effects, the magneto-optical effect leads to the rotation of the plane of polarisation being independent of the propagation direction. (The Faraday effect is also observable in certain ferrites at microwave frequencies.)

Reflection of light from the surface of a material occurs due to the incident light polarising charges near to the surface and a re-radiating of light from the oscillating dipole. The reflection coefficient for light at normal incidence depends on the refractive index according to

$$R = [(n - 1)/(n + 1)]^2 \quad (4.46) \Leftarrow$$

Light absorption occurs due to ionic polarisation (infrared wavelengths), electronic polarisation (visible-ultraviolet range) and excitation of conducting electrons. Ionic and electronic polarisation give rise to narrow-band absorption, whilst excitation of conducting electrons provides a sharp edged absorption band extending below a critical wavelength.

Light scattering occurs due to atomic-sized particles (*Rayleigh scattering*,  $\propto \lambda^{-4}$ ) and micrometre sized irregularities (*Mie scattering*).

Light emission (*luminescence*) occurs via *fluorescence* (emission within 10 ns of energy absorption) or phosphorescence (emission delayed in some cases up to hours).

Energy to produce luminescence may be supplied by higher energy photons (photoluminescence), electron beams (cathodoluminescence), oscillating electric fields (electroluminescence), or by heating following activation by the above (thermoluminescence).

## 4.8 The plasma state

The plasma state may be formally defined as an ionised material in which the concentrations of ions and electrons are approximately equal and are relatively high. Examples of such plasmas are high-temperature gases such as those occurring in electrical discharges (e.g. electric arcs and high-power gas lasers), the ionosphere, or in certain semiconductors.

The electromagnetic behaviour of such materials is governed by the plasma frequency ( $\omega_p$ ) which is the natural frequency of the collective motion of the charges forming the plasma

$$\omega_p = \frac{Ne^2}{\epsilon_0 m} \quad (4.47) \Leftarrow$$

where  $N$  is the number density of the electrical charges. The significance of this parameter is that it governs the refractive index of the plasma according to

$$n^2 = 1 - (\omega_p/\omega)^2 \quad (4.48) \Leftarrow$$

where  $\omega$  is the angular frequency of the electromagnetic wave. Thus the interaction of electromagnetic waves with a plasma depends upon the wave frequency. For  $\omega < \omega_p$ ,  $n$  is imaginary which implies that such waves are reflected. Thus waves of different radiofrequencies are reflected by different ionospheric layers; metals and semiconductors transmit at short electro-magnetic wavelengths and reflect longer wavelengths. The electromagnetic behaviour of such plasmas is, therefore, more complicated than that of conventional conductors, dielectrics or magnetic materials.

## 5.1 Conducting materials

### 5.1.1 Copper

A major part of the world's production of copper is used in the unalloyed form, mainly in the electrical industries. Copper has the highest electrical and thermal conductivity of the common industrial metals with good mechanical properties, resistance to corrosion, easy jointing, ready availability and high scrap value.

#### 5.1.1.1 Conductivity

Pure copper has a volume resistivity at 20°C of  $1.697 \times 10^{-8} \Omega\text{-m}$ , lower than any known material except silver. In 1913 the International Electrochemical Commission established the International Annealed Copper Standard (IACS) by which the conductivity of all other grades and purities of copper and its alloys should be measured. The standard chosen was an annealed copper wire of length 1 m and cross-sectional area  $1 \text{ mm}^2$ , having a resistance of  $0.17421 \Omega$ . The corresponding volume resistivity at 20°C was assigned at  $0.17421 \times 10^{-8} \Omega\text{-m}$  representing 100% IACS. The percentage IACS for any other material can then be calculated as

$$\% \text{ IACS} = \frac{1.7241}{\text{Volume resistivity}} \times 400$$

Since the standard was adopted in 1913, higher purity copper is now commonly produced, explaining why electrical conductivities of up to 101.5% are frequently quoted.

The relative conductivity at 20°C of other metals compared to that of copper (=400) is silver 104, aluminium 60, nickel 25, iron 17, platinum 16, tin 13 and lead 8.

All impurities tend to lower the conductivity of copper but the worst effects are produced when solid solutions are formed. Precipitation by heat treatment can sometimes be used to minimise these effects. The worst impurities include phosphorus, arsenic, antimony and nickel which are commonly found in some grades of copper. Silver, cadmium and zinc produce only a marginal decrease in conductivity whilst improving mechanical properties considerably.

**Figure 5.1** Effect of added elements on the electrical resistivity of copper. (Courtesy of the Copper Development Association)

Figure 5.1 shows the effect of a range of impurities on the electrical resistance of copper. The requirements for copper wires for various electrical purposes are given in BS 4109 and BSEN 12166. More detailed information about standards is given at the end of the chapter.

The resistivity of copper, like that of all pure metals, increases with increasing temperature. The temperature coefficient of resistivity,  $\alpha_T$ , for pure copper is  $3.95 \times 10^{-3}/^\circ\text{C}$ . For accurate work the temperature coefficient must take account of dimensional changes due to thermal expansion. However omission of this correction for copper leads to errors of less than 0.5%.

#### 5.1.1.2 Mechanical properties and electrical conductor applications of copper and its alloys

Copper, as cast, has a tensile strength of 150–170 MN/m<sup>2</sup>. Subsequent rolling, drawing or other hot and cold working can raise the tensile strengths to 230 for the annealed material and to a maximum of 450 MN/m<sup>2</sup> for hard-drawn wire. Over this range of strengths, tensile moduli increase from 110 to 130 GN/m<sup>2</sup>, Vickers hardness values increase from 50 to 110–130 and ductilities decrease from 45–60% to 5–20%. Cold drawn materials start to recrystallise and lose their strength at temperatures in the range 110–200°C. The increase in strength due to cold working is associated with a loss of conductivity. For hard-drawn material of tensile strength T in the range 300–400 MN/m<sup>2</sup>, there is a loss of conductivity of 0.007T% relative to IACS copper.

For low-strength, low temperature applications, fire refined tough pitch (TP) copper is used. Small amounts of oxygen (0.04–0.05%), present as finely dispersed copper oxide, produce some strengthening and act to concentrate harmful impurities such as bismuth, preventing them from forming brittle intergranular films. Because oxygen has negligible solubility in the copper matrix (less than 0.002%) the conductivity is only slightly reduced (less than 1% IACS). Tough-pitch copper is unsuitable for intricate castings or applications where gas welding or brazing is involved. Reaction of oxides with the gas flame leads to hydrogen embrittlement. For these applications, the slightly more expensive oxygen free high conductivity copper (OFHC) containing less than 0.001% oxygen, is used. These two materials are most widely used for wire and strip conductors, for windings of a.c. and d.c. motors and generators and for transformers. Heavier gauge bar, strip and channel section material is used for bus-bars. Large quantities of high-conductivity wire and strip are used in telephone and power cables and as the outer sheathing of mineral insulated copper clad cable for fire and abrasion resistant applications.

Alloying of copper with cadmium, chromium, silver, beryllium and zirconium is used to improve mechanical properties and resistance to wear, especially at high temperatures. Such improvements are always at the expense of some increase in resistivity. Hardening of contacts by dispersions of refractory oxides improves resistance to ablation, fusion and wear.

Copper alloys containing 0.7–1.0% cadmium have greater strengths under both static (up to 750 MN/m<sup>2</sup>) and alternating stresses and greater resistance to wear, making them useful for contacts and telephone wires, although there is little improvement in strength retention at elevated temperatures. Conductivity is between 80 and 97% of that of IACS material, depending on the degree of cold work.

Alloys containing 0.77% chromium can be heat treated to retain their enhanced hardness and tensile strength (up to 480 MN/m<sup>2</sup>) even after exposure to more than 1000 h at

340°C when the tensile strength of OFHC or tough-pitch copper would be reduced to 170–200 MN/m<sup>2</sup>. Both tensile strength and conductivity depend on the heat treatment, high-temperature (solution) treated materials having typical values of 230 MN/m<sup>2</sup> and 45% IACS while for annealed (precipitation hardened) materials the values are 450 MN/m<sup>2</sup> and 80%. These materials are used in electrical engineering for welding electrodes and for light current-carrying springs. Copper-beryllium and copper-zirconium alloys have similar properties and applications with superior notch-fracture resistance.

For applications where the highest conductivity is essential and enhanced creep strength at high temperature is required (e.g. for the rotor conductors in large turbogenerators and for components which have to be tinned, soldered or baked during fabrication), copper alloys containing up to 0.15% silver are used. These have the same conductivity as IACS copper and retain their mechanical properties to 300°C.

Alloys containing tellurium (0.3–0.7%), sometimes with small amounts of nickel and phosphorus, have machining properties approaching those of free-cutting brass and retain their tensile strength (275 MN/m<sup>2</sup>) to 315°C with improved oxidation resistance. Tellurium additions alone produce only small reductions in conductivity as the solubility of tellurium in copper is only about 0.003% at 600°C. Copper-sulphur (0.4%) and copper lead (0.8%) alloys are also finding application because of their easy machining and electroplating properties.

For castings, electrolytically refined copper is sometimes used as the raw material, but more commonly, deoxidised tough-pitch copper is employed. The usual deoxidant for copper is phosphorus which produces large increases in resistivity (as little as 0.04% will reduce the electrical conductivity to about 75% of that for pure copper) and hence more expensive deoxidants such as silicon, lithium, magnesium, beryllium, calcium or boron are required. Cadmium-copper and chromium-copper alloys are also used for castings.

### 5.1.1.3 Other applications of copper and its alloys

**Springs** The material selected depends on whether the spring itself is required to carry current. For low conductivity spring materials, phosphor bronze (3.75–6.75% Sn, 0.1% P) and nickel silver (10–30% Ni, 10–35% Zn) are widely used and have conductivities in the ranges 12–27% and 6–8% IACS, respectively. Beryllium-copper alloys are used in more critical applications; a 2% beryllium alloy can be cold worked and heat treated to give tensile strengths of 1000–1500 MN/m<sup>2</sup>, while retaining a conductivity of 25–35% IACS. With other compositions and heat treatments even higher conductivities can be obtained.

**Resistance and magnetic materials** Copper alloys containing manganese (9–12%), aluminium (0–5%) and nickel (0–10%) are widely used as resistance materials because they have high resistivities ( $38\text{--}48 \times 10^{-8}$  and  $44\text{--}175 \times 10^{-8}$  Ωm, respectively), low or zero temperature coefficients of resistance ( $-0.03$  to  $+1.4 \times 10^{-3}/^{\circ}\text{C}$  over the range 0–100°C) and low thermal e.m.f.s relative to copper (see page 2/9 section 2.2.2.6). Copper is also a constituent of many magnetic materials, both hard and soft.

**Contacts** Palladium-copper and silver-copper (7.5–50% copper) alloys are suitable for light current applications.

For heavy-duty contacts, sintered copper-tungsten materials are tough and durable; similar materials are used for electric discharge machining electrodes.

**Electroplating alloys** Copper alloys containing nickel (7–23%) and zinc (10–35%), known as German or nickel silvers, are widely used for electroplating as they form durable corrosion-resistant coatings with reflectivities equivalent to that of standard silver.

**Heat-transfer materials** Copper alloys are extensively used in nuclear and fossil fuel steam plant for electric power generation for heat exchangers such as feedheaters and condensers, although there is an increasing tendency towards the substitution of mild steel for the former and titanium for the latter. The principal condenser alloys are Admiralty brass (70% Cu, 30% Zn with small arsenic and zinc additions to prevent dezincification) and aluminium brass (76% Cu, 2% Al, 30–10% Ni with 1–2% Fe, 1–2% Mn). These are used where improved corrosion resistance is required. In more erosive conditions caused by suspended solids in the cooling water, cupronickel alloys (70–90% Cu, 30–10% Ni, with 1–2% Fe, 1–2% Mn) are used at higher initial capital cost and with some penalty in heat transfer. For feedheater applications cupronickel alloys are most widely used in older plant.

**Memory-effect alloys** Some copper-zinc-aluminium alloys (8–14% Al, 0–14% Zn, 0.3% Ni) have the useful property of existing in two distinct shapes above and below a critical transformation temperature (within the range  $-70^{\circ}\text{C}$  to  $+130^{\circ}\text{C}$ ) due to a structural change. These alloys are finding applications in temperature-sensitive actuating devices, replacing bimetallic strip or thermistor controlled relay devices.

**Superconducting alloys** Dendritic copper-niobium alloys (20–30% Nb) may be plated or diffused with tin and reacted *in situ* to form fine superconducting Nb<sub>3</sub>Sn filaments intimately incorporated in a copper matrix. Such materials have high critical current densities in the 8–14 K temperature range and an improved tolerance to strain.

## 5.1.2 Aluminium

Aluminium and its alloys are widely used in the electrical industry because of their good electrical and thermal conductivity, generally excellent mechanical properties and corrosion resistance, ease of fabrication, low density and non-magnetic properties. World production of aluminium has steadily increased and has overtaken that of copper which it has replaced in many electrical applications. Weight for weight aluminium is a cheaper and better conductor than copper.

### 5.1.2.1 Resistivity

Pure aluminium has a resistivity of  $2.64 \times 10^{-8}$  Ωm at 20°C with a mean temperature coefficient over the range 0–100°C of  $4.2 \times 10^{-3}/^{\circ}\text{C}$ . Thus it has about 66% of the conductivity of pure copper or 66% of that of the International Annealed Copper Standard (IACS) at 20°C. The density of aluminium is 2.7 compared with 8.9 for copper and hence, weight for weight, the conductivity of aluminium is 2.1 times that of copper and exceeds that of all known materials except the alkali metals.

### 5.1.2.2 Mechanical properties and electrical conductor applications of aluminium and its alloys

The mechanical properties of aluminium depend upon the purity as well as the degree of cold work. Ordinary aluminium of commercial purity contains 99.2% aluminium whilst superpurity grades contain 99.99%. For special purposes aluminium may be zone refined to give a purity of 99.9995%. Tensile strengths and hardness are at a minimum in the high purity 99.99% annealed grades giving values of 59 MN/m<sup>2</sup> and 15 Brinell hardness, respectively. Commercial purity, 99.2% aluminium has tensile strength of about 91 MN/m<sup>2</sup> and Brinell hardness of 22. Cold working will increase these values by a factor of 2. Low strength and hardnesses mean that in most applications aluminium is used in the alloyed form.

**Overhead-line conductors** All-aluminium alloy conductors (AAAC), made from alloys containing 0.3–1.0% silicon, 0.4–0.7% manganese and small amounts of iron and manganese, are being used increasingly for high-voltage ( $\geq 400$  kV) overhead lines. These alloys can be precipitation hardened to give tensile strengths in the range 310–415 MN/m<sup>2</sup>, while retaining conductivities of 52–60% of that of IACS copper.

All-aluminium (AAC) and steel-cored aluminium conductors (ACSR) for overhead lines are constructed to IEC 60207,9 (BS 215) with a maximum permitted resistivity for the aluminium of  $2.83 \times 10^{-8} \Omega\text{m}$  at 20°C and a constant-mass temperature coefficient of resistivity of  $4.03 \times 10^{-3}/^\circ\text{C}$ . All-aluminium alloy conductors (AAAC) are constructed to IEC 60208 (BS 3242) which specifies a maximum resistivity of  $3.28 \times 10^{-8} \Omega\text{m}$  at 20°C and a constant-mass temperature coefficient of resistivity of  $3.6 \times 10^{-3}/^\circ\text{C}$ .

**Reinforced cables** Where cables are steel reinforced the requirements for the steel core wires are given in IEC 60888 (BS 4565) and for aluminium in BSEN 1172 and BSEN 1652-4. In order to prevent galvanic corrosion, all steel wires and fittings must be galvanised—suitable specifications are given in IEC 60888 (BS 4565) and ISO 1459-61 (BS 729). Complete greasing of the central steel core wires and of the inner aluminium wires is necessary to minimise corrosion in marine or industrially polluted environments.

Because of the widely different mechanical properties of aluminium and steel, special jointing and anchoring systems have been designed. These generally take the form of compression fittings applied using hydraulic or mechanical crimping tools. Aluminium conductor alloy reinforced (ACAR) cables overcome many of the shortcomings of steel-reinforced cables in terms of corrosion and jointing, they offer a good combination of conductivity, strength and weight.

**Bus-bars** Bus-bars are commonly constructed from aluminium and aluminium alloys of similar compositions to those employed in overhead-cable manufacture. Specification in terms of strength is lower, permitting lower resistivity requirements of less than  $3.133 \times 10^{-8} \Omega\text{m}$  to be achieved. Alloy materials have lower temperature coefficients of resistivity than pure aluminium so that performance in terms of current-carrying capacity improves relative to pure aluminium as the temperature increases. Aluminium bus-bars of the same current-carrying capacity as copper bus-bars have the added advantage of greater heat dissipation and only half the weight.

Jointing of aluminium or aluminium alloy bus-bar material requires more care than copper. Aluminium brazing,

soldering or inert-gas welding is employed. Alternatively, mechanical jointing may be employed. Where steel or copper fittings are involved, precautions similar to those used with steel-reinforced cables should be used to avoid galvanic corrosion. Sealing with greases, tapes, mastics or paints containing corrosion inhibitors will reduce the need for maintenance. Anodised or aluminium clad alloys are often employed in severe environments.

### 5.1.2.3 Other applications of aluminium and its alloys

#### *Switchgear, generators, motors and transformers*

Aluminium casting alloys containing 0–12% silicon with small additions of iron, copper, magnesium and nickel are widely used for switchgear, transformers, rotors for small induction motors and generator castings where lightness is essential. Tensile strengths range up to 345 MN/m<sup>2</sup> and conductivities to 50% of that of IACS copper.

Aluminium strip and wire are also used for transformer windings and for field coils in starter motors for automotive applications.

**Heat sinks and heat exchangers** Aluminium and its alloys with copper, silicon, magnesium and other metals are widely used as heat-sink and heat-exchanger materials. The thermal conductivity of pure aluminium is 2.38 W/m/K, which is 56% of that of pure copper. Again on an equal weight basis, the thermal conductivity of aluminium is almost twice that of copper.

**Capacitors** High-purity aluminium is widely used as a capacitor-plate material. High-capacity, low-volume capacitors can be fabricated by anodising aluminium electrolytically; the oxide layer produced forming the dielectric. Alternatively, plastic film materials may be aluminised on both sides forming the electrodes of film capacitors for a range of electronic applications.

### 5.1.2.4 Standards

Each country has in the past had its own standards for materials. Over the past twenty years or so there has been a movement towards international standards, which for electrical materials are prepared by IEC (International Electrotechnical Commission). More general standards are prepared by ISO (International Standards Organisation). When an international standard is produced the member countries copy this standard and issue it under their own covers. This now applies to BSI, ASTM, DIN, and the French standards organisation. Where appropriate, standards are also issued as applying to all the European Union Countries.

Leading standards for electrical materials are shown as follows in Table 5.1.

## 5.1.3 Carbon

Carbon occurs in nature in two crystalline forms, graphite and diamond, the former being thermodynamically more stable at ambient temperature and pressures. Synthetic carbons prepared from coke or other precursors may be predominantly graphitic or amorphous depending on the conditions of manufacture. Diamonds may be prepared from graphite using high-pressure techniques but the resulting products are usually suitable only for industrial applications; new techniques have been reported for the production

**Table 5.1** International and British Standards for Copper and Aluminium**Copper**

BS 1432,3 & 4: 1970–1991	IEC 60356	Specifications for copper for electrical purposes.
BS 4109: 1991	BSEN 12166 (replaces BS 2873) ASTM B1 – B3	Specifications for copper for electrical purposes. Wire for general electrical purposes and for insulated cables and flexible cords. (Includes wire tables with diameter, resistance ( $\Omega/\text{km}$ ), and mass ( $\text{kg}/\text{km}$ ).)
BS 7884: 1997	ASTM B258	Specifications for copper and copper-cadmium stranded conductors for overhead electric traction and power transmission systems. Standard nominal diameters and cross-sectional areas of AWG sizes of solid round wires used as electrical conductors.

of gem-quality stones by vapour deposition onto small specimens.

The engineering applications of carbon exploit the following properties:

- (1) it is thermally stable and in the absence of an oxidising atmosphere retains most of its mechanical strength to a temperature of  $3500^{\circ}\text{C}$  at which, under atmospheric pressure, it sublimes;
- (2) its oxides are gases and leave no surface film;
- (3) it is dimensionally stable, does not swell in water and can be machined to close tolerance;
- (4) it has a low expansion coefficient and low density (each about one-quarter that of steel);
- (5) it is a good conductor of heat, with a high specific heat and a great resistance to thermal shock;
- (6) it is not wetted by molten metals;
- (7) it is chemically inert;
- (8) it is self-lubricating under normal atmospheric conditions; and
- (9) it is electrically conductive and has high contact resistance with metals.

Electrical resistivity is lowest in the graphitic materials, which in the form of graphitised carbon black finds wide use in the manufacture of electrical carbons. Resistivity is dependent upon origin, composition and manufacture; typical values are in the region of  $10^{-5} \Omega\text{m}$ .

**5.1.3.1 Carbon brushes**

Current collection in moving contacts forms one of the most important electrical applications of graphitic carbon. Brushes must carry heavy current without excessive over-heating or wearing of the parts contacted. Low friction, high contact resistance and infusibility are amongst the most desirable characteristics. *Table 5.2* gives data on some widely used brush grades.

**Commutators** Contact resistance is of major importance in commutation. High contact resistance reduces losses due to high circulating currents, minimising problems due to over-heating and sparking. Commutator machines use non-metallic 100% carbon brushes, except in low-voltage

applications where metal-graphite grades are necessary to reduce voltage drop and hence losses. Current density and surface speed must be considered in selection of suitable grades. Low-friction materials and good design serve to reduce chatter, ensuring good contact between brush and commutator bars. Friction characteristics may be affected by a number of factors, including the chemical and mechanical properties of the commutator metal as well as humidity, temperature, contaminants and abrasives. The ash content of the brush material is important in determining friction and abrasion characteristics and in some types of commutator may serve to wear down insulation between commutator segments. The performance of a brush on a commutator machine is influenced by its position on the commutator, i.e. the circumferential and axial stagger.

**Slip-rings** When commutation phenomena are absent, brush grades with low contact drops, particularly those in the metal-graphite class, can be employed. Again, current density and surface speed must be taken into account; at the highest surface speeds it is necessary to select a grade from the natural graphite class. For applications in instrumentation, such as pick-ups for thermocouples and strain gauges, silver-graphite (SM) brushes on pure silver rings are needed to give minimal and constant contact drop.

**Wear** The rate of wear of brushes is not directly related to the hardness of the brush material but more to the grade, the current density and quality of mechanical features (surface roughness, eccentricity, stability of brush holders and brush arms and angle of brush relative to the pick-up surface).

**Spring pressure** The pressure specified for a particular brush grade is determined from laboratory and field tests to give the optimum performance and life, and should be carefully adhered to. Pressures are normally of the order of 14–21 mN/mm<sup>2</sup>, but in conditions of considerable vibration (as in traction and in aircraft) pressures may be as high as 28–50 mN/mm<sup>2</sup>.

**Brush materials** Brushes using lampblack base are widely used for medium- and high-voltage machines, d.c. motors and generators and universal motors. These materials possess high contact resistance which is necessary for good commutation. Graphitised petroleum coke is used for non-metallic slip-ring brushes where high contact resistance is not required. Metal powders, copper or silver, blended with graphite may be used for slip-ring or low-voltage commutating machinery. The bond in most non-metal brush grades is carbon from pyrolysis of the coal-tar pitch binder. Some graphite grades are bonded with synthetic resins. Final properties are controlled by use of impregnating agents combined with heat treatments which are designed to control contact resistance, filming action and friction characteristics.

**Brush design** For standards of brush design, reference should be made to BS 4999 and to IEC Publication 136, on which the British Standard is based.

#### 5.1.3.2 Linear current collection

This is the reverse of the machine condition in that the conductor is stationary and the collector (equivalent to the brush) is moving. Current collection of this type is found on rail and trolley traction systems, cranes and line process

plants. In many applications the collector and conductor are open to aggressive environments including adverse weather conditions. Arcing which results from such situations roughens the conductor and accelerates wear in the collector. Carbon as a contact material provides the real benefits of a very low rate of conductor wear, long collector life and good contact stability. The carbon element, which needs no applied lubrication, is very hard and strong. Carbon shoes are in competition with brass or bronze wheels and copper shoes. Radio interference is minimised by use of carbon shoes; the grades most generally used are Link CY and Link MY, the latter being metal impregnated.

#### 5.1.3.3 Carbon contacts

Electrical contacts include components for switches, circuit-breakers, contactors, relays and sliding contacts. The properties of carbon and graphite of importance in such applications include: self-lubricating and filming characteristics; non-welding; unwetted by molten metals; and high thermal stability. These properties make carbon the ideal contact material, particularly where arcing may occur under severe contact-bounce conditions. Carbon requires higher voltages to maintain arcing conditions than do many metals and the effects of arcing on carbon are less significant as carbon sublimates rather than melts at temperatures in excess of 3500°C. The material does not tarnish, giving constant contact resistance in the absence of any surface films.

Selection of carbon contact grade for such applications is in accordance with the required contact resistance, the metal-impregnated and metal-graphite classes giving the lowest and the carbon class the highest values.

#### 5.1.3.4 Resistance brazing and welding

Using the relatively high resistance characteristics of carbon, it is possible to obtain a heating effect that can be used for the joining of metals. The major application is in resistance brazing where one component in the system is melted, or a low-melting alloy solder is introduced to complete the bond.

The absence of melting of carbon at high temperatures prevents sticking or welding of the carbon to the workpieces and prevents distortion of the tips of the tool even at white heat under pressure. Design of the carbon tips, in terms of shape and area of contact, is used to control the amount of heat generated in the joint. The lower strength of carbon, compared to the alternative water-cooled metal electrode, limits its use in resistance-welding and spot-welding applications; plain carbon or electrographites are used, the latter generally giving better life.

#### 5.1.3.5 Arc welding

Electrodes of carbon are very suitable for arc welding. The weld is achieved by either a fusion process (i.e. fusion of butting edges) or by feeding a weld rod into the arc formed between the workpiece and the electrode. Carbon arcs find limited use in metal cutting, typical applications being in the cutting of risers from castings or the grooving of metal plates. Carbon arcs are widely used for brazing of thin mild-steel sheet.

#### 5.1.3.6 Granules

Carbon granules for microphone applications are made in sizes of 60–700 µm, the largest being suitable for maximum

response but developing more background noise. The smallest granules give better quality but a lower response. For normal telephone work, granules of the smaller range of sizes are employed to give good response and acceptable noise. Carbon is superior to metal powders in these applications due to high specific and contact resistance and the absence of any tendency to oxidise or tarnish. The result is a stable and reproducible performance essential to audio applications.

Telephone granular carbon is a crushed product made from petroleum coke; particle size and shape are important in determining performance characteristics. Special non-ageing grades are available.

### 5.1.3.7 Fibres

Fibres are the latest form in which carbon is manufactured; they possess a near-perfect orientation of the graphitic structure parallel to the fibre axis. Fibres have high strengths and elastic moduli which may be controlled by the maximum temperature attained during heat treatment. Low density confers high specific strength and stiffness of particular value in aerospace applications. Selective use of carbon fibres in composites is employed to maximise properties in desired directions. Carbon fibres are graphitic structures produced by carefully controlled pyrolysis of polyacrylonitrile or cellulose fibres under tension. More recently, petroleum or coal-tar pitch have been used.

## 5.2 Superconductors

Superconducting materials lose all electrical resistance below a temperature called the *critical temperature* ( $T_c$ ) which is different for different materials. The phenomenon was first observed in mercury in 1911. Engineering interest in superconductors became really significant in the early 1960s when materials capable of carrying high current densities (up to  $10^9 \text{ A/m}^2$ ) in high magnetic fields (several tesla) were discovered. These opened the way for high-field electromagnets. The interest was reinforced by advances (partly spurred by superconductor development) in the technology of large-scale helium refrigeration (hundreds of watts cooling at 4 K) which could produce cold gaseous or liquid helium for cooling purposes. The discovery of the Josephson effect (1962) led to small, low-field, superconducting electronic devices (see Section 5.2.5). More recently the interest has multiplied with the discovery of the high temperature superconductors in 1986 and there are now power transformers and power cables at the prototype stage.

Two groups of materials have superconducting properties. The 'classical' or low- $T_c$  superconductors (LTS) are metals or alloys all of which show superconducting properties below 23 K. Virtually all industrial applications use materials from this category, in particular, NbTi or Nb<sub>3</sub>Sn. The second group are metal oxide compounds based on copper oxide (CuO<sub>2</sub>) subunits. These are known as ceramic or high temperature superconductors (HTS) and the compound with the highest known critical temperature (HgBaCaCuO;  $T_c$  133 K (−140°C)) belongs to this group. The coolant for LTS material is liquid helium which is liquid below 4.2 K and for HTS material the coolant is liquid nitrogen which is liquid below 77.3 K (−195.8°C).

Once cooled below the critical temperature, superconductors can carry resistanceless current up to a maximum determined by the ambient magnetic field and the temperature. If the limiting combination of current, magnetic field and

temperature is exceeded, the material reverts to an electrically 'normal' condition. The temperature, magnetic field and current density are independent variables, the critical values of which characterise the material. The capability to carry large lossless currents in magnetic fields of several tesla is a primary requirement of any superconductor if it is to be used in electrical plant.

### 5.2.1 Low temperature superconductors

For engineering purposes there are two varieties of superconductor—surface superconductors and bulk superconductors—determined as much by the way they are used as by their intrinsic properties. Surface superconductors carry superconducting current only in a surface layer and only in low magnetic fields. The magnetic field at the surface is equal to the current per unit width of the surface. In general, the resistance of superconductors to a.c. is not zero, though small; that of surface superconductors can be virtually zero. The small power losses that do then occur arise mainly from factors such as surface irregularities.

Bulk superconductors can carry currents throughout their section. Losses under changing current are relatively high and bulk superconductors are difficult to use at power or high frequencies. The loss is effectively a hysteresis loss. Both the high- $T_c$  superconductors and ultrafilamentary superconductors (see Section 5.2.2) may ameliorate this problem. Some bulk superconductors, often referred to as 'hard' superconductors, can carry large current densities in strong magnetic fields (see Table 5.3). Materials with good superconducting properties tend to have high normal resistivities.

Physicists divide superconductors into types I and II. Type I materials are perfectly diamagnetic below the critical magnetic field, they carry surface currents only and exclude all magnetic flux from their bulk. The depth of current and field penetration is determined by quantum mechanical considerations and is typically  $10^{-7} \text{ m}$  say 1000 atoms. Above the critical field type I materials lose all diamagnetic properties. Type II materials also show diamagnetism but lose the property gradually as the field is raised above a first critical field. The magnetic field penetrates the bulk in quantised flux bundles or fluxons ( $2 \times 40^{-15} \text{ Wb/bundle}$ ) which can be detected with sensitive techniques. Electrical resistance returns above the critical field.

The quantum theory of superconductivity envisages a low-temperature condensed state of electrons in which they interact, through the atomic lattice, to form temporary pairs. Each member of the pair distorts the lattice in such a way as to attract the other. Because of their energy state, these pairs are not readily scattered and flow unimpeded. This mechanism is well established for metallic superconductors but the exact coupling mechanism which generates the pairs in high- $T_c$  materials is uncertain. Without detailed prior knowledge of the electronic and atomic structure of a material, the theory is not sufficiently quantitative to predict whether or not the material will exhibit superconducting properties, let alone what the properties will be. Analogy with known superconductors has proved the best guide to new ones.

Typical low  $T_c$  materials used for engineering purposes are shown in Table 5.3. Niobium is the surface superconductor most commonly envisaged for use in a.c. equipment such as power cables. Lead is cheaper but not usually preferred unless for special reasons a low-field capacity is satisfactory. Bulk superconductors can be used in low fields as surface superconductors, e.g. niobium-tin (Nb<sub>3</sub>Sn). Of the bulk superconductors, niobium-titanium is a ductile alloy,

**Table 5.3** Some low  $T_c$  superconducting materials and their properties

<i>Material</i>	<i>Critical Temperature*</i> (K)	<i>Upper critical magnetic field at 4.2 K† (T)</i>	<i>Critical current density (in superconductor) at 4.2 K and 5 T (GA/m<sup>2</sup>)</i>
Lead	7.2	0.06	—
Niobium	9.2	0.4	—
Niobium-tin (Nb <sub>3</sub> Sn)	18.1	23	5–10
Niobium-germanium (Nb <sub>3</sub> Ge)	23	37	5–15

\*All the superconductors listed are type II except lead (type I). Critical current densities are very dependent on the way in which the material is prepared.

†4.2 K is the boiling point of liquid helium.

which needs to be cold-worked to produce good current carrying capacity. Niobium-tin is a compound and very brittle; it is usually made by diffusion of tin into niobium, sometimes from a bronze, sometimes in ribbon form to reduce mechanical stresses during handling. The diffusion is often produced by heat treatment of the magnet coil after it has been wound.

### 5.2.2 Stabilisation of magnet conductors

Bulk superconductors suffer from electrothermal instability, especially when used near their critical conditions. A small increase in temperature lowers the critical current density, which can lead to a further increase in temperature, ultimately driving the material into its normal resistive state; heat generation then becomes very rapid and the whole coil becomes 'normal'. Stabilisation can be achieved in several ways. All methods use a composite conductor in which ordinary conductors, frequently of copper, are in intimate contact with the superconductor. The copper has a much lower electrical resistance than the superconductor in its normal state. The most robust stabilisation system is the so-called cryostatic method. The design provides plenty of copper in parallel with the superconductor and good cooling of the composite. It envisages some agent causing the temperature to rise and current to transfer into the low-resistance copper over a short length of conductor. The thermal conditions are designed to be such that the composite conductor will cool so that once more the superconductor element regains its superconducting capacity. This method requires coolant access to most of the winding.

A more compact scheme for coils aims to limit localised temperature rises. Magnetically induced electrical losses in the superconductor during current changes are reduced by using a composite of fine strands of superconductor co-processed in a matrix, often of copper. The diameter of the superconducting filaments can be as small as 100 nm and each composite wire may contain upwards of half a million strands. Such ultra-fine filamentary conductors have very low a.c. losses and may potentially be used at power frequencies. Although normally the superconducting filaments have diameters in excess of 1  $\mu$ m, strands can be twisted and the matrix incorporates components with high resistance, such as cupronickel, to control circulating currents and losses. The need for additional metal means that current density in terms of the total conductor cross-section is up to 10 or more times lower than that in the superconductor itself. This is especially so for Nb<sub>3</sub>Sn and Nb<sub>3</sub>Ge. Perhaps most importantly, the winding can be encapsulated in resin to prevent frictional heating as the winding takes up mechanical loads; preventing cracking of the resin is an important part of the technology.

The thermal instability is a consequence of the very small specific heat of most materials at liquid helium tempera-

tures and, consequently, a localised energy input can easily lead to a significant increase in temperature. However, at liquid nitrogen temperatures the specific heat is some orders of magnitude greater and thereby the problem is considerably eased.

### 5.2.3 Applications of superconducting magnets

To produce magnetic fields greater than about 2T using conventional copper windings can require powers of the order of megawatts. The outstanding success of superconductors has been in providing strong fields for medical imaging, laboratory experiments and for high energy nuclear physics equipment without a massive power burden. The power to drive the helium refrigerators or liquefiers is a factor of 100 or even 1000 less. This advantage can extend to lower fields, especially when the field is required over a large volume. Magnets generating fields in excess of 15 T are readily obtainable with sufficient stability and homogeneity for use in magnetic resonance experiments.

#### 5.2.3.1 Magnetic resonance imaging

The main commercial market for low- $T_c$  superconductors is as magnets for medical imaging systems based on the magnetic resonance of hydrogen and other nuclei. More than 1500 magnetic resonance imaging (MRI) units are installed world-wide. A superconducting solenoid with a large room temperature is the heart of the system and represents about 25% of the total cost. Although these MRI units have to be topped up with liquid helium, with the latest sophisticated designs, this is usually required only annually. They have been further improved by the use of high temperature superconductor tape for the leads which reduces the heat leaking to the liquid helium by 90%. These MRI instruments provide a non-invasive diagnostic technique without the dose restrictions of conventional X-ray tomography. MRI can provide information concerning the structure of tissue and the flow of fluids in the body by the measurement of various relaxation times which, combined with its anatomical imaging ability allows detailed diagnostic characterisation. Although whole-body scanners using superconducting solenoids generating fields of more than 2T are in use, a typical system has a room temperature bore diameter of 1.2m with a central field of less than 1.5T, and a homogeneity of about 10 ppm over half the bore. An example of a MRI system illustrating the superconducting magnet is shown in *Figure 5.2*.

#### 5.2.2.2 High energy physics

Many superconducting magnets are used for particle accelerators, for beam handling and for analysing particle

**Figure 5.2** A magnetic resonance imaging (MRI) system with a superconducting magnet operating at 4.2 K. (Courtesy of Oxford Magnet Technology and Siemens)

reactions in bubble chambers. Beam-bending dipoles are made in large numbers and when the US superconducting supercollider (SSC) is built it will represent a market of a size similar to that of the MRI industry. The electron-proton colliding beam facility at Deutsches Elektronen-Synchrotron (DESY) in Hamburg, Germany has for example 416 dipoles each 8.8 m long with a central field of 4.7 T. Radiofrequency cavities employing surface superconductors are also used in some accelerators. The good performance of all these devices and the associated refrigeration plant has shown that equipment using superconductors can run economically and reliably. If magnetically confined thermonuclear fusion is to be a future power source, the windings needed will have to be superconducting. Such magnets have already been built for experimental investigation.

#### 5.2.3.3 Magnetic separators

Superconducting magnets can be used for extracting weakly magnetic materials. This is a very good application for low temperature superconductivity magnets which are readily available. A fine magnetic particle will move in a magnetic field gradient and will be attracted onto the magnet providing the gradient. This technique has been used throughout the world for removing iron oxide from china clay to give a good white colour and to prevent low temperature localised melting during firing of the clay.

The strong magnetic fields and field gradients are also used for separating quite weakly magnetic materials such as ferro-manganese and ferro-titanium oxides. It is also used for separating haemoglobin from blood.

#### 5.2.3.4 Traction and machines

A pilot development for trains uses superconducting coils mounted underneath the carriages. The field from the coils provides lift from a conducting surface placed between the rails when the train is moving fast enough. The principle offers a possible efficient alternative to the wheels used on very high speed trains.

Homopolar d.c. motors using superconducting exciter coils have been built and work satisfactorily. A generator

and motor operated back-to-back can form a quiet efficient 'gearbox' for ship propulsion.

An a.c. generator with a superconducting exciting winding on the rotor is more efficient than one with a conventional copper winding: about 0.5–1% more output is achievable for a given mechanical input. Prototype superconducting rotors have been built and tested up to 400 MVA using NbTi technology. Continued development indicates that these machines will eventually become available.

#### 5.2.3.5 A.c. power switches and current limiters

At the moment a superconductor becomes 'normal' it very quickly regains its resistance. The transition phenomena can be used as the basis of a simple power switch, but such applications have been limited by the poor a.c. performance of conventional superconductors. High- $T_c$  superconductors should improve the position.

The conventional transductor intended for fault current limitation in electric power systems has a d.c. bias winding to saturate the core of an inductor, and so reduce the a.c. impedance of a coil on the same core. The core can come out of saturation on one half-cycle if the a.c. current attempts to rise excessively; the impedance of the transductor then increases. Superconductors offer an attractive method of providing the d.c. bias.

#### 5.2.3.6 Other power applications

If hydrodynamic generators are to be used to produce electricity efficiently, their windings will have to be superconducting.

For energy storage, gigantic inductors holding perhaps 500 MWh are being discussed. Such a store could retain electricity generated cheaply at night for use during the day. A small superconducting energy store for controlling stability in a power system is being used on an experimental basis.

Because superconductors that carry a.c. do not function satisfactorily in strong fields, they give no benefit to power transformer design. However, ultra-fine filamentary NbTi has a sufficiently improved a.c. performance that consideration of such a design is possible. A small 70 kV-A transformer using such wires has been constructed.

### 5.2.4 Power transmission

High power superconducting cables, either a.c. or d.c. appear to be more economical than conventional ones for power transfers in excess of a few gigawatts; such power transfers in single circuits are not at present required. A.c. cables would use superconductors in a surface mode to avoid excessive hysteresis losses.

### 5.2.5 Electronic devices

When two pieces of superconductor are connected together by a 'weak' link, many intriguing phenomena occur which form the basis for a variety of electronic devices. Niobium and lead are commonly used and the link, rather poorly conducting or even insulating, may consist of a point contact, a fine constriction or a thin (2–5 nm) layer of oxide. The resulting junction can carry supercurrents (typically up to a few hundred microamps) by tunnelling of electron pairs through the barrier without any voltage drop. This is the d.c. Josephson effect. If the current exceeds some critical value, which depends on the magnetic flux in the barrier,

the junction switches to a resistive state with a voltage drop of typically a few millivolts. When there is a voltage across the junction, the supercurrent component oscillates at a very high frequency determined by the voltage (483.6 GHz/mV). This is the a.c. Josephson effect: it can be used as a precise voltage standard.

### 5.2.5.1 SQUIDS

An extremely sensitive measuring device may be made from a pair of Josephson junctions connected in parallel by a superconductor; this is known as a SQUID (superconducting quantum interference device). The total critical current then depends periodically on the flux (the period being the flux quantum) within the loop formed by the two junctions. Field changes as low as  $10^{-14}$  T can be detected. Careful screening, together with differential techniques, are needed to eliminate unwanted responses. Small voltages in low-resistance circuits (e.g.  $10^{-10}$  V in 1  $\Omega$ ) and small currents may be measured by using the SQUID to determine the associated magnetic field. Sometimes just one junction is used in a superconducting loop with the flux being sensed by its effects on an inductively coupled radiofrequency bias circuit. With sufficiently high bias frequencies, measurements into the microwave region are possible.

Instruments incorporating SQUIDS are finding application particularly in geophysics (studies of rock magnetism, exploration based on anomalies, determination of deep earth conductivity) and in biomagnetism (e.g. investigation of electrical activity in the heart, brain and muscles).

### 5.2.5.2 Computer elements

Many groups are exploring the possibility of using SQUIDS and related devices in computers. The bistable characteristics, small size, ultra-short switching times (as low as 10 ps) and very low power consumption make SQUIDS attractive components for large high-speed computers which must be compact to reduce signal-transit times. The need for liquid helium cooling is not seen as a serious disadvantage.

As a logic gate, currents in control lines overlying the SQUID induce transitions between the zero voltage and resistive states by altering the flux linking the device. For memory cells, superconducting loops may be used with the binary values 1 and 0 being represented by the presence or absence of a persistent circulating current. One Josephson junction in series with the loop and one inductively linked to it are required to 'write' and 'read', respectively. Arrays

of junctions may be deposited on a substrate using many of the processes developed for fabricating silicon microcircuits. Using such technology with niobium superconductor random-access-memory (RAM) devices of 1-kbit capacity and access times of less than 0.5 ns can be made.

### 5.2.5.3 Electronic devices

Devices other than digital circuits have been fabricated. Infrared and millimetre wavelength receivers based on superconducting-insulator-superconducting (SIS) quasi-particle heterodyne mixers and on bolometric detection are readily available. Real-time signal processing with bandwidths approaching 10 GHz are required in many front-end radar and communication applications. Superconducting analogue signal-processing components with bandwidths exceeding 2 GHz have been achieved in striplines, microstrips and co-planar devices. They exploit the unique property of superconducting thin films, i.e. low radiofrequency surface resistance. This property allows the fabrication of delay lines or high-Q resonators in compact planar structures. The component is manufactured in a similar manner to conventional microwave stripline, etc., except for the substitution of a superconducting film for copper.

### 5.2.5.4 Outlook

While many of the applications above are in everyday use it appears that eventually the low  $T_c$  superconductors will be replaced by high  $T_c$  superconductors. This may take some time particularly for MRI instruments which are part of a many million dollar industry. The coming use and application of high  $T_c$  superconductors is discussed below.

## 5.2.6 High temperature superconductors

Although certain metal oxides were known to superconduct at a few degrees kelvin for many years, they were only of academic interest until 1986 when an LaSrCuO compound was discovered which had a  $T_c$  around 30 K, a full 7 K higher than any previously known  $T_c$ . This discovery has generated world-wide activity and a number of other compounds have been discovered. The principal superconducting compounds to emerge are compounds of YBaCuO (YBCO), BiSrCaCuO (BISCO), TlBaCaCuO and HgBaCaCuO, all of which have critical temperatures significantly above the boiling point of liquid nitrogen

**Table 5.4** Properties of some high  $T_c$  superconductors

Material	Critical temperature $T_c^*$ (K)	Upper critical magnetic field (T)		Critical current density at 77.4 K and zero field (GA/m <sup>2</sup> )	
		4.2 K	77 K	Bulk† $\Leftarrow$	Thin film‡ $\Leftarrow$
YBa <sub>2</sub> Cu <sub>3</sub> O <sub>7</sub>	92	90	15	0.01	20–50
Bi <sub>2</sub> Sr <sub>2</sub> CaCu <sub>2</sub> O <sub>8</sub>	86	—	—	—	—
(Bi,Pb) <sub>2</sub> Sr <sub>2</sub> Ca <sub>2</sub> Cu <sub>3</sub> O <sub>10</sub>	106	140	60	0.01	10–30
Tl <sub>2</sub> Ba <sub>2</sub> Ca <sub>2</sub> Cu <sub>3</sub> O <sub>10</sub>	122	220	100	0.01	20–40
HgBa <sub>2</sub> Ca <sub>2</sub> Cu <sub>3</sub> O <sub>10</sub>	133	—	—	—	—

\*Critical temperature depends on the exact stoichiometry.

†Sintered untextured material.

(77.4 K). They each form homologous series, the superconductivity depends on the exact stoichiometry of the particular compound. Table 5.4 lists some of the more important compounds together with their properties. The use of liquid nitrogen as the coolant is a major breakthrough because it simplifies the cryogenic engineering, it gives a 50-fold reduction in the refrigeration power requirement, and, being about 1/30 of the cost of liquid helium, it gives a substantial reduction in the cryogenic costs. In addition, significantly better thermal properties at liquid nitrogen temperatures improve the superconductor's stability (see section 5.2.2). Below 30 K certain classes of compounds (e.g. BiSrCaCuO) have very good current-transport properties and a remarkable ability to carry current in fields up to 25 T, out-performing the best conventional metallic superconductors.

#### 5.2.6.1 Applications

Developments to replace the conventional conductors copper or aluminium by high temperature superconductors (HTS) are very active in many parts of the world including USA, Europe and Japan. There are prototypes of power transformers, underground power cables, large motors and generators and fault current limiters in active development and in use. The electricity supply of the city of Geneva in Switzerland is completely provided by power transformers wound with HTS conductors. It is expected that there will be definite power savings with the use of HTS and this will provide a considerable contribution to the reduction of environmental pollution. All of the applications for low temperature superconductors mentioned in sections 5.2.3.2 to 5.2.5.3 are candidates for replacement by HTS.

These HTS materials are better than LTS for 50/60 Hz a.c. current and can even be used for radiofrequency and microwave applications. Here the main requirement is a low radiofrequency surface resistance for antenna arrays and microwave resonators and the HTS tape has this property.

#### 5.2.6.2 Tape

High temperature superconductors are very brittle and this has provided a considerable challenge for the production of suitable conductors. This is gradually being mastered and narrow composite tape of the HTS is currently being produced. There are a number of variations of the substrates but the following is typical. A nickel tape is used as the base and a buffer layer of palladium followed by ceria and yttria-zirconia layers are applied to the tape. This is the basic substrate and the high temperature superconductor is then deposited onto the tape using pulsed laser deposition. The

tape is 3 mm wide and cables up to 100 metres in length are currently under test at various locations. The production of this tape is essential to all the power applications and the production rates are increasing and the cost is decreasing.

#### 5.2.6.3 Outlook

The outlook for HTS is very good with many prototypes of applications at the test stage in utilities and elsewhere. While there is need for cheaper tape, this will inevitably come as production increases. The highest  $T_c$  has remained at 133 K for the last few years however it has been found that the  $T_c$  can be increased by pressure. This may provide a lead for producing materials with higher values of  $T_c$ . The dream of a  $T_c$  higher than room temperature may remain unfulfilled but we must remember that the highest  $T_c$  remained at 23 K for over 20 years and we can always hope for a further break through.

My thanks are due to the staffs of The City of Sunderland College and the University of Sunderland for their assistance with this section.

## 6.1 Silicon, silicon dioxide, thick- and thin-film technology

Silicon is unrivalled as a semiconductor material for active devices such as rectifiers, metal oxide semiconductor field effect transistors (MOSFETs), bipolar transistors, thyristors and a wide variety of other structures particularly designed for power applications. Few of the properties of silicon are ideal but none are so far from ideal as to exclude its use in all but a small fraction of current devices. Perhaps the most important application where it is excluded is in the generation of electromagnetic radiation, optical infra-red or microwave. Such emitters usually require a material where electrons can lose energy directly with emission of light rather than by interaction with the lattice of semiconductor atoms. For this application a variety of compound semiconductor materials are available such as gallium arsenide and gallium phosphide. Much research is, and has been, focused on producing optically emitting alloys of silicon with other elements such as germanium which can be integrated on a silicon substrate using the existing highly developed technology.

### 6.1.1 Materials for integration

Quite fundamental to silicon technology is the existence of a natural oxide which can be produced thermally in oxygen or steam and which is hard, uniform in thickness, has an acceptable value of relative permittivity (3.9) and high electrical breakdown field strength ( $2 \times 10^7 \text{ Vcm}^{-1}$ ). Many semiconductor devices have at the surface electron densities of between  $10^{11}$  and  $10^{12} \text{ cm}^{-2}$ . It is important that these carriers remain mobile, rather than being trapped at spare or dangling bonds at the interface between the single-crystal silicon and the amorphous oxide with its much more randomly oriented atoms. Less than 1% of the silicon atoms should have such a bond if an acceptable number of electrons is to remain mobile. This can be achieved through hydrogen treatment at temperatures below  $650^\circ\text{C}$ . Too high a level of trapping leads to devices of low gain and high electrical leakage.

Silicon dioxide is near ideal for carrying thin-film conductors from and to adjacent regions of active devices. When it contacts silicon, however, to make an ohmic contact it will take it into solid solution, essentially etching the silicon. Spikes of aluminium, with dissolved silicon, occur which may short out the device. For this reason aluminium already doped to the level of solid solubility with silicon is used for the starting material. Contact to the package is made with aluminium wire which is ultrasonically welded to thick aluminium pads on the silicon dioxide. The bond-wire is also doped with silicon. Polycrystalline silicon also serves as a current carrier on integrated circuits. Impurities such as phosphorus and arsenic are used to dope the polysilicon and this renders it much more conducting. Its conductivity can also be improved by converting it to one of the silicides of metals such as platinum, cobalt or tungsten. Silicon dioxide must be etched to allow the conductors on its surface to reach the underlying active regions. These holes in the silicon dioxide are required to be as small as possible, of 'minimum feature size', and methods of etching it employing either gaseous or aqueous fluorides have been developed.

There is considerable advantage in having an insulating layer buried beneath the transistors. Device capacitance is reduced as is a wide range of spurious transistor latch phenomena which can destroy the transistors. Silicon dioxide is

used in the form of a thin film, often implanted into the silicon. This kind of implantation requires very high current densities, followed by annealing at temperatures of  $1350^\circ\text{C}$ , when there is a condensation of the oxygen ions to produce a layer of not very dense silicon dioxide. Wafer bonding is also used for this application. Two oxidised wafers are bonded together by heating the two oxidised surfaces in contact. One of the slices is then etched back to produce a thin film suitable for devices. An intriguing technology is that of porous silicon. The slice is anodised in hydrofluoric acid, when the selected regions acquire a large number of microscopic holes which are later oxidised to produce silicon dioxide. Porous silicon also has possible applications for light-emitting devices. The presence of pores substantially modifies the electronic properties of silicon, the confined electrons being able to fall through large energy differences without interaction with the lattice of silicon atoms. A particular problem of this type of technology is the very poor thermal conductivity of the oxide. Power dissipated in the silicon islands containing the devices produces temperature rises of the order of  $150^\circ\text{C}$ . An earlier form of 'silicon on insulator' employed sapphire as substrate, partly because of its crystalline structure but also because of its high thermal conductivity.

### 6.1.2 Silicon and impurities

The devices produced in silicon depend for their properties on the addition of very low concentrations of impurities coming from group 3 or 5 of the periodic table. The silicon atom belongs to group 4 and it bonds in the single crystal in a tetrahedral configuration with each atom having four nearest neighbours. This configuration gives the material its brittleness which can be a problem when it is being handled. The lattice constant is  $5.4 \text{ \AA}$  which is the length of the side of the cubic unit cell. Group 5 elements such as phosphorus and arsenic have five outer electrons available for bonding, leaving one electron unused and in orbit. The application of Bohr theory to such an orbiting electron is justified as long as the effect of the crystal is taken into account via the use of the effective mass of the electron and the relative permittivity (12) of the silicon. The calculated radius of orbit is very much larger than the lattice constant and the electron is only very weakly held. Thermal vibrations of the lattice can easily shake the electron loose at room temperature and it can then contribute to the conductivity. Suppose  $10^{16} \text{ cm}^{-3}$  of phosphorus atoms is added to an otherwise pure crystal (an impurity level of 1 ppm). The electron concentration is increased from  $1.5 \times 10^{10}$  to  $10^{16} \text{ cm}^{-3}$  and the conductivity is increased by approximately  $10^6$ . This remarkable change is the basis of the usefulness of impurities in producing semiconductor devices.

In order to consider the effects of substituting group 3 atoms for silicon it is necessary to understand the nature of electrical conductivity in single-crystal solids. Bohr theory describes the properties of the isolated atoms in terms of electrons in orbit around a positive nucleus. When isolated atoms condense to produce a solid we must also apply the Pauli exclusion principle which states that the electrons must each have a different orbit. Instead of a single energy level of the Bohr model we have bands of levels each containing the same number of energy levels as the number of atoms. The free or conduction electrons fit a similar model. When an applied field acts on an electron it will increase its kinetic energy and move it to a higher level, but it must still obey the exclusion principle. A consequence is that no

conductivity can take place in a full band. In a semiconductor the highest filled band at 0 K is called the *valence band*; the first unfilled band is the *conduction band*. At higher temperatures some of the electrons in the valence band will be able to jump across the energy gap leaving behind a few vacancies in the valence band and giving some free electrons in the conduction band. At 300 K the number of such electrons in the silicon is the *intrinsic carrier concentration*. The presence of vacant energy levels in the valence band provides an additional form of conductivity since the sea of electrons in this band can experience an overall gain in energy and, because the band has an electron deficiency, it can be ascribed a positive charge. The total conductivity of all the electrons is equivalent to that of a single positively charged particle. We term this a *hole*. The intrinsic hole concentration is therefore equal to the concentration of electrons in the conduction band since, as expected, the material remains electrically neutral.

When a group 3 atom substitutes for silicon it is short of an electron to complete all the bonds to the four nearest neighbour silicon atoms. This electron is gained from the valence band, leaving a vacancy and the remaining electrons can contribute to the conduction. A hole is therefore created.

Two types of material can therefore be created by the addition of impurities. Group 5 elements become positively charged fixed centres which release electrons making the material *n type*. Group 3 elements take up an electron from the valence band leaving behind a mobile positive hole and the material is then said to be *p type*. The intersection of a p-type material with an n-type one gives rise to a p–n junction which is a rectifier but is also the building block of almost all other semiconductor devices.

Impurities can be added to the melt during the growth of the single-crystal material. This process involves pulling a seed of the crystal from the melt whilst also rotating it. A long single crystal is so produced up to 8 in. diameter. This is sawn many times along the same well-defined crystal plane and each resulting slice is ground and polished on one of its two faces. The doping level and, therefore, the resistivity can be controlled to within a few per cent of the desired value. In most cases later doping during device fabrication will overdope this background level. Such impurity atoms can be introduced from a solid or gaseous source in a furnace at temperatures in the region of 1000°C. Patterning silicon dioxide guarantees that the surface of the slice will only be doped in the areas required. This stage is termed the *predeposition stage*. In order to get the atoms on the desired silicon sites it is necessary to heat the silicon for a prolonged period in the absence of the dopant. This is termed the *drive-in stage* and must be carried out in an oxidising atmosphere in order to produce a layer of silicon dioxide on the surface of the silicon, sealing in some of the impurity. Even with this precaution a large amount of impurity is lost. The final depth of the p–n junction will be much deeper than that after the predeposition. A major difficulty with this technology is that the spread in the resistance can be as high as 20%, which is unacceptable for the more advanced processes. Better control is achieved by ion implantation. Here a beam of suitably charged ions delivers a closely monitored number of ions to the surface. The ions are energetic and much surface damage is caused. The ions sit interstitially in the silicon and must be activated by prolonged annealing. Control is greatly improved but the cost of a commercial implanter is high. The process is essentially serial and, therefore, time consuming, in contrast to diffusion where many slices of silicon can be loaded into a furnace for simultaneous predeposition. Control of the temperature–time cycle

is difficult with simple furnace processing and a ramped temperature cycle is increasingly used. This factor is of great importance in very low dimensional structures since any unnecessary heating during the warm-up period produces an unwanted lateral spread of the impurities and loss of dimensional control. For this reason a well-controlled temperature cycle is employed giving precise control of geometry. This is a single-slice process and is often termed *limited reaction processing*. Batch processing is less popular since it can, on equipment failure, lead to the loss of expensive part-processed wafers.

In a small but significant number of cases it is necessary to produce a layer which is less heavily doped than the background of the crystal. This is done using epitaxy. Silicon tetrachloride, dichlorosilane or silane is decomposed at high temperature (1200°C down to 900°C). The resulting silicon atoms which have high mobility on the silicon surface are able to migrate to appropriate crystal sites, reproducing the orientation of the underlying silicon. Gaseous dopant is added to the gas stream and can be varied in type and concentration during the growth. The high temperatures required in the reactor guarantee high atom mobility and good crystal quality; however, they do lead to short growth times and relatively poor thickness and doping control, particularly across a slice. The reactor consists of a cold-wall vessel which prevents unwanted deposition of material, and heating either with radiofrequency in small-scale systems or lamps in large commercial apparatus.

### 6.1.3 Mobility and the materials limitations of device size

Throughout the history of silicon circuit development there has been a particular emphasis on making devices, and hence circuits, smaller. This need is associated with the statistics of defect creation, both in single-crystal silicon and in the associated silicon dioxide and conductors. The fraction of working circuits increases in an exponential fashion with decreasing area of silicon and the cheapness of producing the finished chip follows, therefore, a similar very sharp function.

Producing the windows for selective addition of impurities is a critical process which utilises a photosensitive liquid spun on the surface, and after heat treatment is exposed through a photomask to produce the desired pattern. The silicon dioxide can then be etched to leave windows of exposed silicon. Alternatively, a material can be applied to the surface which is chemically sensitive to electron beams. A scanning electron beam can be used to define features in this 'resist' layer, which masks the surface in selected areas during a subsequent manufacturing process. As the physical dimensions of transistors are reduced, the electric-field strength in the silicon and the silicon dioxide becomes very high. At low field, the drift velocity of the electrons, or holes, depends linearly on the applied field. The rate of change of velocity with field is the *mobility*. Reducing the chip supply voltage in proportion to the device dimension should be possible without degradation of speed of operation. Unfortunately, as the intensity of the fields becomes higher the velocities of the electrons become field independent, mobility falls and circuit designers are forced to drive the circuits harder by maintaining a high supply voltage, typically 5 V. The silicon shows carrier multiplication through hot electrons or holes exciting other electrons and holes, by collision, across the energy gap. Modern circuits are often so complex that adjacent n and p regions form unwanted four-layer thyristors which can switch into a

state where very high currents can pass. The same carrier multiplication can generate white light. Long-term degradation of silicon dioxide is known to be associated with the generation of very energetic carriers in very small transistors where the electric field strengths are very high.

### 6.1.4 Materials for large-area circuits

The prime limitation on the production of large-area circuits is the very strong relationship between the fraction of working circuits and the defect density. Attempts at wafer-scale integration (WSI) have been made. This is an attractive possibility in that it reduces packaging costs and the overall size and weight of equipment. Clearly, to overcome the problems of the relationship between yield and area it is necessary to build in large amounts of redundancy through the duplication of power lines and circuits. There is little materials technology which is specific to this kind of circuit.

Although single-crystal silicon slices have increased in area and have fallen in cost over the years, they are still impractical for some applications. In some cases it is possible to get satisfactory performance from devices made in silicon on glass or other cheap flat substrates. Silicon deposited at room temperature is usually amorphous. It has randomly oriented atoms and thus a large number of dangling bonds which can be taken up by treating the film with hydrogen. Dopants can be introduced during growth and relatively poor p-n junctions are obtained. The energy difference between conduction and valence bands is larger than for single-crystal silicon and this reduces leakage currents. A major cause of such leakage is the excitation of electrons from the valence band to the conduction band which becomes less probable with a larger energy gap. Amorphous silicon can be very photosensitive and the availability of large areas on panes of glass make it a major contender for solar cells. A second application is in liquid-crystal displays for television monitors. These are termed *active matrix* displays and they use a primitive form of the MOSFET. Each small element of the picture (or pixel) is independently accessed by a thin-film device which supplies, when required, a suitable voltage to the cell. Each row and column is accessed via a shift register which is ideally produced on the plate of glass in order to reduce cost. The electrons in amorphous material are insufficiently mobile and polycrystal-line material is preferred for this application. A reactor, similar to that used for silane epitaxy, is employed. A capacity for operating at low pressures is important if the grain size and hence mobility are to be sufficiently high. An interesting, if more costly, method is to laser anneal amorphous silicon to produce polysilicon in those regions where higher performance circuitry is required. This large-area technology is also ideal for very big circuits where the speed limitations of the individual devices can be overcome by parallel, or neural, processing.

## 6.2 Thick- and thin-film microcircuits

Hybrid microcircuits use patterns of thick and thin conducting films on an inert substrate to replace individual resistors, and to connect components such as capacitors, transistors and ICs into a complete circuit, thus saving both space and weight compared with PCBs. The first application of microcircuit techniques was for the wartime production of proximity fuses, using printed carbon composition resistors on ceramic substrates. The basic methods

are recognisable 60 years later, even though modern materials have greatly improved performance.

Hybrid technology is always extending in new directions, as new components are being developed, which need novel packaging and interconnection techniques, for example;

- MCM multi-chip modules
- LTCC low temp. co-fired ceramic packages
- DBC direct bonded copper for power circuits
- Metal substrates for heater applications

For any electronics application, an appropriate construction can be selected which will meet the specification on performance, size and price.

Thick-film hybrids are most suitable for volume replication of relatively simple circuits, for example, the duplicated circuits in telephone exchanges. Screen printing is used to deposit patterns of conducting pastes on ceramic substrates, often at rates of thousands per machine per day. High-temperature firing fuses the pastes to the substrates, forming circuit elements of less than one-thousandth of an inch in thickness. Even so, these are still 'thick' films, compared with the film thickness of 'thin' film circuits. The process here is completely different, using photolithography and selective etching on purely metallic films to generate the circuits.

Microcircuits are discussed here in terms of materials and processes, and how they are applied to a range of circuit applications.

### 6.2.1 Thick-film materials

The materials used for hybrids are being continually up-graded and extended, to improve the final product. The basic properties of the materials are as follows.

The substrate material must be insulating, flat, non-reactive and thermally stable to the firing temperature (about 850°). The most widely used material is high purity (96%) alumina, used in plates from 50 × 50 mm (2 × 2 in.) to

**Table 6.1** Common alloys and their properties

<i>Material</i>	<i>Resistivity (mΩ/sq)</i>	
Ag	2–5	Inexpensive. Poor leach resistance in molten solder.
Ag/Pd 30:1	3–6	Budget conductor. Adequate leach resistance.
Ag/Pd 3:1	20–35	Less used because of price. Good adhesion, leach resistance. Wire bondable.
Pd/Au	50–90	Expensive. Better adhesion, leach resistance. Wire bonding fair.
Pt/Au	70–100	Very expensive. Excellent adhesion, leach resistance. Wire bonding poor.
Au	3–4	Most widely used multilayer conductor. Excellent conductivity, good wire bonding, not solderable.
Au/2% Pd	5–7	Modified gold for aluminium wire bonding.
Cu	2–4	Good solderability but needs non-oxidising furnace atmosphere (nitrogen).

**Figure 6.1** Typical resistor network in single-in-line form

175 × 425 mm (7 × 16 in.), and usually 0.63 mm (0.025 in.) in thickness, although any thickness between 0.25 and 2.5 mm (0.010–0.100 in.) can be obtained.

Exotic materials such as beryllia and aluminium nitride are occasionally used because of their better thermal conductivity in high power dissipation situations. Stainless steel, suitably insulated with glaze, is also used in power applications.

For any particular application, a conductor is chosen which will give adequate performance in terms of adhesion, solderability, etc., at an economic cost. The air-firing conductors are based on the precious metals silver, gold, palladium and platinum. The industry standard has been 3:1 Silver/Palladium, but demand for palladium for automobile catalytic converters has increased the cost greatly. Manufacturers now use conductors with ratios as low as 30:1, as well as replacing part of the palladium with platinum in a ternary alloy.

Copper and nickel systems have been developed because of the lower cost of the metal, but these conductors must be fired in a non-oxidising atmosphere (nitrogen, with oxygen <20 ppm).

Modern resistor pastes are based upon ruthenium, either as the dioxide or as bismuth ruthenate. Resistivities between 1 Ω/sq and 10 MΩ/sq can be obtained, and intermediate values can be made by blending. The temperature coefficient of resistance (TCR) is ±400 ppm or better, and load

stability is good. Fired resistors are often overglazed with low-temperature glaze (550–600°C) which contributes to the mechanical and environmental protection of the resistors.

The circuit need not be limited to a single level on the substrate. Crossovers, using areas of dielectric glaze, enable conductors to cross one another, and if this is extended to cover the majority of the substrate, these circuits are known as 'multilayers'. Multilayer hybrids are built up from layers of conductor tracks, separated by layers of dielectric glaze and interconnecting through windows (called *vias*) in the glaze. The glaze must tolerate multiple re-fires as each layer is added, and have a low dielectric constant, to minimise stray capacitance between tracks which cross. Resistors can be fired on top of glazes loaded with ceramic, giving results similar to resistors on alumina substrates.

Screen-printable protections are printed over trimmed resistors and cured at 200°C or less. Complete circuits can be dip-coated in liquid resin suspensions, powder coated, moulded or potted. The usual resin types which are used are silicones, epoxides or phenolics. Resins can be cured very quickly by U.V. lamps.

The components which can be attached to hybrids are of all shapes and sizes. The name 'hybrid circuit' is derived from the ability of this technology to mix all kinds of component to achieve the desired circuit characteristics.

Hybrids with only resistive, capacitive or inductive elements are called 'passive' hybrids. If semiconductor elements are included, they become 'active' hybrids. Miniature plastic-packaged semiconductor components are designed to be attached with solder, to pads on the hybrid. In this technique, known as 'Surface Mount', solder cream is printed over conductor pads on the substrate, into which the component feet are placed, prior to reflow. The solder cream consists of small solder balls, flux and solvent, and it is printed through a metal-foil stencil screen to give a suitable thickness of deposit.

Semiconductor chips are used in many packaging styles. Bare chips without any protective coating are wire bonded into circuits, and chips with moulded plastic protection are soldered. Complex chips are packaged in chip carriers, which are small hermetic packages, and permit the electrical parameters to be fully tested before soldering into a circuit.

The availability of active components for surface mounting led to the development of chip resistors which could be attached in the same way. Resistors are printed in a matrix on large ceramic substrates, which are divided into individual resistors. Solderable terminations at the ends are added by sputtering and plating. The immense market for mobile phones and the pressure to make them smaller has led to resistor chips as small as 0.5 × 0.25 mm (0.020 × 0.010 in.) which can be robotically placed. These tiny sizes are also popular because they use less ceramic and materials, hence they are more economical.

Chip capacitors consist of alternate layers of dielectric and conductor, sintered into a solid block, and with metalised terminations. The sizes range from 0.5 × 0.25 mm to 6 × 5 mm (0.020 × 0.010 in. to 0.240 × 0.220 in.) and in value from 1 pF to 1 μF. High-value capacitors are miniaturised tantalum capacitors with metal end caps, or moulded with metal tabs.

Small wire-wound components such as inductors and transformers have also become available for hybrid use. A fibre-optic cable can be fed through the side wall of a hybrid package, for conversion of light information into an electrical output.

**Figure 6.2** Typical hybrid, with add-on components, in dual-in-line form

### 6.2.1.1 Thick-film processes

There are many stages between the customer's original drawing and the final circuit.

The circuit elements are laid out using computer-aided design (CAD), from which photopositives are made with a photoplotter for each different ink to be printed on the substrate. The CAD will also prepare all the necessary drawings and instructions for production personnel. Typical conductor line width is 0.25–0.75 mm (0.010–0.030 in.) and resistors are usually not less than 1.25 mm (0.050 in.) square.

The photopositive is exposed and developed on a screen coated with U.V. sensitive emulsion. The screen mesh is stainless steel or synthetic fabric, with between 2.4 and 16 meshes/mm (60–400 meshes/in.). A thick film paste placed on the screen is printed onto the substrate by a moving flexible squeegee blade.

Printing machines can be loaded by hand, or fitted with mechanical feed systems, which take substrates from magazines, and transfer printed substrates to belt driers. The dried pastes are fired in multizone belt furnaces through a controlled temperature-time profile. A typical profile for conductors/resistors is 60 min through-time, with 10 min at a peak temperature of 850°C.

Resistors are trimmed by laser energy, which has the advantages of speed, precision and cleanliness. Substrates, printed with multiple circuits, are scribed using a more powerful laser, so the individual circuits can be snapped out.

Components attached by solder joints are placed on printed solder cream pads. To achieve the volume of work necessary, this is usually done by computer-controlled pick-and-place machines, which take each component from a separate reel, and place them in the correct position. There are several methods used to reflow the solder cream, which use heated belts, tunnel furnaces under nitrogen, and IR lamps, for example.

After soldering processes involving fluxes, the units may be cleaned, but many solder systems now are 'non-clean', because the flux is not a hazard to the operation of the circuit.

It is planned to cease using solders containing lead in electronics, for environmental reasons. There are several systems that could be used as alternatives, using tin alloyed with a variety of other metals. The greatest change affecting their use in hybrids is that the melting point is usually 30–40°C higher than the tin/lead eutectic, and the components have to withstand being heated to a higher temperature during assembly.

Semiconductor chips are usually glued into position with epoxy. This can be made conductive with silver or gold powder. Conductive epoxy is also used to attach capacitors to gold conductors, because solder dissolves gold very quickly. Bare chips are bonded with aluminium or gold wires of about 0.025 mm (0.001 in.) diameter. Aluminium wire is not used with pure gold conductors, because the bond strength deteriorates rapidly.

Hybrids may be mounted on their own terminals, or mounted inside a metal or ceramic package, which has its own terminals. The terminals are supplied on reels with perhaps 50 000 on a continuous strip. Insertion machines crop unwanted terminals and insert substrates into the strip, reeling up the strip afterwards. The strip is then fed through a continuous wave-soldering machine, then the soldered strip may be processed by a finishing machine, which crops each unit from the strip, tests it and packs it.

Metal packages are closed by soldering or welding a lid or cover to the header on which the substrate is mounted.

A dry nitrogen atmosphere is maintained inside the package, to preserve the circuit from corrosion. The packages themselves are protected by plated films of tin, solder, nickel or gold.

## 6.2.2 Thin-film materials

The preferred substrate materials are glass or 99.6% alumina, because the surface finish has to be very smooth to allow the deposition of a uniform metal film. The film itself has a sheet resistivity between 50 and 500  $\Omega/\text{sq}$  with TCR  $\pm 40$  ppm, and many materials are in use, such as nichrome or tantalum nitride. The resistive film is overlaid by a conductive metal film. Conductors for wire bonding use gold, whereas if solderable conductors are required, nickel covered with a gold flash is used. To optimise conductor properties, there is a complex layered structure, with titanium and palladium layers under the gold to minimise diffusion effects, especially of chromium to the surface of the conductor.

Substrates can be metallised in-house, or bought-in with a film of known resistivity from an outside supplier. The add-on components are the same as for thick film.

### 6.2.2.1 Thin-film processes

Typically, the smallest resistor line width is 10  $\mu\text{m}$  and conductor lines can be 50  $\mu\text{m}$ . Designs can avoid cross-overs by wire-bonding over several lines, using the fine-line capability to crowd the conductor tracks. Designs cannot be photoplotted at this line width, so must be produced at a magnified scale, and reduced photographically. The photopositives are produced on glass because of the dimensional stability required.

A thin film of liquid photoresist is spun onto the surface of a substrate, and dried. The pattern is exposed and developed. Selective etchants remove the metal layers as required to produce the circuits.

Thin-film circuits produced in a matrix on glass substrates are separated by dicing with a diamond cutting wheel. Thereafter, individual circuits are assembled using the same methods as for thick film, although generally they are used in hermetic packages, which protect the glass substrates.

Thin film is less widely used than thick film for a number of reasons. The low resistor film resistivity means high value resistors take up too much area, the photomechanical process is not amenable to volume production, and the final package cost is high.

## 6.2.3 Types of hybrids, and their applications

With the wide range of materials and components available, the hybrid process can be used to produce any kind of circuit, from simple resistor networks to complex multilayers which can cost 1000 times the price of the simple unit. The following examples illustrate the capability of hybrids to produce circuits of increasing complexity.

### 6.2.3.1 Resistor networks

These networks are usually fabricated on ceramic substrates using thick film techniques, where the wide range of paste resistivities can be used to achieve any mix of resistor values. The package may be terminated by a single row of terminals along one edge (single-in-line SIL) or with two

rows of terminals along 2 edges (dual-in-line DIL) with the substrate horizontal against the PCB. With a substrate thickness of 0.063 mm (0.025 in.), SIL circuits can be easily fitted to printed circuit boards on 2.5 mm (0.1 in.) pitches, and the height above the board can be between 3.75 mm (0.150 in.) and the maximum the customer will allow.

Design of a hybrid is very flexible, both in the size and shape of the substrate, and in the number and position of the terminals (the 'pin-out'). Both sides of the substrate may be printed with resistors, provided the total dissipation does not exceed the substrate capability. If the network has to withstand power pulses from lightning surges, a thicker substrate may be used, which is stronger, and withstands the sudden heating effect. Many millions of these simple resistor networks are used in Telecoms, for example, as line feed resistors.

Divider networks made with the same resistor paste have good tracking performance, but to obtain the ultimate performance in this application, thin film is best.

#### 6.2.3.2 Units with surface-mounted devices

It is a small step to convert a passive resistor network into an active circuit by incorporating semiconductor devices and capacitors. Every kind of component is available suitable for surface mounting. The components are assembled using pick-and-place machines, and reflow-soldered to the hybrid. The circuit may be protected by printed or dipped organic resin, or the circuit may be left in its overglazed state, since the add-on components have their own protection.

This is the most widely used type of circuit. It is used in Automotive applications for engine management systems and vehicle safety systems, and for general industrial applications.

#### 6.2.3.3 Networks with wire-bonded chips

A substantial improvement in packing density can be realised by using bare chips, but the wire bonds must be protected, inside hermetic packages, or inside a globule of hard resin ('globtop'). Thick or thin film can be used, depending on the resistor values and tolerances required. The semiconductor dice are attached by conductive epoxy or eutectic bonding, then they are wire-bonded to the conductor pads. Manually, this can be a relatively slow operation, but automatic bonders are available with pattern recognition cameras, which can identify the bonding pads and make the bonds.

These circuits are used for military and aerospace applications—for radio and radar, sonar, ordnance fuses, electronic gauges for Head-up-displays. Other applications have been for proximity detectors, and control circuits for laser displays.

#### 6.2.3.4 Power microcircuits

The hybrid process has been adapted to make motor drive circuits. These need very low conductor resistance, and the ability to bond 250  $\mu\text{m}$  (0.010 in.) Al wire to the circuit and the power devices. These circuits use Direct-bonded Copper (DBC) substrates. Copper foil 300  $\mu\text{m}$  (0.012 in.) in thickness is bonded directly to the alumina substrate, and the pattern is etched. The copper is given a nickel flash plate, then the components are attached and wire-bonded. The ceramic is then bonded to a heatsink, to prevent the semi-conductors overheating.

#### 6.2.3.5 Multilayers and multichip modules

The interconnect density of a hybrid can be multiplied several times by using multilayered conductors. It is possible to fit into a 30-pin package  $40 \times 25 \text{ mm}$  ( $1.6 \times 1 \text{ in.}$ ) about 15–20 integrated circuit (IC) chips, which would normally need a PCB at least 400 mm (4 in.) square. A high-conductivity conductor is used, which may be gold or silver.

A circuit can often be assembled from standard 'building blocks', which are already available as separate chips. Much time and expense may be saved, by making a hybrid to interconnect the separate chips, rather than designing a custom IC, with the necessary design and mask costs. This type of hybrid is known as a multichip module. One example made this way was an aircraft fuel status indicator.

#### 6.2.3.6 LTCC modules (low temperature co-fired ceramic)

This is a multilayer, without the ceramic substrate. Dielectric is produced as a 250  $\mu\text{m}$  (0.010 in.) 'green tape'<sup>TM</sup>, which is punched with vias, and printed with conductors. Circuit levels are made on separate sheets, which are stacked like a book, and fired at 850°C. The stack sinters into a solid block, containing all the interconnections, with excellent robustness and repeatable electrical characteristics. This technique is only viable for very large volume applications which can justify the tooling costs for punching the ceramic tape.

This manufacturing technique has been used in the 'Bluetooth' project. This is a system to allow any kind of computer-controlled device to link up with any other.

#### 6.2.3.7 Microwave circuits

These circuits are made chiefly in thin film, because of the better control of line sizes and edge definition with this process, and the substrate material can be varied to exploit different dielectric constants.

#### 6.2.3.8 Metal substrates

Although ceramic has admirable properties as a substrate, it is brittle, and the thermal conductivity is not as good as metals. Applications have arisen for heater elements, for example, in domestic kettles, which have been met by printing conductive elements on an insulating layer on a steel substrate. By careful matching of expansion coefficients, the element can withstand the thermal cycling, and in the case of the kettle elements, the rate of heat transfer is excellent.

The process is versatile; elements have been printed on tubes for electric showers, and on panels to prevent condensation in mobile phone base-stations, for example.

#### 6.2.3.9 Standards

The appropriate UK Standard for hybrids is BS 9450, but this is now being replaced by a European standard in the form of EN 165000, which covers Capability and Qualification Approval. This incorporates best practice from UK, European and US standards. An additional standard EN 265000 is being produced for Technology Approval. The EN 165000 has been submitted for approval for conversion to an IEC standard.

## 7.1 Insulating materials

Electrical insulating materials can be solid, liquid or gaseous, often in combination such as in oil-impregnated paper. The materials may be organic or inorganic and natural or synthetic. Both the electrical and mechanical properties of the materials are important, the variation of these properties with temperature being particularly important. In some applications the variation in electrical properties with frequency is significant and the chemical properties of the materials can often be vital because of the problems of compatibility between materials and of the behaviour of a material under fire conditions.

### 7.1.1 Classification

Insulating materials, especially those used in generators, motors, transformers and switchgear, are often classified on the basis of their thermal stability according to the scheme described in BS 2757:1986 and IEC 60085:1984. This scheme uses nine temperature classes, allocating materials to a class with 'temperature limits that will give acceptable life under usual industrial conditions of service'. These standards recommend that temperatures above 250°C should increase in steps of 25°C and the class is designated accordingly.

Temperature limits

Class	Y	A	E	B	F	H	200	220	250
Temperature (°C)	90	105	120	130	155	180	200	220	250

Examples of materials in each class are given below.

*Class Y:* Unimpregnated paper, cotton or silk, vulcanised natural rubber, various thermoplastics that have softening points that would only permit their use up to 90°C. Aniline and urea formaldehydes.

*Class A:* Paper, cotton or silk impregnated with oil or varnish, or laminated with natural drying oils and resins or phenol formaldehyde. Polyamides. A variety of organic varnishes and enamels used for wire coating and bonding.

*Class E:* Polyvinyl formal, polyurethane, epoxy resins and varnishes, cellulose triacetate, polyethylene terephthalate, phenol formaldehyde and melamine formaldehyde mouldings and laminates with cellulosic materials.

*Class B:* Mica, glass and asbestos fibres and fabrics bonded and impregnated with suitable organic resins such as shellac bitumen, alkyd, epoxy, phenol formaldehyde or melamine formaldehyde.

*Class F:* As class B but with resins that are approved for class F operation such as alkyd, epoxy alkyd and silicone alkyd.

*Class H:* As class B but with silicone resins or other resins suitable for class H operation. Silicone rubber.

*Classes 200, 220, 250:* Mica, asbestos, ceramics and glass alone or with inorganic binders or certain silicone resins. Polytetrafluoro-ethylene.

The allocation of materials to classes such that their life will be adequate under usual industrial conditions means that the materials may not give adequate life if the service is unusually severe, e.g. equipment normally operated very near to full load. Conversely, it may be economical to use materials of a lower temperature class for equipment operated infrequently or normally operated at very low load.

### 7.1.2 Temperature index

Various suggestions have been made for alternative temperature classification systems, especially as techniques such as cross-linking enable the thermal stability of materials

to be significantly improved and new high-temperature materials are constantly being developed. IEEE 98:1984 has withdrawn the term 'Temperature Classification' but the institution has suggested that a 'temperature index' related to the temperature capability of the material should be assigned to a material on the basis of experience or comparison with materials that have established indices. The index would be based on the life of the material in particular environmental conditions and would preferably be a number chosen from the series 90, 105, 130, 155, 180, 200, 220. For temperatures above 250°C, no index has been established yet.

### 7.1.3 Effect of frequency

Insulating materials can have a very large variation in the dielectric loss and permittivity of the material with the frequency of the applied signal. Whilst this is important for insulation used in high-frequency electronics, it is not normally important in conventional power equipment, except for some condition of very fast transients. *Table 7.1* shows the loss tangents ( $\tan \delta$ ) at 50 Hz, 1 kHz and 1 MHz. Fortunately, the losses generally decrease with frequency for the materials that are used in electrical power insulation. Occasionally there can be significant changes at low frequencies and polymethylmethacrylate has a peak in dielectric loss at around 2 Hz, depending on temperature, where it increases by a factor of 3.

### 7.1.4 Fire behaviour

Despite the extensive precautions that are normally taken to prevent fire in electrical installations, fires do occasionally occur. There may be hundreds of wires bunched together in ducting and this presents serious problems in the event of a fire. One problem is that if fire propagates along the insulation, electrical systems will fail completely and these may be essential to the orderly shut-down of the equipment, or they may be responsible for important telecommunication systems. Another problem is that the fumes that are produced by combustion of the insulating material may be toxic and may also cause corrosive damage to neighbouring materials. It is therefore important that electrical insulation is assessed for behaviour in the event of fire. Some materials that have been used in the past are liable to produce toxic fumes. The former use of polychlorinated biphenyls as transformer insulation is a particular cause for concern.

Ease of ignition, or flammability, has traditionally been considered the most important property of a material when assessing fire hazards, but it has now been realised that this is only one of several factors that must be considered. The amount of heat, smoke and toxic gases released by the material and the way that the flame spreads in the material are all important. The traditional tests use very small quantities of the material which means that the information obtained is of limited value. More realistic tests require more specialised facilities and tend to be expensive to perform.

Gaseous insulation does not normally present any fire problem, although sulphur hexafluoride can decompose into toxic fractions under certain conditions. Commonly used insulating liquids, such as transformer oil, are flammable and so present a fire hazard. This is often unacceptable for transformers or switchgear situated in substations in blocks of offices or flats and alternative designs using air insulation or non-flammable liquids must be used. The same problems occur for equipment to be used in hazardous environments such as mines. Polychlorinated biphenyls

were once used as non-flammable insulation in these applications, but the discovery of their toxic nature has required a search for alternative non-flammable liquids. Silicone oils are used but, although these are less flammable than transformer oil, they are still flammable.

Fire tests that are used to try to give more relevant fire hazard information for liquids use pools of the liquid from about 15 cm diameter to 9 m<sup>2</sup> of burning liquid area.

Much of the work on fire behaviour is concerned with insulation for cables. Here the standard tests such as BS 6387:1994 only require a flame of between 650 and 950°C, depending on the fire resistance category, to be applied to about 600 mm of the cable for 3 h (only 20 min for the highest temperature) without the insulation failing. However, more stringent tests involving longer lengths of cable on cable trays in vertical ducts are often required so that the conditions met in situations such as power stations can be reproduced more accurately. A typical test involves 8 m of cable on a cable rack ignited by an 88 kW methane flame with a forced air draft to propagate the flame. Measurements are made of the distance that the flame spreads and the optical density of the smoke produced.

Tests are now being made of the heat evolution of materials in a fire. There is still a lack of agreement about exactly what tests are most appropriate and how reliably small-scale tests can be scaled to possible full-scale fire scenarios. There is particular lack of agreement about toxicity testing.

## 7.2 Properties and testing

The properties of insulating materials fall into the following categories:

- (1) physical,
- (2) mechanical,
- (3) electrical, and
- (4) chemical.

Insulating materials may have to operate in the vicinity of apparatus producing high intensity radiation such as nuclear reactors, isotopes, microwave and electron generators, and considerable work has been done on the properties of materials under these conditions.

## 7.2.1 Physical properties

### 7.2.1.1 Density

This is of importance for varnishes and oils. The density of solid insulants varies widely; in a few cases it is the measure of relative quality (as in pressboard).

### 7.2.1.2 Moisture absorption

This usually causes serious depreciation of electrical properties, particularly in oils and fibrous materials. Swelling, warping, corrosion and other effects often result. Under severe conditions of humidity, such as occur in mines and in tropical climates, moisture sometimes causes serious deterioration; products made from linseed-oil varnishes, for example, are prone to complete destruction of the varnish film in a damp atmosphere. Fungus growth and electrolysis are other examples of effects due to moisture.

It is usual to determine the absorbency of solid materials by ascertaining the weight of water absorbed by a standard specimen when immersed for a specified period: however, the quantity of water absorbed is not a reliable criterion of the electrical performance of a material if taken in isolation. Some British Standard methods require that electrical tests, especially those for insulation resistance and loss tangent, be carried out immediately after the samples have been removed from water following a period of immersion of 24 h.

### 7.2.1.3 Thermal effects

These often seriously influence the choice and application of insulating materials, important features being: freezing point (of gases and liquids); melting point (e.g. of waxes); softening or plastic yield temperatures; flash point of liquids; ignitability, flammability, ability to self-extinguish if ignited; resistance to electric arcs; liability to carbonise or track; specific heat; thermal resistivity or conductivity; and coefficient of expansion.

### 7.2.1.4 Ageing

Although ageing has been placed in the physical-properties section, ageing involves changes in the physical, mechanical, electrical and chemical properties of the material when

subjected to prolonged thermal and electrical stresses. In some applications mechanical stress may also be important.

A major part of life testing is the determination of the maximum temperature that a material, or combination of materials, can withstand for a long period without serious degradation of important properties. It is necessary for all components of an insulation system to be present during ageing tests because of the possibility of *compatibility* problems. Testing of this type is generally carried out on models made to reproduce, as far as possible, the conditions met in service. Such model investigations, often called 'functional testing', are generally accelerated by using temperatures considerably above those envisaged for service; but, provided that agreed procedures are used, it is often possible to extrapolate long-term results from comparatively short tests. A statistical technique that is often used for extrapolation is called *Weibull* statistics.

Thermal analysis tests that are routinely used to evaluate insulating materials are shown in Table 7.2. There is increasing interest in conducting ageing tests with a combination of heat and electric stress in order better to predict lifetime since there is an interaction between the decomposition products of electrical discharge and products released due to purely thermal effects in the material. Both increased temperature beyond that encountered in service and increased electric stress beyond the service stress can be used to accelerate ageing, but it is difficult to verify the prediction of service lifetime from the effect of a combination of acceleration techniques.

### 7.2.1.5 Miscellaneous characteristics

These include viscosity (of liquids such as molten bitumen), moisture content (of wood, pressboard, etc.), uniformity of thickness and porosity (of papers, porcelain, etc.).

## 7.2.2 Mechanical properties

The usual mechanical properties of solid materials are of varying significance in the case of those required for insulating purposes, *tensile* strength, *cross-breaking* strength, *shearing* strength and *compressive* strength often being specified. Owing, however, to the relative degree of inelasticity of most solid insulations and the fact that many are quite brittle, it is frequently necessary to pay attention to *compressibility*,

**Table 7.2** Thermal-analysis techniques

<i>Technique</i>	<i>Parameter measured</i>	<i>Applied stress</i>
Differential scanning calorimetry (DSC)	Energy necessary to establish zero temperature difference with a reference material	Environment heated or cooled at a controlled rate
Differential thermal analysis (DTA)	The difference in temperature between the material and a reference material	Environment heated or cooled at a controlled rate
Evolved-gas analysis (EGA)	Nature and quantity of volatile products formed	Heating
Thermally stimulated current measurement (TSC)	Polarisation or depolarisation current	Temperature change while electric field is applied
Thermogravimetry (TG)	Weight change with time or temperature	Heating or cooling
Thermomechanical analysis (TMA)	Mechanical strain	Mechanical vibration with heating or cooling

*deformation under bending stresses, impact strength and extensibility; tearing strength and ability to fold without damage* are important properties of thin-sheet insulations such as papers, pressboards and varnished cloths.

Methods of test for the above properties are given in British Standards.

Many other mechanical features of insulating materials have to be considered, for example: machinability (especially as regards drilling and punching) and resistance to splitting, the latter being of particular importance in the case of laminated materials, wood and pressboards.

### 7.2.3 Electrical properties

The essential property of a dielectric is, of course, that it shall insulate. But there are properties other than resistivity that determine the insulation value: these are the electric strength, permittivity and loss tangent.

#### 7.2.3.1 Resistivity

This concerns volume resistivity (a bulk property) and surface resistivity (concerning leakage current across the insulator surface between electrodes having a potential difference). The former is specified in ohm-metres (or megohm-metres) and the latter in ohms per square: the surface resistance between opposite sides of a square surface is independent of the size of the square. The properties are affected by surface or bulk moisture, so that measurements of insulation resistance of pieces of material or of insulated systems are often used to assess the state of dryness. Values of volume resistivity are given in *Table 7.1*.

#### 7.2.3.2 Electric strength

Electric strength (or dielectric strength) is the property of an insulating material which enables it to withstand a given electric field magnitude without failure. It is usually expressed in terms of the minimum electric field magnitude (i.e. potential difference per unit thickness) that will cause failure or 'breakdown' of the dielectric under specified conditions, e.g. shape of electrodes, temperature and method of application of voltage, as these and several other features all influence the liability of the material to fail under electric stress. It is, therefore, important to state most of these conditions when quoting values of electric strength, and they have been standardised accordingly by BSI and others. The standard method for testing oils for electric strength is given in BS 148:1998, and that for proof tests on bitumen-based filling compounds in BS 1858:1975. Details of the standard method for proof tests on solid insulations, such as moulded compounds and sheet materials, are given in BS 5734:1990, BS 6091:1995 and BS EN 60243:1998.

The electric strength of most materials falls with increasing temperature and it is usual to carry out tests for this property at suitably elevated temperatures.

Other features which vitally affect the apparent electric strength are: the sharpness or radius of edges of electrodes; the waveform of the voltage (as breakdown is dependent on the *peak* value); the rate of increase in voltage and the time any voltage stress is maintained; the moisture content of the material; the thickness of specimen tested and the medium (usually air or oil) in which the test is made. Comparisons of electric strength are made generally by determining the electric stress that will cause failure 1 min after its application. Specifications frequently call for a *proof test*, the material

being required to withstand for, say, 1 min a specified electric stress under controlled conditions.

In view of all the features which affect the apparent electric strength of dielectrics it is preferable to obtain comparative values, say, at a range of temperatures, thicknesses and test durations. Tests may be made with alternating or direct voltages; and it is now becoming more usual to test with lightning or switching-impulse voltages if the material is liable to sustain transient voltages in operation such as occur with overhead-line insulators, switchgear, power transformers and some machine windings. The object is to determine the highest stress that a material or assembly will withstand indefinitely. An indication can be obtained from a voltage/time curve (*Figure 7.1*) plotted from the stresses that cause breakdown in measured periods. The safe operating stress is then settled by experience, the use of safety factors, and the data from comparative tests. *Figure 7.1* gives typical results of the variation of electric strength with thickness of specimen and with temperature.

#### 7.2.3.3 Surface breakdown and flashover

When a high-voltage stress is applied to conductors separated only by air where they are closest together, and the stress is increased, breakdown of the intermediate air will take place when a certain stress is attained, being accompanied by the passage of a spark from one conductor to the other, i.e. the electric strength of the air has been exceeded. If the stress is sustained, this may also be followed by a continuous arc. The voltage at which this occurs is the *sparkover* or *flashover* value. Similar conditions can be obtained with oil as the insulant when a spark passes through the oil between the conductors.

In electrical assemblies where the live parts are separated by both solid insulation the ambient air, failure may take place either by breakdown of the solid material or by flashover through the air. Often the process involves surface leakage, deterioration and surface flashover. This phenomenon is generally due to the nature and design of the metal parts, as sharp edges of nuts and washers (for example) give local concentrations of stress. In addition, the onset of surface discharges at metal edges (which can initiate breakdown) is influenced by the permittivity of the dielectric material. The higher the permittivity, the lower the voltage at which flashover is likely to occur. Pollution on the insulation surface can reduce flashover voltage by a factor of 100. Insulating materials are sometimes tested for surface breakdown or flashover between two electrodes on a typical surface but, unless the material itself or its surface is poor electrically, flashover in air takes place in preference, usually at values of about 20 kV r.m.s. for 25 mm distance between two 38 mm diameter electrodes with fairly sharp edges.

**Figure 7.1** Effect of time, thickness and temperature on electric strength

### 7.2.3.4 Tracking

Leakage along the surface of a solid insulating material, often a result of surface contamination and moisture or of discharges on or close to the surface, may result in carbonisation of organic materials and conduction along the carbonised path. This is known as 'tracking'. It is usually progressive, eventually linking one electrode to another and causing complete breakdown along the carbonised track. The methods for evaluating the resistance to tracking and erosion of electrical insulating materials are given in BS 5604:1986 and its IEC equivalent IEC 60587:1984.

### 7.2.3.5 Permittivity

This property is specific to a material under given conditions of temperature, frequency, moisture content, etc. When two or more dielectrics are in series and an electric stress is applied across them, the voltage gradient across each individual dielectric is inversely proportional to its permittivity. This is particularly important when air spaces exist in solid and liquid dielectrics, as the permittivities of these are always higher than that of air, hence the air is liable to have the higher stress and may fail and cause spark-over through the air space in consequence. The permittivity of dielectric materials is strongly dependent upon frequency with a tendency to fall to low values at higher frequencies. In the case of ferroelectric materials, increasing the temperature will lead to an increase in permittivity up to the 'Curie Point' after which permittivity falls rapidly with temperature.

Values of permittivity for some insulating materials are given in *Table 7.1*.

### 7.2.3.6 Dielectric loss

A capacitor with a perfect dielectric material between its electrodes and with a sinusoidal alternating voltage applied takes a pure capacitive current  $I = \omega CV$  with a leading phase angle of  $90^\circ$ . In a practical case, conduction and hysteresis effects are present, the phase angle is less than  $90^\circ$  by a (normally) small angle  $\delta$ . The power factor, no longer zero, is given by  $\cos(90^\circ - \delta) = \sin \delta \approx \tan \delta$ : the latter is called the *loss tangent*. The power loss is, to a close approximation,  $P = V^2 \omega C \tan \delta$  where  $\omega = 2\pi f$ : it is proportional to the square of the voltage and to the product  $\epsilon \tan \delta$ , because the absolute permittivity  $\epsilon$  determines the capacitance of a system of given dimensions and configuration.

The loss tangent varies, sometimes considerably, with frequency and also with temperature; values of  $\tan \delta$  usually increase with rise of temperature, particularly when moisture is present, in which case the permittivity also rises with the temperature, so that total dielectric losses are often liable to a considerable increase as the temperature rises. This is very often the basic cause of electric breakdown in insulation under a.c. stress, especially if it is thick, as the losses cause an internal temperature rise with consequent increase in the dielectric loss, this becoming cumulative and resulting in thermal instability and, finally, breakdown.

Permittivity and loss tangent are usually determined by means of a Schering bridge (BS 7663:1993). For power devices such as cables and bushings, the test is made at 50 Hz; but for high-frequency equipment it is necessary to determine loss tangent and permittivity at much higher frequencies. BS 2067:1953 and BS 4542:1970 cover such measurements by the Hartshorn and Ward method at frequencies between 1 kHz and 100 MHz. Other methods are

available for other frequencies (see IEC 60250:1969). Typical values of loss tangent and permittivity for some of the principal insulating materials used for high voltages and for high frequencies are given in *Table 7.1*.

## 7.2.4 Chemical properties

The chemical and related properties of insulating materials of importance may be grouped as follows:

- (1) resistance to external chemical effects,
- (2) effects on other materials, and
- (3) chemical changes of the insulating material itself.

Under (1) there are such properties as resistance to:

- (a) the effect of oil on materials liable to be used in oil (in transformers and switchgear), or to be splashed with lubricating oil;
- (b) effects of solvents used with varnishes employed for impregnating, bonding and finishing;
- (c) attack by acids and alkalis, e.g. nitric acid resulting from electrical discharge, acid and alkali vapours and sprays in chemical works, and deposits of salts from sea spray;
- (d) oxidation, hydrolysis and other influences of atmospheric conditions, especially under damp conditions and in direct sunlight; and
- (e) effects of irradiation by high-energy nuclear radiation sources, e.g. neutrons,  $\beta$  particles and  $\gamma$  rays.

In group (2), typical effects of the insulating materials on other substances with which they may be used are:

- (a) direct solvent action, e.g. of oils and of spirits contained in varnishes, on bitumen and rubber; corrosion of metals in contact with the insulation; and attack on other materials by acids and alkalis contained in the insulating materials in a free state;
- (b) effects of impurities contained in the insulation; and
- (c) effects resulting from changes in the material, for example acids and other products of decomposition and oxidation affecting adjacent materials.

These effects are generally referred to under the heading 'compatibility'. If meaningful test results are to be obtained, all components of an insulation system must be present and they must have been treated in the same way as will be used in manufacture.

Group (3) includes such features as:

- (a) oxidation resulting from driers included in varnishes;
- (b) deterioration due to acidity (e.g. in oils, papers and cotton products);
- (c) chemical instability of synthetic resins;
- (d) self-polymerisation of synthetic compounds; and
- (d) vulcanisation of rubber-sulphur mixtures.

Most of these chemical properties are determined by well-known methods of chemical analysis and test. The principal tests are for acidity and alkalinity, pH value, chloride content in vulcanised fibre, and conductivity of aqueous extract (for presence of electrolytes). Some of these are dealt with in BS 5591:1978, BS 2782:1991, BS 5626-2:1979 and BS EN 1413:1998.

Increasing attention is being paid to chemical features of the raw materials and processes used in the manufacture of insulating materials—particularly varnishes, synthetic resins and all manner of plastics—and much research work is being carried out on these features and on the correlation of the chemical structure of dielectrics with their physical, electrical and mechanical properties.

### 7.3 Gaseous dielectrics

#### 7.3.1 Breakdown mechanisms in gases

As a gas is a highly compressible medium, breakdown processes in gases depend on the density of the gas and values quoted for air in Section 7.3.2 must be corrected for the air density ( $d$ ) relative to normal temperature and pressure (20°C and 1013 mbar, respectively):

$$d = \frac{p}{1013} \frac{273 + 20}{273 + t}$$

where  $p$  is the pressure in millibars and  $t$  is the temperature in degrees Celsius.

A discharge in a gas and subsequent development into a visible spark or flashover starts with the production of electrons in the gas by emission from one of the electrodes, or even from cosmic rays. The initial electrons are then multiplied by various processes of ionisation that give a growth in the current and lead, ultimately, to breakdown. In most gases, when an electron collides with a neutral molecule an extra electron and a positive ion will be produced, provided the energy of the original electron is higher than the ionisation energy of the molecule (Figure 7.2(a)) but in electronegative gases such as sulphur hexafluoride an electron can be captured by the molecule to give a negative ion (Figure 7.2(b)). This process is the opposite of electron multiplication so these gases have a high breakdown strength.

The breakdown strength of a gas is affected by the uniformity of the electric field, the waveform of the applied voltage, the support insulators and solid particle contaminants, in addition to the gas density. The effect of non-uniform field is particularly significant for d.c. insulation as the breakdown voltage is quite different depending on whether the point in a point-plane system is positive or negative. For large gaps the breakdown strength for the negative point is more than twice the voltage obtained when the point is positive.

In practical apparatus the breakdown strength of compressed gas can be reduced severely by the presence of dust and solid particles. Particles near an electrode can induce a spark at a substantially lower voltage than for a particle-free situation. In one study on sulphur hexafluoride, breakdown voltages were reduced to between 20% and 90% of the particle-free values, depending on the number and size of the particles present.

#### 7.3.2 Air

Air is the most important gas used for insulating purposes, having the unique feature of being universally and immediately available at no cost. The resistivity of air can be considered as infinite under normal conditions when there is no ionisation. There is, therefore, no measurable dielectric loss,

**Figure 7.2** Electron-molecule collisions in gases: (a) normal gases; (b) electronegative gases

**Table 7.3** Typical breakdown voltages in air under normal atmospheric conditions (kilovolt peak at 50 Hz)

Two-electrode system	Spacing or gap (mm)				
	10	50	100	200	300
Spheres, diameter 1.0 m	—	137	266	503	709
0.25 m	31	137	243	363	—
Needle points	13	50	78	127	178
Parallel wires, diameter 8.25 mm	—	38	57	83	117
Concentric cylinders:					
outer/inner radius (mm)	38/1.3	38/11	67/17	67/2	103
Breakdown voltage (kV)	26	55	88	103	—

negligible  $\tan \delta$ , and a relative permittivity (for all practical purposes) of unity. The electric strength under normal atmospheric conditions is 30 kV/cm (peak) for a uniform field. In a practical airgap the voltage gradient is a maximum at the electrode surfaces. The sparkover (breakdown) voltage of an air gap is therefore a non-linear function of its length. The gap geometry and configuration affect the breakdown voltage, and empirical expressions have been derived to account for the 'gap factor'.

Partial breakdown of air, locally, often occurs when the voltage gradient in a particular region exceeds the critical value for air. This happens readily at points of electric flux concentration, e.g. sharp edges of metal parts. If this local breakdown becomes unstable—as it will when the voltage between conductors is increased sufficiently—sparkover will occur. This may be an isolated spark from one conductor to the other, and the intervening air then re-heals itself. If the voltage is maintained (or increased), the spark may be followed by a continuous stream of sparks.

Typical values of breakdown voltages for gaps of different forms and sizes of electrodes (under normal atmospheric conditions) are given in Table 7.3.

Partial or complete breakdown of air in gaps can be influenced by suspending sheets of material at particular places in the electric field. In some cases, the sheets may be of metal, and in others of insulating materials; even woven fabrics can have an effect. The effect of this barrier is generally greater for more divergent fields. This solution can be useful where clearances are limited inside equipment, or particularly in high-voltage test areas.

For plane gaps, all gases exhibit a minimum breakdown voltage known as the Paschen minimum; this occurs at a given value of the product  $Pd$  of absolute gas pressure and gap length. For air this minimum occurs at  $Pd \approx 6$  (in torr-millimetre). Thus as the value of  $Pd$  is reduced from a higher region the breakdown voltage falls to the minimum value quoted, and further decrease in either  $P$  or  $d$  results in an increase in the voltage required to break down the gap. This explains why quite small gaps under conditions of high vacuum can sustain very high voltages. Table 7.4 gives the values of  $Pd$  and the minimum voltages for several gases.

##### 7.3.2.1 Sphere gaps

As the electric strength of air is dependable, standard sphere gaps can be used as reliable and accurate means for measuring high voltages (Table 7.5), particularly where peak voltages are to be measured, as it is, of course, the peak value

**Table 7.4** Minimum breakdown voltage for gases: 1 mmHg, 1/760 atm

\*In air at 20°C, 1013 mbar. One sphere earthed. For alternating voltages of either polarity; and for standard negative impulse voltages (50% breakdown value). Figures in brackets not reliable.

which determines the breakdown. Standard sizes of spheres are generally used as electrodes, as, provided the size is appropriate and proper precautions are taken (e.g. to avoid effects such as those due to the proximity of other objects and uncontrolled irradiation of the gap by other discharges), clean, smooth, metal spheres are most reliable as a means of determining high voltages; this is largely due to the absence of corona prior to flashover if the spacing does not exceed the radius of the spheres. Sphere gaps are suitable also for the measurement of impulse voltages. Voltages of about 2 kV and upwards can be measured reliably. BS 358:1960 gives detailed information on the effects of humidity, air density (or barometric pressure), etc. The effect of density is pronounced in the case of equipment used at high levels above 1000 m, in aircraft where altitudes up to 15 km may be met, or in spacecraft where outer space is an almost perfect vacuum.

### 7.3.2.2 Needle gaps

Humidity has here a strong influence on breakdown voltage where the electrode shape leads to field concentration. For this reason, as well as that of a degree of frequency dependence, needle gaps are unreliable for high-voltage measurements. Rod gaps (e.g. 12 or 16 mm square-section rods with sharp corners) are used for chopping impulse voltages, but with these too a humidity correction is necessary.

### 7.3.2.3 Corona

This term is used to describe the glow or 'brush' discharge around conductors when the air is stressed beyond the ionisation point without flashover developing. It is of more or less serious consequence according to the application concerned. It causes a certain amount of energy loss with alternating current, which may become appreciable on high-voltage transmission lines. It produces radio interference and may initiate surface deterioration and breakdown on solid insulation surfaces. Corona is also known to produce secondary chemical effects.

In thin films, particularly in spaces between layers of sheet insulation, air can readily become ionised due to the electric stress across such spaces exceeding the critical value. This is often due to the fact that, with dielectrics in series, the stress in each section is inversely proportional to its permittivity. When the critical stress in the air or gas is exceeded, discharges occur (often called corona, ionisation, glow or brush discharges) and this causes splitting up of the gas molecules. In air this leads to the formation of ozone and nitrogen oxides which in the presence of moisture produce nitric acid. The ozone has, of course, a strong oxidising effect, but the more serious chemical effects of ionisation are those due to the nitrogen products, as the nitric acid attacks most of the organic insulating materials and causes corrosion of metal parts. The action of either or both the ozone and the nitrogen oxides on many materials is to cause decomposition and

often the formation of acids; for example, oxalic acid, known for causing brittle fracture in polymeric insulators, by the oxidation of cellulose materials, and acetic acid from the decomposition of cellulose acetate.

In addition to the chemical effects, discharges in spaces, films or cavities within dielectrics can have serious consequences mainly due to the high energy in some of the individual discharges. Mechanical electrical and thermal damage can occur and breakdown in service may result after long periods. There has been considerable advance in the methods for detecting the presence of such partial discharges in various types of equipment especially where oil-impregnated paper dielectrics are used. Discharges within air or gas films in such material can cause severe damage often followed by complete breakdown.

7.3.2.4 Compressed air

This is used as the arc-extinguishing medium and dielectric insulation in air-blast circuit-breakers.

7.3.3 Nitrogen

Instead of air, which is a mixture of approximately 21% oxygen and 79% nitrogen, nitrogen alone is sometimes used when there is a risk of oxidation of another material such as insulating oil. Nitrogen is often used in gas-filled high-voltage cables, as an inert medium to replace air in the space above the oil in some transformers, in low-loss capacitors for high-voltage testing, etc. There is no appreciable difference between the electric strength of nitrogen and that of air. Some results relating to the electric strength of nitrogen for uniform fields at pressures above atmospheric up to 20 atm are given in Table 7.6. Included are some similar results for carbon dioxide.

**Table 7.6** Breakdown voltages of nitrogen and carbon dioxide (kilovolts at peak) under uniform field conditions

Gas	Gap (mm)	Pressure (abs) (atm)				
		3	5	10	15	20
Nitrogen	1	10	15	27	35	45
	8	90	123	180	220	—
Carbon dioxide	1	13	17	27	38	52
	8	85	115	200	260	—

7.3.4 Sulphur hexafluoride

Sulphur hexafluoride is an electronegative gas which has come into wide use as a dielectric (in X-ray equipment, in waveguides, coaxial cables, transformers, etc.) and as an arc-quenching medium in circuit-breakers. Its electric strength is of the order of 2.3 times that of air or nitrogen, and at a pressure of 3–4 atm it has an electric strength similar to that of transformer oil at atmospheric pressure. The gas sublimes at about –64°C and it may be used at temperatures up to about 150°C. Although the gas is considered to be non-toxic, non-flammable and chemically inert, under the influence of arcs or high-voltage discharges, there may be some decomposition with consequent attack on certain insulating materials and metals, and more importantly some recent environmental concerns. In circuit-breakers this problem is overcome by careful selection of materials (e.g. polytetrafluoroethylene for interrupter nozzles) and by the use of filters and absorbents to remove the products of decomposition after circuit interruption. Some figures relating to the electric strength of sulphur hexafluoride and mixtures of this gas with nitrogen are given in Table 7.7.

Numerous other electronegative gases such as perfluoropropane (C<sub>3</sub>F<sub>8</sub>), octafluorocyclobutane (C<sub>4</sub>F<sub>8</sub>) and perfluorobutane (C<sub>4</sub>F<sub>10</sub>) have been developed, but few have found such widespread use as sulphur hexafluoride. The main interest for these gases is as dielectrics in transformers, waveguides, capacitors, etc., but one difficulty is that the temperature at which condensation occurs may not be sufficiently low for safety in outdoor equipment likely to remain un-energised for long periods. This problem can be overcome partly by fitting heaters or by using admixtures with a more volatile gas (such as nitrogen). Addition of nitrogen often improves some of the characteristics, while at the same time reducing the overall cost. Some of these gases can be used at temperatures well above 200°C.

Most of the fluorinated gases have an electric strength between two and five times that of air or nitrogen under the same conditions but, as with sulphur hexafluoride, care must be taken to prevent high-voltage discharges or arcs in the gas because of the dangers of producing decomposition products. Recent research efforts in the electrical power industry focussed on improving the use of gas mixtures (essentially 90% nitrogen and 10% SF<sub>6</sub>), which are more environmentally acceptable. Gas insulated high voltage lines are now in operation using these gas mixtures.

Some electric machines and special devices have to operate in a gas other than air—for example, most refrigerator compressor motors operate in gaseous refrigerants mostly

**Table 7.7** Breakdown voltage of nitrogen and sulphur hexafluoride (kilovolts at peak): direct voltage and uniform field

Gas	Pressure (atm)	Positive polarity gap (mm)					Negative polarity gap (mm)				
		5	10	15	20	25	5	10	15	20	25
Nitrogen	1	—	30	—	56	—	—	30	—	56	—
	2	30	55	—	100	—	30	54	—	100	—

	2	85	171	252	—	—	84	171	251	—	—
	3	132	260	—	—	—	131	258	—	—	—

based on chlorofluorohydrocarbons (such as Arcton, Freon, etc.). These materials can act as solvents for some of the components used in insulating materials with consequent failure of the equipment due to blocked tubes and valves in the refrigerator circuit. Careful selection of materials for resistance to these fluids is essential.

### 7.3.5 Hydrogen

This gas is used as a cooling medium in some large turbo generators and synchronous motors; the main advantages are the efficient removal of heat and reductions in windage loss. Although there is a fire and explosion risk, troubles of this kind have been few during the many years that the gas has been used commercially for electrical machines. The electric strength of hydrogen at atmospheric pressure is about 65% that of air but most machines operate at pressures of 2–5 atm, and over this range the electric strength is higher than for air at atmospheric pressure. High-voltage discharges are thus not likely to be any more severe, and as discharges in hydrogen do not produce ozone or oxides of nitrogen, injurious effects are considered to be negligibly small.

### 7.3.6 Vacuum

Considerable investigation has been made into the utilisation of high vacua both for the insulation of equipment and as the interrupting medium in vacuum circuit breakers and contactors. The major advantage is due to the fact that very high electric field strengths can be achieved with a maximum operating pressure of 1 atm (negative), whereas with gases, very high operating pressures are generally essential and this complicates the mechanical design of the tank or other containing structure. Vast improvements in high-vacuum technology together with the need to replace oil-insulated switchgear has led to compact vacuum bottles used to retrofit old oil-filled circuit breakers.

## 7.4 Liquid dielectrics

The liquids which are most commonly used for electrical insulation are petroleum oils. For some applications these are being replaced by synthetic hydrocarbon oils, particularly as impregnant for oil-impregnated paper insulated power cables. Polychlorinated biphenyls (askarels) were widely used where non-flammable insulation was required for transformers, and for capacitor dielectrics. However, these have now been withdrawn for most applications because of environmental pollution effects and health risks. Silicone oils are now used for non-flammable transformer insulation. Capacitors often use silicone liquids or synthetic hydrocarbons as dielectrics, but various esters are now being introduced that offer a higher permittivity and hence a higher capacitance value for the same dimensions. An insulating liquid that is sometimes used is castor oil.

The principal uses of liquid dielectrics are:

- (1) as a filling and cooling medium for transformers and some electronic equipment, and as a filling medium for capacitors, bushings, etc.;
- (2) as an insulating and arc-quenching medium in switchgear;
- (3) as an impregnant of absorbent insulation, e.g. paper, porous polymers and pressboard—these are used in transformers, switchgear, capacitors and cables; and

- (4) as a heat transfer medium in addition to its insulation rôle in power cables, especially in force-cooled high-pressure oil-filled cables.

The important properties of the liquid used vary with the application, but they include electric strength, permittivity, chemical and thermal stability, gassing characteristics, fire resistance and viscosity.

### 7.4.1 Breakdown mechanisms in liquids

Breakdown strengths of liquids are very dependent on liquid purity and all the breakdown mechanisms that are met in the practical use of liquids as electrical insulation are contamination mechanisms. Breakdown is caused by one of three contaminants: particles, water, or gas bubbles.

Particle-induced breakdown requires that there are dust particles, cellulose fibres from adjacent solid insulation or similar particles present in the liquid. If the particle has a higher relative permittivity than the liquid, electrostatic theory tells us that there will be a force acting on the particle moving it towards the region of greatest stress between the electrodes. If the particle contains moisture the force will be larger because of the high  $\epsilon_r$  value for water. Other particles will be attracted to the same region and they align end-to-end, eventually forming a bridge between the electrodes. Current flows along this bridge giving localised heating and breakdown.

Water itself is inevitably likely to be present in practical liquids. Careful procedures for filling equipment and maintaining desiccants at breathing points in the apparatus can normally keep moisture levels to less than 20 ppm. Any globule of water present in the liquid will become elongated in the field direction by the action of an applied field. Breakdown channels will propagate from the ends of the globule and produce total breakdown. The electric strength of an oil can be halved by the presence of 50 ppm of water. The presence of water will significantly increase the dielectric loss in the oil and reduce the breakdown strength.

Bubbles can be formed by gas pockets in pits or cracks on surfaces containing the liquid, or they can arise from dissociation of liquid molecules, or local liquid vaporization through electron emission from sharp points on an electrode. Such bubbles will become elongated by the field in a similar way to water globules. As the breakdown strength of the gas in the bubble will be much lower than that of the liquid, the field inside the bubble may exceed the breakdown strength of the vapour. This will give a spark in the bubble which may cause dissociation of some of the surrounding liquid to generate more gas. Eventually the bubble will become so large that a complete breakdown between the electrodes will ensue.

### 7.4.2 Insulating oils

The insulating oils used extensively are highly refined hydrocarbon mineral oils obtained from selected crude petroleum, and have densities in the range 860–890 kg/m<sup>3</sup> at 15°C. Oil for transformers and switchgear is dealt with in BS 148:1998. A number of special mineral oils are employed for impregnated paper capacitors and cables and others—usually of higher viscosity and flash point—for rheostats and for filling bus-bar chambers in switchgear. Typical properties are given in *Tables 7.3 and 7.9*.

#### 7.4.2.1 Electric strength

This is a property involving similar phenomena to spark-over in gases. On raising the voltage between two electrodes

**Table 7.8** Effect of contaminants on electric strength of mineral insulating oil: breakdown voltage in kilovolts r.m.s. (between 13 mm diameter spheres, 4 mm gap)

Contaminant	(g/m <sup>3</sup> )	Water present (parts/10 000)			
		0.2	1.0	2.5	5
Clean oil	0	86	80	80	80
Cotton	0.02	68	36	30	28
	0.28	33	11	10	10
Pressboard fibres	0.08	82	64	56	54
	0.37	56	30	29	28
	1.4	26	12	11	11
Carbon	1.9	83	80	80	79
	35.0	73	70	70	69

in oil, electrical discharges may first appear in the space surrounding the electrodes—particularly at sharp corners—and at a higher voltage, sparks pass across the intervening space between the conductors: these are often intermittent ('pilot') sparks, and, on raising the voltage further, a continuous stream of sparks usually occurs and may develop into an arc, with complete breakdown of the oil.

The electric strength is generally tested with electrodes consisting of two metal spheres of about 13 mm diameter separated by a gap of 4 mm. For clean, dry oil the breakdown voltage should be in the region of 100 kV r.m.s. or more, but careful treatment, storage and handling are needed to maintain this level. For the oil to comply with BS 148:1998, it should withstand for 1 min without breakdown 40 kV r.m.s. applied between the spherical electrodes under conditions laid down in the Specification.

The electric strength of insulating oil is strongly affected by impurities, especially water and particles of fibrous material. The latter are attracted to the testing gap by the electric field and readily align themselves across the shortest space. The presence of moisture in oils is shown by electric strength tests when particles of such solid impurities—particularly organic fibres—are present, the breakdown voltage being reduced considerably by even small quantities.

Typical values of electric strength in different conditions are given in Table 7.8. Water and other impurities can be removed from oil by means of filter presses, centrifuges or (where high voltages are concerned) the application of vacuum. In addition to removing moisture, the vacuum will remove dissolved gases, but it is necessary to heat the oil and to spread it out over a very large surface area to facilitate the process. Once oil has been treated in this way, it must be stored out of contact with air and for preference at a temperature higher than the ambient.

#### 7.4.2.2 Viscosity

This property, particularly at low temperature, is of great importance in oils used primarily for cooling in transformers and rheostats, it being necessary for the viscosity to be sufficiently low to ensure the necessary convection at the operating temperatures. This property is usually determined by methods such as those described in BS 188:1997, and the viscosity is expressed in centistokes (cSt), and the viscosity to BS 148:1998 has a maximum viscosity (kinematic) of 37 cSt at 21.1°C (70°F). This is approximately equivalent to 151 s at 21.1°C and 200 s at 15.5°C (60°F) obtained with a

**Figure 7.3** Viscosity-temperature characteristics of insulating oils

Redwood No. 1 viscometer. Figure 7.3 gives typical viscosity-temperature characteristics.

#### 7.4.2.3 Flash point

For standard oil this is not less than 146°C, and may be as high as 240°C for rheostats. These values refer to a *closed* flash-point tester.

#### 7.4.2.4 Thermal properties

The specific heat is about 1900 J/(kg K) at 15°C and 2200 at 80°C. The thermal conductivity is of the order of 0.15 W/(m K).

#### 7.4.2.5 Chemical stability

Insulating oils should be stable and not liable to deteriorate other materials or cause corrosion. The *acidity* is therefore closely controlled and oils are tested to ensure that they do not cause discoloration of copper. The worst feature of oils in this connection is the formation of sludge. This is mainly due to the oxidation of unsaturated hydrocarbons, particularly at high temperatures, and is accelerated by exposure of the oil to air and light, and (due to catalytic action) to copper. BS 148:1998 includes tests for acidity, discoloration of copper, tendency to sludge formation and development of acidity.

Useful guidance on means of maintaining insulating oils in service is given in the British Standard BS 5730:1979, for the *Code of Practice for Maintenance of Insulating Oil with Special Reference to Transformers and Switchgear*. This refers to oil supplied to BS 148:1998 and describes the nature of deterioration or contamination likely to occur in storage, or in the course of handling or in service. It also gives recommendations for routine methods of sampling and testing to enable the suitability of oil for further service to be determined.

BS EN 50195:1997 and BS EN 50225:1995 give guidance on the safe use of oil-filled equipment containing Askarel and PCB contaminations respectively.

**Table 7.9** Properties of typical oils and fluids

Property	Unit	$M^*$	$S^{\dagger}\Leftarrow$
Density at 15°C	kg/m <sup>3</sup>	880	970

$\ddagger$  In standard test cell.

The properties of a typical mineral oil, complying with BS 148:1998, are shown in *Table 7.9*.

### 7.4.3 Inhibited transformer oil

Oils operating at comparatively high temperatures, in the presence of oxygen and various catalytic materials, develop sludges and high acidity. These effects can be alleviated by adding various inhibiting substances to the oil, the most widely known being di-tertiary-butylparacresol used in quantities generally less than about 0.5% of the oil by weight. Materials of this type delay the point at which sludge and acid formation begin; but once the inhibitor has been used up, deterioration will proceed at the same rate as if no inhibitor had been used. For large power transformers, it has not been found necessary to use these inhibiting substances because of improvements in the construction which have reduced access of oxygen by conservators, hermetic sealing or the use of a nitrogen blanket above the oil surface. Another improvement has been the covering of copper surfaces so reducing the catalytic effect. For transformers operating under more adverse conditions of temperature such as distribution or pole-mounted units, a better case can be made for using inhibited oils.

### 7.4.4 Synthetic insulating liquids

Synthetic hydrocarbons are fairly widely used for power-cable insulation and as capacitor dielectrics. These are more expensive than petroleum oils but they generally have better electrical properties because of their lower contamination levels and they can have better gas-absorbing properties. A commonly used synthetic oil is poly-iso-butylene, commonly known as polybutene. Different polymer chain lengths can be produced giving a wide range of viscosities from low viscosity liquids to sticky semi-solids. The high molecular weight tacky and rubbery materials can be used mixed with oil, resin, bitumens, polyethylene and inorganic fillers to produce non-draining and potting compounds. Another synthetic oil that is used for cable insulation is dodecylbenzene, an aromatic compound. The physical properties are similar to mineral oils, but the viscosity-temperature characteristics show much higher low-temperature viscosity than comparable polybutenes. However, the

gas-absorbing characteristics are good. Electrical properties are generally similar to mineral oils but the permittivity is somewhat higher for dodecylbenzene.

Polychlorinated biphenyls (also called askarels) have been used as high permittivity (3–6) fire-resistant insulating liquids since the 1930s but their effect as an ecological poison has limited their use to sealed equipment in recent years and all use of these liquids is being discouraged.

Silicone fluids (poly-dimethylsiloxanes) have been used as alternative fire-resistant insulating liquids, but their fire resistance is inferior to the askarels. They are generally gas evolving and their arc products can cause problems. However, they are very stable and have good electrical properties and are used in transformers and capacitors.

Several liquids have been developed as alternative high permittivity insulating liquids to replace the askarels for capacitor dielectrics. One possible group of materials is the organic esters. They have good viscosity temperature characteristics and are less flammable than mineral oil and can be either gas producing or gas absorbing, depending on their composition. When carefully purified, their electric strengths are about 20 kV/mm and dissipation factors average 0.001 at 20°C. Diesters have relatively high permittivities (4.3 for di-2 ethylhexylphthalate). Other liquids that may be suitable for electrical insulation are phosphate esters, halogenated hydrocarbons, fluoroesters and silicate esters. Castor oil is a good insulation material for d.c. stress with a permittivity of 4.7, but it has a high dissipation factor of 0.002 that makes it unsuitable for most a.c. applications.

BS EN 60867:1994 and BS 61099:1992 give specifications for unused liquids based on synthetic aromatic hydrocarbons and for unused synthetic organic esters respectively.

## 7.5 Semi-fluid and fusible materials

A few semi-fluid or semi-plastic compounds, and various fusible materials which are solids at normal temperature and melt to liquids of low viscosity or soften considerably with heat, are used principally in the following ways:

- (1) for filling small cavities and large spaces, e.g. in metal-clad switchgear, transformers, cable-boxes and capacitors;
- (2) for impregnating absorbent materials and windings;

- (3) as the bond in laminated materials;
- (4) as the basic material in moulding compounds; and
- (5) for external coverings of parts and apparatus (i.e. envelopment and encapsulation).

The materials most commonly used for these purposes are bitumen, natural waxes, shellac, synthetic waxes and synthetic resins; with the exception of many of the latter, and shellac, these are all *thermoplastic* materials, i.e. they soften and melt on heating and solidify again on cooling without any substantial chemical change, and they can be re-softened or re-melted. In the case of some of the synthetic resins, especially those of the phenolic type, gradual hardening takes place as they are heated, and the melting point rises, so that, after being melted, solidification takes place on further heating, the material then becoming infusible: i.e. the process of melting and solidification on cooling is not repeatable; they are therefore known as *thermosetting* materials. Shellac also has thermosetting properties, but it requires longer heating to effect marked rise of melting point than in the case of many synthetic resins.

The properties of chief importance in such materials are: mechanical strength; electric strength; freedom from impurities; softening and melting temperatures; viscosity at pouring or impregnating temperatures; coefficient of expansion; and chemical effects on other materials.

Several materials which are *semi-fluid* at normal temperatures are used for filling and sealing purposes. For example: good grades of petroleum jelly of the Vaseline type are preferred to oil for filling apparatus and components where a liquid is undesirable, or where molten compounds cannot readily be poured or may affect other materials which are present (e.g. rubber and thermoplastic materials).

Various '*semi-plastic*' compounds or cements, of a putty-like consistency, are also used for plugging and filling purposes, where semi-fluid and molten compounds cannot readily be applied. Some of these are almost permanently plastic and are therefore preferred where, for example, a certain amount of flexibility is required (e.g. where leads of coils may be moved slightly in assembly or service). Others may harden gradually in course of time (as in the case of ordinary putty), or they may harden quickly by chemical action (e.g. litharge and glycerine cement) or by heating—the latter usually being necessary with synthetic-resin compounds.

### 7.5.1 Bitumens

Highly refined bitumens, which are usually steam distilled, and of numerous grades, varying from semi-liquids to hard

bitumens of melting point over 120°C, are used extensively for filling cable boxes, transformers and switchgear. These have high electric strength and are very inert and stable. As the coefficient of expansion is high, care has to be taken in filling large spaces to prevent voids and cracks on cooling. Some of the bitumens, especially those of high melting point, are rather brittle; all are soluble in oil, but they have excellent resistance to moisture. BS 1858:1973 deals with bitumen-base filling compounds for electrical purposes. Properties of typical bituminous compounds are given in Table 7.10. Some bitumens are used as ingredients in varnishes and paints, rendering these very resistant to moisture and chemical attack. A few impregnating compounds contain bitumens, especially those used for treating high-voltage machine bars and coils.

### 7.5.2 Mineral waxes and blends

Various mineral waxes such as paraffin, ceresine, montan and ozokerite—including microcrystalline waxes—also blends and gels of these, having melting points in the range 35–130°C, are used for impregnating capacitors, radio coils and transformers, also for other purposes such as cable manufacture. Properties of mineral waxes are given in Table 7.11.

### 7.5.3 Synthetic waxes

A few synthetic waxes—principally chlorinated naphthalene—with melting points up to 130°C have certain advantages over natural waxes, particularly higher permittivity which enables smaller paper-insulated capacitors to be made. Properties of a typical synthetic wax of this type are given in Table 7.11.

### 7.5.4 Natural resins or gums

These materials, which may be classified broadly as shellac, rosin (colophony), copals and gum arabic, are used principally as ingredients in varnishes or liquid adhesives. In some cases they are used direct, e.g. as powders, for a bonding medium between layers of mica which are hot pressed, but they are usually dissolved in spirit solvents, e.g. methylated spirits (or water in the case of gum arabic), and applied as a solution to mica, paper, etc., for subsequent laminating and hot rolling, pressing or moulding (see Table 7.11).

### 7.5.5 Miscellaneous fusible compounds

Numerous compounds of bituminous and other types are used for all manner of cavity-filling purposes, some (mainly rosin) are oil resisting and are employed where bituminous compounds cannot be used owing to the presence of oil, e.g. for bushings of oil circuit-breakers and oil-immersed transformers. Others are used for sealing over the tops of primary batteries and accumulators. Compounds containing beeswax are useful impregnants for small coils not exposed to heat, e.g. on telephone apparatus; and sulphur, 'sealing wax' and 'Chatterton's compound' are examples of materials finding uses for miscellaneous applications where, say, the heads of screws in insulating panels and mouldings require to be sealed over.

### 7.5.6 Treatments using fusible materials

Treatments with bitumen, waxes, etc., usually consist of thorough vacuum drying of the coils, capacitors or other parts to be treated, followed by complete immersion in the compound while in a molten condition and at a temperature such that the viscosity is low enough to facilitate penetration; the molten compound generally being admitted to the impregnating vessel under vacuum. Pressure (up to 10 atm) is often applied during the immersion period to assist penetration. Such treatments enable spaces in windings to be filled thoroughly, and absorbent materials such as papers and fabrics are often well saturated with the impregnants, especially in the case of waxes. These treatments provide good resistance to moisture absorption and improve transference of heat from the interior of coils, also eliminating discharges in high-voltage windings and capacitors by the filling of air spaces.

### 7.5.7 Synthetic resins

An increasing number of the well-known synthetic resins, which form the basis of the principal 'plastics', are of great use to electrical engineers on account of their fusibility or softening characteristics at elevated temperatures, which enables them to be converted to desired shapes. The

4-Methylpentene-1	
Acrylonitrile-butadiene-styrene	

synthetic resins can be divided into two groups: thermoplastic and thermosetting (see Table 7.12).

**Thermoplastic synthetic resins** In the case of most of the thermoplastic materials of this type, heating to temperatures within a certain range causes considerable softening and sometimes melting of the material to a viscous liquid. This enables them to be cast, formed, moulded or extruded into various required shapes by virtue of re-solidification on cooling again to normal temperatures. Some of the resins (e.g. acrylates and alkyd resins) have good adhesive properties and can therefore be used for bonding purposes either in the form of a solution or, more usually, by the application of heat. Layers of sheet materials, such as paper and fabric, can thus be bonded together into boards, simple mouldings, tubes, etc. The resins are often used alone, but more usually mixed with materials such as fillers and plasticisers, and in both varieties these synthetic materials are usually capable of being formed to all manner of shapes by the usual moulding processes (see Table 7.13).

**Thermosetting synthetic resins** These enable useful compositions to be made, and withstand temperatures in excess of

\*R.m.s. for 3 mm thickness.

100°C. The most widely used are the phenol formaldehyde type. The materials pass through three stages of physical condition:

- (1) in which the resins are fusible at temperatures such as 80°C, and are soluble in suitable solvents;
- (2) results from heating the stage (1) resin until it becomes relatively infusible and insoluble; and
- (3) the infusible and insoluble state reached by continued heating after stage (2); no further change occurs and the materials are 'fully cured' or 'completely polymerised'.

These physical stages make thermosetting resins suitable for three main uses.

- (1) In spirit solutions; as ingredients in varnishes for impregnating purposes and the production of surface finishes; as enveloping, potting or encapsulating materials, and as ingredients in filling compounds.
- (2) As adhesives for bonding layers of wood, paper, fabrics, etc., together to form laminated sheets, wrappings, and other simple shapes.
- (3) As the basic material in moulding compositions for use in making articles by compression or injection moulding, extrusion or casting.

Properties of typical thermosetting resins of the phenol formaldehyde type, unfilled, are given in *Table 7.14*.

Many of the thermosetting resins, e.g. phenol formaldehyde and melamine formaldehyde, require heavy pressure during the heating and hardening processes (2) and (3) above. Several resins requiring little or no pressure (polyesters, epoxies and polyurethanes) have been developed as 'low-pressure', 'contact' or 'casting' resins, or as 'solventless varnishes'. These resins are initially in a low-viscosity liquid state, to which a 'hardener' or catalyst (e.g. a peroxide) is added. In some cases polymerisation sets in at normal room temperatures, or at temperatures of only 80–100°C, the hardening process taking place more rapidly as the temperature is increased. Thus the resins can be readily cast to required shapes in 'moulds', and can also be used for

impregnating and coating windings as they readily fill interstices and do not leave voids on hardening owing to the fact that no volatile constituents evaporate—hence their use as 'solventless varnishes'. Mixed with suitable fillers (e.g. glass fibres, asbestos or other minerals) or applied to fabrics, papers and other sheet materials (usually of glass fibres), they are used extensively for producing castings, mouldings and laminates of varying degrees of mechanical and electrical strength, sometimes in very large pieces which could not readily be made by normal moulding methods; they are usually referred to as 'reinforced plastics'.

A brief description of the principal synthetic resins in electrical use is given below. Some are suitable for moulding with or without fillers, some for the preparation of laminated materials. Rod, sheet and tube forms are available in certain cases.

BS 1133-16:1997 deals with packaging adhesives and gives information on their characteristics and end use including advice on storage and precautions in use.

### 7.5.8 Thermoplastic synthetic resins

*Polyethylene* is waxy, translucent, tough and flexible, with a sharp melting point at about 110°C, and is used for high-voltage and high-frequency applications. It is readily injection moulded, extruded as wire coverings, and in sheet, rod and film form.

*Polytetrafluoroethylene* a white powder that can be moulded or extruded. It is highly resistant to moisture and chemicals, and withstands temperatures up to 250°C. It is used in high-frequency application.

*Polystyrene* softens at 70°C. It can be compression or injection moulded and may be used with a mineral filler to improve heat resistance.

*Polyvinyl acetate and copolymers* Polyvinyl acetates are obtained from acetylene and acetic acid: they are used as adhesives and enamels.

*Polyvinyl chlorides* These are obtained from the combination of acetylene and hydrochloric acid as a white powder used with stabilisers, plasticisers, etc., to produce various rubber-like materials that can be extruded as tubes for wire protection. Sheet and moulded polyvinyl chloride have a loss tangent too high for high-frequency use. Copolymers of the acetate and chloride forms are tough, rigid and water resistant and can be injection moulded.

*Acrylates* The most important product is polymethylmethacrylate, a rigid glass-clear material with good optical, electrical and mechanical qualities. It can be obtained in sheet, rod and tube form, and as a moulding powder. Its low softening point (60°C) limits its application to moderate temperatures.

*Polyesters* Some non-hardening *alkyds* have limited use as adhesives.

*Polyethylene terephthalate* This has a sharp melting point at about 260°C and is formed into filaments for textile manufacture. Also extruded to form films. It has a high resistance to temperature and ageing and to water absorption. The textiles

\* In stage (1); other properties are for stage (3) (see text).

are suitable for class E insulation and, when suitably varnished, may withstand temperatures greater than class E.

*Cellulose acetate and triacetate* These are also esters. Produced as lacquers, textiles, sheet, rod, film and moulding powder, they are suitable for machine windings. The acetate softens at 60–80°C, the triacetate at 300°C. The materials are available as fibrous cotton or paper tapes.

*Polyamides* Super-polyamides are known as 'nylon': they produce monofilaments and yarns, with very good mechanical properties. The electrical properties are not outstanding, but nylon gives tough and flexible synthetic 'enamel' covering for wires. Films and mouldings can also be produced.

*Polyacetal* The material has good dimensional stability and is tough and rigid. It can be injection moulded and extruded, and is replacing metal parts in relays.

*Polypropylene* This material has a low density, dielectric loss and permittivity. Special stabilisers may be necessary when the material is extruded on to copper conductors.

*4-Methylpentene-1* is similar to polyethylene and polypropylene and with similar resistance to chemicals and solvents. It is the lightest known thermoplastic. The high melting point (above 240°C) cannot be fully exploited because of softening and oxidation. Its permittivity and loss are low and remain fairly constant over a wide frequency and temperature range.

*Polycarbonate* approaches thermosetting materials in retention of stability up to 130°C. It is self-extinguishing and useful for structural parts, housings and containers for hand tools and domestic appliances.

*Polyphenylene oxide* is stiff and resistant to comparatively high temperatures. Its permittivity and loss tangent are fairly constant at frequencies up to 1 MHz.

*Acrylonitrile butadiene styrene* has good dimensional stability and mechanical strength from –40 to 100°C.

### 7.5.9 Thermosetting synthetic resins

*Phenol formaldehyde* These versatile resins are available in varnishes, adhesives, finishes, filling and impregnating compounds, laminated materials (boards, tubes, wrappings and sheets), moulding powders, and cast-resin products. The principal resins (Bakelite) are made by reacting phenolic material with formaldehyde. The final polymerising ('curing') time, which vitally affects the use, varies at 150°C from a few seconds to an hour or more. The resins are normally solids of softening point between 60 and 100°C. They are readily soluble in methylated spirit for coating papers, fabrics, etc., in the manufacture of laminates. Varieties are suitable for pouring molten into moulds followed by polymerisation. The most extensive use is as moulding powders with fillers (wood flour, powdered mica, fibres and colourings) to give mechanical strength and suitable electrical properties.

*Phenol furfural* is produced by the reaction of phenol with furfural, an aldehyde obtained by acid treatment of

bran and fibrous farm waste. It is suitable for injection moulding.

*Urea formaldehyde* The main use is as the binder of cellulose, wood flour or mineral powder in mouldings, made by compression at 115–160°C. Mouldings can be delicately coloured.

*Melamine formaldehyde* Its properties are superior to those of the urea formaldehydes. It is suitable for mouldings for ignition equipment and has good resistance to tracking.

*Silicones* These are organic compounds of silicon. By variation of the basic silicon-oxygen structure and of the attached organic groups, many different products can be made, including fluids, resins, elastomers and greases. Their main properties are water repellency (their hydrophobicity makes them a better choice for outdoor high voltage insulation), stability to heat, cold and oxidation, and good electrical properties maintained up to 200°C and higher. Some silicones can work continuously at 200°C and intermittently to 300°C: they can be applied to insulation in classes F, H and C. Silicone resins are used for bonding mica, asbestos and glass-fibre textiles and for producing compounds, varnishes, micanite, wire coverings, etc.

A number of silicone compounds can be used for filling and sealing where heat and moisture resistance are required. One such, of the consistency of petroleum jelly, is of use as a waterproof seal in high-voltage ignition systems: it protects cable insulation from moisture, oxidation and electrical discharges.

*Polyesters* Alkyd resins are more rubbery than phenolic resins, have good adhesion and do not readily track; they are therefore of use for finishes and for varnishing glass fibre and similar material to produce heat-resisting varnished cloths. *Unsaturated polyesters* are useful for casting and potting, as solventless varnishes, and in the manufacture of laminates with glass fabric or mineral fillers.

*Epoxyes* The epoxy resins have become important as casting, potting, laminating, adhesive and solventless varnish agents. They have good electrical properties and resistance to heat, moisture and tracking, and adhere well to metal parts. They have been applied for high-voltage insulation in switchgear and for casting, in which case they are often mixed with mineral fillers. Earlier epoxy resins showed damage when subjected to severe weather and to high electric stress on creepage surfaces. New types have been based on cycloaliphatic resins which, because of the different molecular structure, produce less carbon during the passage of surface discharges and leakage currents under polluted conditions. Further improvements have been made in this application by using specially selected and treated mineral fillers which also reduce the effects of weathering and surface tracking. These products have many uses on high voltage outdoor equipment.

*Polyurethanes, isocyanates* These are used mainly for coating fabrics (such as glass- and polyethylene-terephthalate fibre) to produce heat-resisting flexible sheet insulation and for coating wires.

*Polyimides* These have been specially developed for use at high temperature as mouldings, films, wire enamels and laminate bondings. The materials can be used continuously at temperatures in the 200–240°C region; and for very short

periods, they can withstand temperatures up to 500°C without apparent damage. Their mechanical and electrical properties are good and their resistance to most chemicals, solvents and nuclear radiation is excellent. *Polyamide imide* resins are similar to the polyimides and are available in the same forms. The performance at high temperatures is marginally lower but the resins are simpler to use in the manufacture of laminates, and have longer shelf-life.

*Polyaralkyl ether/phenols* These have a high-temperature performance not quite as good as that of the polyimides, but are cheaper. The resins can be used as bonds for glass and asbestos laminates and mineral filled moulding powders are available. A high proportion of room temperature strength is retained at temperatures up to 250–300°C and long-term operation at temperatures of 220–240°C is possible. Their resistance to most chemicals and solvents is excellent.

### 7.5.10 Encapsulation

When electronic or electrical components and circuits must resist the effects of climate, industrial atmospheres, shock or vibration they may be encapsulated. They are then generally known as 'potted circuits'.

Certain thermosetting synthetic resins are of the greatest use as they can be easily poured from low-viscosity liquids and made to set without the use of pressure and, in some instances, with very little heat. A suitable material must: (1) be a good insulator over a wide range of temperatures (volume resistivity say  $10^6 \Omega\text{-m}$ ); (2) polymerise or set without spitting off water or other products; (3) have low viscosity at pouring temperature, low vapour pressure, and freedom from deleterious side-effects on personnel who are using it; (4) show small shrinkage, especially when changing from the liquid to the solid state; and (5) must adhere to all materials commonly found in electrical equipments, e.g. to brass, solder, steel and insulating boards. Only the epoxy resins possess all the essential requirements for successful encapsulation and even these need an inorganic filler to obtain the best heat resistance, low shrinkage, good electrical properties and high thermal conductivity.

The epoxide resins of use in potted circuits are derived from a condensation reaction between epichlorhydrin and bisphenol A. They are cross-linked with aliphatic or aromatic amines, acid anhydrides and a few other chemical compounds to give thermally, electrically and mechanically stable resins. The addition of inorganic fillers improves them and reduces their shrinkage, tendency to crack at low temperatures and cost. The mixture of resin and cross-linking agent (known as a hardener) is called a system. An accelerator may be added, as well as various diluents, both reactive and non-reactive. Accelerators and promoters alter the speed of reaction and the pot life.

Typical potting formulations, in parts by weight, are:

- (A) resin 100, hardener 10, mica flour filler, 15; and
- (B) resin 100, hardener 82, quartz flour filler 375, accelerator 1.

Formulation A is satisfactory for small units of about 0.1 kg of mixture. It sets at room temperature, but is post-cured at an elevated temperature dependent on the heat resistance of the included components; 18 h at 65°C is usually satisfactory. Such a unit is suitable for small electronic packages containing small components, including semiconductors. Larger masses, depending on their geometry, may exhibit a strong exotherm (i.e. generate heat) which may damage the included components.

Formulation B is used hot (usually at about 65°C) and is very fluid at this temperature besides possessing a long pot life. This makes it suitable for the potting of transformers. Vacuum impregnation is essential to eliminate voids, which would result in ionisation and corona discharges. The large amount of filler greatly improves the thermal and mechanical properties and allows a larger casting to be produced without a high exotherm. Again, a post-curing cycle is essential to bring out the best properties; in this case about 18 h at 120°C is satisfactory and will produce a material with high volume resistivity and heat resistance. The pot life of this mixture is about two hours at 65°C, which may be compared with formulation A whose pot life is less than half an hour at room temperature.

In use the resin and dried filler of A are mixed together and stored under vacuum or in a desiccator until used. The hardener is added and thoroughly mixed just before pouring into the mould or other article to be potted. It stands at room temperature to set or 'gel' and is subsequently post-cured; this latter process may be carried out after removal from the mould if required.

For formulation B the resin, hardener and dried filler are all mixed and stored as before, and the accelerator is added to the mixture just before use and heated to 65°C. It is poured into the mould or other article. For transformers this is usually done under a vacuum of about 1 mmHg to 1 cmHg. Although a large amount of inorganic filler is used, this is filtered to some extent by the windings of the transformer so that the insulation between turns is mostly of unfilled resin, giving high breakdown strength and freedom from corona discharges. Good adhesion at the terminals is ensured by the nature of the resin system, but this also means that it sticks to the mould unless a release agent is used. Various preparations are used, including mixtures of high polymers, silicones, greases and waxes. The agent must be confined to the mould and not allowed to contaminate the components inside the casting.

The requirements of low shrinkage and low exotherm have been stated. The effect of the former is to damage components by compressional forces and is particularly severe on some nickel-iron alloys used in making inductors; thin-film resistors and capacitors are also vulnerable to this form of damage. Isolating the components from the resin by means of low modulus materials can appreciably reduce this defect. The heat of reaction (exotherm) is also damaging to organic materials and to semiconductors; this often results in a loss of volatile matter causing shrinkage and the effects already noted above.

All adhesives contain polar bonds in their molecular structure. These give rise to changes in dielectric properties as the frequency and temperature varies, causing the electrical behaviour of the components inside the casting to change as the frequency and temperature changes.

Another disadvantage of potted circuits is that they are irreparable: they must be designed as 'throw away' subunits and made at an economical price. For this reason they are rarely used in domestic applications such as radio or television, but are of particular use in military electronics, for machine control and similar purposes where the utmost reliability is essential and first costs are relatively unimportant.

## 7.6 Varnishes, enamels, paints and lacquers

Numerous liquid materials, which form solid films, are used extensively in the manufacture of insulating materials and for protecting windings, etc.

### 7.6.1 Air-drying varnishes, paints, etc.

One class of air-drying varnishes and lacquers consists of plain solutions of shellac, gums, cellulose derivatives or resins which dry (e.g. in 5–30 min) and deposit films by evaporation of the solvent. Other air-drying varnishes and paints form films which harden by evaporation of solvent accompanied by oxidation, polymerisation, or other chemical changes which harden and toughen the film. These processes take several hours.

### 7.6.2 Baking varnishes and enamels

Where the toughest and most resistant coatings are required, baking varnishes and enamels are used, the evaporation of solvents and hardening of the material being effected by the application of heat. Typical varnishes of this class require baking at, say 90–110°C in a ventilated oven for 1–8 h. During the baking (or 'stoving') the hardening is usually caused by oxidation, but in some cases polymerisation takes place. The latter process does not require oxygen and, provided that the solvents are first removed, drying can take place within the interior of coils. In consequence these varnishes are preferred to the oxidising types which skin over and leave liquid varnish underneath. Such thermosetting impregnating varnishes are used extensively for treating coils, and the windings of small machines and transformers.

### 7.6.3 Solventless varnishes

Thermosetting synthetic resins are used for impregnating windings and, owing to the manner of hardening during which little or no volatile matter is evolved, spaces in the interior of windings can be filled completely with non-porous resin. One type consists mainly of oil-modified phenolic resins, similar to the oleo-synthetic resinous varnishes but without solvents; they are consequently termed *solventless varnishes*. When used for impregnating they are in a hot liquid condition, the material solidifying within the winding by baking after impregnation.

Specially formulated low-viscosity resins of the polyester or epoxy type are also used for impregnation. It is possible to use solventless resins in conveyerised plants where the parts are dipped in the resin, allowed to drain and then passed through a heated tunnel to cure the resin. In other cases, particularly for tightly wound apparatus, the parts are treated in the resin using a vacuum-pressure process to ensure that a high level of impregnation is attained.

The most recent development in treating industrial machine windings is the 'trickle' process. The wound part is heated and mounted at a slight angle so that it can be rotated slowly about its axis. A metered quantity of the resin is allowed to trickle on to the winding and under the action of gravity and the rotational forces, the resin penetrates to all parts of the winding and completes the impregnation. It is possible to completely fill the interstices of the winding without loss of resin by draining. Radiant heat may be applied to complete the cure while the parts are rotating, or heating currents may be circulated through the winding. Trickle impregnation can be performed automatically and the process can be completed in a few minutes without removing the wound parts from the production line.

### 7.6.4 Silicone varnishes

Varnishes based on silicone resins are in general use. Some include other resins, etc., such as alkyd resins. Silicone

varnishes are used for impregnating and coating cloths, tapes, cords, sleeveings, papers, etc., made from glass fibres and polyethylene-terephthalate fibre; for bonding mica, glass cloths and papers, e.g. for slot insulation; for coating and bonding glass; for 'enamelling' wires for windings; and for all manner of impregnating, bonding, coating and finishing purposes such as the treatment of windings for classes B, F and H.

### 7.6.5 Properties of varnishes, etc.

The properties of the solid films formed after drying and hardening varnishes, paints, etc., naturally depend mainly on the principal basic materials, e.g. gums, resins and oxidising oils. Other materials added are: 'driers' to accelerate drying; 'plasticisers' to improve the flexibility; and pigments to provide the required colour and improve the hardness and filling capabilities.

Treatments of windings and insulation parts, by varnishes, enamels, lacquers or paints, take the form of (a) application of external coatings—chiefly for providing protection against moisture and oils, or (b) impregnation of windings and absorbent materials, for rendering them less susceptible to moisture and improving their electrical and heat-resisting properties. Both air drying and baking materials are used for (a), but only baking varnishes and enamels are suitable for (b). In practically all cases, thorough drying prior to application of the varnish is essential as for compound treatment, but with varnishes, extra care is required to remove excess varnish by proper draining and to extract solvents thoroughly before hardening the material by baking. This is usually done in well-ventilated ovens at temperatures of 80–150°C and sometimes by the application of vacuum for a period to assist the removal of solvent. These processes are not required when solventless varnishes are used. In the case of silicone varnishes, the solvents must be removed and baking must then be carried out at temperatures in the range 150–260°C.

Insulating varnishes are the subjects of BS 5629:1979, BS 7831:1995 and BS EN 60464:1999. Typical properties are listed in *Table 7.15*.

## 7.7 Solid dielectrics

The many solids that can be used for insulating purposes are considered in groups according to their form.

### 7.7.1 Breakdown in solids

The breakdown strength measured for a solid is very dependent on the time of application of the voltage. Strengths of 100 kV/mm to 1.5 MV/mm can be obtained for short pulses under carefully controlled laboratory conditions, but in practical insulation systems breakdown strengths of only about 20 kV/mm are obtained. The high laboratory value is known as the *intrinsic electric strength* of the material, with breakdown due to electronic processes. In practical insulation, however, breakdown is due to: erosion, thermal effects, electromechanical effects, or treeing.

*Discharge/Erosion breakdown* originates at internal voids in the insulation. These are left at the fabrication stage and all solids contain them, although in a high-quality material they will be very small (*microvoids*). These voids will be filled with air or another gas with a permittivity and dielectric strength much lower than that of the solid. Electric field enhancement in the micro-void takes place due to the relative permittivity difference in the two media. Consequently, the gas filling the void will break down at a voltage lower

than the normal breakdown strength of the material and this *partial discharge* will erode the solid at the ends of the spark on the surface of the void. These discharges will occur twice for every cycle of an alternating supply, so over a period thousands of millions of these discharges will occur in a cavity. The erosion effects of these discharges can eventually be sufficient to cause complete failure of the insulation. This is the primary reason why the insulation of a component may fail after a number of years in service.

*Thermal breakdown* is breakdown caused by internal heating in the insulation due to dielectric loss. Insulating materials are not perfect capacitors and they do have internal energy losses. The quality of the insulation is often measured in terms of how small these losses are, with the *loss factor*  $\tan \delta$ , where  $(90-\delta)$  is the phase angle between the voltage and current for a sample of the material, commonly used as the parameter to assess the losses. This energy dissipated within the insulation will cause heating and electrical insulation is usually a poor thermal conductor, so a significant temperature rise in the insulation will be produced. In some circumstances the internal losses may increase as the temperature increases and a thermal runaway situation results. The temperature of the material will rise, losses will increase and the temperature will rise further until the material fails. Thermal breakdown is most likely to occur in power cables operated beyond their power rating, polymers operating near their softening points or in high-frequency applications.

*Electromechanical breakdown* results from the mechanical forces that an applied electric field produces. This force will

reverse for every cycle of the applied voltage and can produce cracks or other damage in solid insulation.

There are two types of *treeing breakdown*. The first type originates at sharp points on electrodes which act as the root of fine branching channels that propagate through the insulation. Over a period of time these fine channels gradually extend towards the other electrode until complete failure of the insulation occurs. This is another mechanism which can produce failure after equipment has been in service for months or years. The second type of treeing is known as *water treeing* and only occurs when there is water in contact with the surface of the insulation. Microscopic damage to the insulation gradually spreads out from a high-field region until failure of the material occurs. A major difference between this type of treeing and the previous one is that the damage cannot be seen once the material has dried out.

## 7.7.2 Rigid boards and sheets

### 7.7.2.1 Panels and simple machined parts

*Asbestos-cement boards* (3–100 mm) are incombustible and arc-resistant, and are used as barriers and arc-chutes. *Glass-bonded mica*, in sheets 0.5 m × 0.4 m of thickness 3–30 mm, are especially good for high-frequency, high-voltage and high-temperature (400°C) application. *Micanite*, mica splittings bonded with shellac or synthetic resins, in thicknesses

as phenolic resins or casein. In the USA, pressboards are available with special treatments which are claimed to permit operation at higher temperatures than untreated materials. In one case the material is treated with an amine; in another the cellulose molecule is modified chemically by cyanoethylation.

#### 7.7.2.2 Pressboard

This is a paper product, widely used in oil-immersed transformers in thicknesses up to 10 mm. Thicker boards are built up by bonding plies together with adhesives such

### 7.7.2.3 Laminates

These are sheets of paper, fabric, etc., bonded with gums, shellac or synthetic resins under heat and pressure usually in hydraulic presses. Resins can be phenol formaldehyde, melamine formaldehyde, polyester, epoxy, silicone, polyimide, polyamide imide, etc. These are some of the most useful insulating materials for panels, terminal boards, coil flanges, packings, cleats, slot wedges and many other uses. The principal varieties are: *synthetic resin bonded paper* in thicknesses of 0.2–50 mm in several grades. *Synthetic resin bonded cotton fabric* (0.2–100 mm), the most common being bonded with phenolic resin, but an epoxy bonded type has been developed: both are tough and have good machinability.

Curves for water absorption for some types of s.r.b. paper and cotton fabric are given in Figure 7.4. *Synthetic resin bonded asbestos* paper, fabric and felt, used for low-voltage work at somewhat higher temperatures, e.g. 130–150°C. *Synthetic resin bonded glass fibre*, bonded under heat and pressure with synthetic resins of the melamine, epoxy, phenolic, polyester and silicone types in the thickness range up to 12.7 mm. Most of these materials have good electrical and mechanical properties and low water

**Figure 7.4** Water absorption of typical synthetic resin bonded paper and fabric boards: (a) type I; (b) type II; (c) type III; (d) type IIIA

absorption (see Table 7.17). Similar materials are available where the reinforcement is a web of random laid glass fibres—known as mat. These materials are generally cheaper than those based on fabrics, although some of the properties are not as good. By arranging for a preponderance of the fibres to be in one direction, it is possible to produce boards with very good mechanical properties in certain planes. Such boards bonded with epoxy resins can have flexural strengths as high as 1300 MN/m<sup>2</sup> and flexural moduli approaching 5 GN/m<sup>2</sup>.

In addition to the resins mentioned, high-temperature materials are now available which are thoroughly suitable for use with all forms of glass and other reinforcement. Some of these materials give thermal lives as good as the silicones but with mechanical properties more nearly equal to the epoxies. Typical materials in this class are resins based on acrylics, polyimides, polyamide imides and combinations of polyalkyl ether with phenols, etc. Also, resins are now available for all types of laminate especially phenolic, epoxy and polyester where, in order to decrease the fire risk, the resin has flame-retardant properties (see Table 7.18).

Synthetic resin bonded (SRB) laminates of various types are made with a thin layer of copper (or other metals such as nickel and cupronickel) bonded to one or both surfaces. These materials are known as metal clad (or specifically copper clad) laminates and are used for printed circuit board applications.

A material in rigid form is produced by bonding high-density polyamide paper plies by heat and pressure only to give a tough, strong board with a long life at temperatures up to 220°C.

Other materials from the wide range of plastics are available as rigid boards or sheets although most of these materials are thermoplastic. Often such materials are moulded to produce finished products but it is possible to cut shapes and panels from sheets. Typical materials are based on polyvinyl chloride, acrylonitrile-butadiene-styrene, polyolefin, polymethylmethacrylate, etc. Many are flame-retardant or self-extinguishing; and reinforcing materials such as glass and asbestos fibres, glass spheres and mineral fillers can be added to improve mechanical properties and resistance to high temperatures. The well-known material ebonite, a mineral-filled rubber-based material, was a forerunner of this class.

The properties of typical sheets and boards are given in Table 7.19.

### 7.7.3 Tubes and cylinders

Tubes and cylinders can be produced by several methods. Materials capable of being moulded can be treated by compression or casting techniques. Many plastics can be extruded. Vulcanised fibre tubes are wound from paper treated with zinc chloride solutions. Laminated materials are generally wound on special machines with heated rollers

while tension and pressure are applied to consolidate the layers. In this way SRB paper and fabric tubes and cylinders can be produced by rolling the treated material convolutely on heated mandrels. Some of the smaller tubes are moulded in a split mould while still on the mandrel. Cylinders (considered as tubes with internal diameters above 76 mm) are made by similar techniques. These tubes which are generally for use in large transformers may have diameters as high as 2 m and lengths of 4 m. SRB cotton fabric tubes and cylinders are produced by similar methods; SRB glass-fibre tubes and cylinders can be rolled from most of the rigid-board materials.

Pressboard tubes and cylinders (mainly for oil-immersed transformers) are produced by winding presspaper on mandrels under tension, applying adhesives resistant to transformer oil (gum arabic, casein, phenolic resins, etc.). Tubes previously rolled from shellac bonded micanite for high voltage use are now widely superseded by tubes rolled from mica paper bonded with epoxy or silicone resins.

In addition to the convolutely wound tubes, a wide range of products can be produced by helical winding of strips (papers, fabrics, film, etc.), adhesives being applied meanwhile. The edges of the strip are generally butted together and this technique makes it possible to produce tubes the length of which is limited only by the requirements of transport.

Yet another method of winding tubes, chiefly with glass fibres, is known as filament winding. Strands of resin treated glass fibre are applied to mandrels in special winding machines. Restrictions on shape are less stringent, and very good mechanical properties are obtained.

#### 7.7.4 Flexible sheets, strips and tapes

In very many applications a certain amount of flexibility is necessary, mainly to enable the materials to be readily applied to conductors, coils and various shapes, often irregular. The following are the principal flexible insulating materials, used for such purposes as wrappings on conductors and connections of machines and transformers,

bus-bars and other parts; interlayer and connection insulation of coils; and slot linings of armatures.

##### 7.7.4.1 Micanite

Tapes and sheets of micanite (micafolium) are widely used for high-voltage and high-temperature machine windings. It consists of mica splittings bonded with gum, bitumen or synthetic adhesive, often backed with thin paper or fabric (especially glass fibre) to assist taping and to give mechanical support for micanite slot liners and coil insulation. Synthetic bonds, especially epoxies and silicones, are used for the higher temperature applications, i.e. for classes B, F and H. Similar sheet and tape materials are made from mica-paper produced by a paper-making process using minute particles of mica, the sheet being treated subsequently with shellac or synthetic resins; these mica-paper products are like micanite but are more adaptable and uniform.

##### 7.7.4.2 Vulcanised fibre and presspaper

These are useful flexible materials for coils, slot liners and many uses in machines, transformers and other apparatus.

##### 7.7.4.3 Papers

Chiefly made from wood pulp, cotton or manila fibres, these are employed in capacitor and cable manufacture, as insulations in coils and in the manufacture of SRB paper boards, tubes and bushings, also as backing material for flexible micanite products. Asbestos paper had uses for high-temperature conditions.

Papers are produced from other bases, such as ceramic, silica and glass fibre. A polyamide paper will not melt or support combustion, and has good electrical and mechanical properties; as with most cellulose papers it can be supplied in creped form to facilitate the taping of irregular forms, and it can be obtained in combination with mica platelets to give greater resistance to high-voltage discharges. Papers made

from polyester fibres are used normally in combination with materials such as polyester film.

Properties of some flexible sheets are given in *Table 7.20*.

#### 7.7.4.4 Fabrics

Cotton, nylon and polyethylene terephthalate (PETP) cloths are used mostly as bases for varnished fabrics for small coils where flexible dielectrics 0.1–0.25 mm thick are wanted. Woven asbestos and glass-fibre cloths are applied where temperatures are too high for organic textiles. The introduction of PETP fabrics with heat-resisting (e.g. alkyd and polyurethane) varnishes has provided a range for class E or even class B insulation. Varnished glass-fibre cloths and tapes—for which special coating materials have been formulated, including silicone resins and elastomers—are able to meet most of the high-temperature requirements of classes B, F and H apparatus. Fabrics of polyamide fibre can be coated with high-temperature resins and elastomers to give a material suitable for use at temperatures above 200°C.

*Table 7.21* gives some typical properties.

#### 7.7.4.5 Tapes

Pressure-sensitive adhesive tapes are used in the construction of all types of equipment and are invaluable for holding and positioning conductors, preventing relative movement, identification of parts, exclusion of moisture, etc. Many types of such material are available based on most of the papers, fabrics, films and metal foils together with adhesives which can be thermoplastic or can be made to cure on the application of heat. Extra care has to be taken to reduce corrosiveness since these tapes are often used in fine-wire coils where electrolysis can cause erosion of a conductor.

#### 7.7.4.6 Films

Many plastic materials are available in film form and many are used for the production of composite materials. Films with thicknesses of about 0.008 mm up to about 0.5 mm are

usual. Most are strong, have good electrical properties and good resistance to moisture, but some have certain limitations in operating temperature. The thermoplastics often soften or melt at comparatively low temperatures and some films which melt at very high temperatures are damaged by oxidation processes at much lower temperatures.

*Cellulose acetate, triacetate and similar acetates* These films have been available for a long time and still find use in machines and in coils at temperatures up to class Y conditions.

*FEP* This copolymer of tetrafluoroethylene and hexafluoropropylene (which is hardly affected by any known chemicals and solvents) has a service temperature range from about –250°C up to more than 200°C. It can be bonded to itself and to other materials by heat and pressure and has excellent high-frequency characteristics.

*PTFE and PTFCE* Polytetrafluoroethylene and polytrifluorochloroethylene have excellent chemical stability and electrical properties. The former material does not soften, but degrades above 300°C; the latter is thermoplastic at high temperatures. Both materials suffer from flow at high pressures even at moderate temperatures. Operating temperatures are otherwise similar to those given for FEP above.

*PVF and PVF2* Polyvinyl fluoride and polyvinylidene fluoride are produced by substituting fluorine for some of the chlorine in PVC. Both have the excellent temperature and chemical stability shown by fluorine substituted materials. Electrical properties are not as good as those of PTFE and FEP.

*Polyethylene* This is not widely used as electrical insulation, mainly because of the low softening temperature. Controlled radiation with high-energy electrons produces a film which has similar properties to the original film but because cross-linking has occurred, there is no sharp melting point. This enables the material to be used at higher

† R.m.s.

temperatures without damage; also, with this treatment, the material can be made heat shrinkable.

**Polyethylene terephthalate** These films are widely used for slot insulation in motors, as the dielectric in capacitors, for coils, etc. For slot insulation the film is frequently combined with polyester fibre paper but may be used alone in smaller equipments. It is suitable for class E temperatures although some manufacturers claim it can be used at class B temperatures. When protected from oxygen by films or varnishes with higher temperature resistance, some users claim temperatures up to class F are suitable for this material.

**Polyamide (nylon)** Films show moisture absorption in humid atmospheres, but are strong, solvent resistant and have a high melting point; they cannot be used at temperatures exceeding 80°C in air because of oxidation.

**Polycarbonate** The film is strong, flexible and highly stable against temperatures up to 130°C. Electrical properties are excellent and the film is finding use as a capacitor dielectric.

**Polypropylene** This dielectric film has a higher softening point than polyethylene film and the dielectric properties are similar. The material is resistant to hot mineral oils and chlorinated polyphenols and is finding widespread use in low-voltage and power capacitors.

**Polyimide** An outstanding film of recent development. The material has no melting point and can withstand exposure at temperatures above 500°C for several minutes. Life at 250°C is over 10 years, and more than 10 h at 400°C. It remains flexible down to the temperature of liquid helium. The film is replacing glass and mica insulation in motors especially for traction. As thin layers can be obtained, considerable space saving (often as high as 50%) can be achieved. The film cannot be bonded easily, but can be supplied with a very thin layer of thermoplastic FEP on one

or both sides, and layers can be bonded at temperatures approaching 300°C.

**Polyvinyl chloride** These films have low water absorption and resist most chemicals and solvents. The high elongation makes it possible to apply tapes neatly and tightly over irregular shapes. This class of material is often used as a pressure-sensitive tape.

A summary of the properties of materials available in the form of thin film is given in Table 7.22.

**Silicone elastomers** Silicone rubbers or elastomers are a range of heat stable elastic silicone materials used for electrical insulation as sheet, tape, wire and cable coverings, extruded sleeveings and mouldings, unsupported, but more extensively as coated glass-fibre cloths, tapes and braided glass sleeveings. Such fabric tapes impregnated with a silicone elastomer are available straight or bias cut in thicknesses of 0.07–0.5 mm. Other fabric tapes, coated on one side with partially cured silicone elastomer, are used for taping bars and coils and the curing subsequently completed by baking. The cured taping forms a homogeneous coating having good resistance to moisture, discharges and heat, e.g. for continuous use at about 180°C and up to 250°C for short periods, and possessing high electric strength and low dielectric losses. Most grades of silicone rubbers remain flexible at temperatures down to –60°C and some can be used down to –90°C.

#### 7.7.4.7 Composite sheet insulations

These combine two or more materials, especially varnished cloth, presspapers, vulcanised fibre, plastic films bonded with special adhesives. Particularly widely used have been cellulose fibres combined with polyester or cellulose acetate film, polyester fibre paper combined with polyester film and various combinations of mica, varnished glass fabrics and polyester film. Among the newer developments are combinations of aromatic polyamide paper with polyimide film, giving a material suitable for use at temperatures above

220°C. Another combination is aromatic polyamide paper with polyester film, having good class B performance.

### 7.7.5 Sleeveings, flexible tubings and cords

Tubular sleeveings made of cotton, polyester, asbestos, glass, ceramic, quartz, silica, polyamide and other fibres supplied untreated in flat tubular form are suitable for low-voltage insulation of connections of coils, etc. Glass sleeveing given a high-temperature treatment before use has the fibres set in place, thus preventing unravelling during assembly. Varnishing of all these sleeveings during treatment of the coils is the usual practice.

Similar sleeveings may be varnished or treated with resins and polymers before use; these types are known as coated sleeveings. Most colours can be produced, thus helping in identification of circuits. The coating materials in general use for cotton and rayon sleeveings are natural or synthetic varnishes. For glass fibres, high-temperature polyvinyl chlorides, polyurethanes and silicone elastomers are widely used as well as high-temperature varnishes such as those based on acrylics, polyesters, silicones or polyimide resins. Coatings of fluorinated resins on glass fibres are available.

Flexible tubings can be extruded from most of the materials mentioned in Section 7.7.4.6, but as many of these materials are thermoplastic and also liable to oxidation problems, care is required at temperatures above 90°C.

Other methods of making tubing are by helical winding with adhesives as a bond, when very thin walls (e.g. 0.025 mm) are required or only small quantities are needed. Many of the extruded tubings and some of the helix types can be caused to shrink by applying heat after the tubes have been assembled. Most shrinkage takes place in diameter but there is sometimes a small amount in length. These sleeves are useful for insulating connections and joints, for covering capacitors, resistors, diodes, etc., for colour coding, sealing and moisture proofing. The two

main shrinkage processes are: (1) thermoplastics stretched during manufacture, and allowed to cool so that the mechanical strains are frozen in, shrink next time the material is heated; and when certain materials are exposed to high-energy radiation, molecular cross-linking occurs, and they shrink when the temperature is subsequently raised.

Cords for lashing bundles of switchboard wiring, holding leads in position and for tying down coils in machines and transformers, may be made from yarns laid together and twisted or braided, or from narrow woven or slit tape. The trend is away from cellulose materials (linen and hemp) to synthetics, especially glass and polyester fibres. Because of the poor abrasion resistance of glass fibres, glass cords are often pretreated with epoxy or silicone resins or with various polymers. Normally the type of treatment depends on the application.

For high-voltage machines, a useful material is a round cord 3–5 mm diameter comprising a central core of straight polyester fibres surrounded by a braided polyester sheath. This material shrinks slightly on heating, and tightens. For smaller windings, polyester mat can be slit into tapes and several tapes twisted together. Polyester fibre cords of all kinds have the advantage over glass cords that knots can be made without appreciable loss in strength. Glass and polyester bands can be treated after application with varnishes and both have good resistance to abrasion and to mould growth. For rotors straight unidirectional glass-fibre bands pretreated with epoxy, polyester, or acrylic resins are used. These bands must be applied under controlled tension to ensure that the windings are held against centrifugal force. Such bands can be placed safely near voltage carrying parts and (unlike wire bands) are not affected by magnetic fields.

For switchboard wiring, cable harnesses, etc., neat lashings can be made with small-diameter extruded polyvinylchloride threads. These materials do not burn readily and are obviously well suited for use with PVC insulated switchboard wiring.

### 7.7.6 Wire coverings

Wires for coils and armature conductors are insulated with lappings of cotton, asbestos, glass fibre and polyamide fibre, all of which are hygroscopic and require treatment with oils, compounds or varnishes, usually after winding. Relevant specifications are BS 1497, 1933, 2479, 2480 and 2776. A recent addition to the range of wire and strip coverings is lapped polyimide film, bonded to itself and to the conductor with FEP polymer: the films are thin and flexible, electrically good and workable at 220°C.

Orthodox oleo-resin (BS 156) and polyvinyl formal and acetal enamels (BS 1844) are tough, resistant to abrasion and to softening by varnishes. Enamelled wires have a better space factor than those with fibre covering.

Some wires are covered in separate operations with synthetic enamels of widely differing characteristics, giving a range of finely balanced properties. The inner coat can be considered as the insulant; the outer coat can give improved resistance to solvents and abrasion, better cut-through resistance, heat-bonding of turns into a solid coil, etc. Wires coated with polyurethane polymers are useful because they can be soldered without first removing the enamel (BS 3188).

For high-temperature working, the performance of PTFE coverings is limited by cold flow of the insulant under mechanical pressure. Silicone resin gives a high-temperature covering but the solvent resistance and mechanical properties are not very good. Better mechanical characteristics are given by polyimide, polyamide imide, polyester imide and polyhydantoin, but these materials are still uncommon.

### 7.7.7 Moulded and formed compositions, plastics, ceramics, etc.

Articles of various shapes, often quite complicated, which cannot readily or economically be matched or built up from sheet, rod or tube materials may be obtained by forming, moulding, coating or casting one of the 'plastics' (which are all essentially organic), or a ceramic such as porcelain, or glass or other inorganic materials. The materials can be grouped approximately as follows.

*Organic thermoplastic* Examples are: compounds made of natural gums, bitumen, etc., not specially processed; synthetic resin products such as polyvinyl chloride, nylon, polystyrene; cellulose derivatives such as cellulose acetate.

*Organic thermosetting* These are, chiefly: cured shellac products including micanite (for simple shapes, e.g. commutator cones); rubber sulphur and similar vulcanisable compositions; compounds made from synthetic resins of the phenolformaldehyde type, urea formaldehyde, silicones, polyesters, alkyds, epoxies and polyurethanes.

*Inorganic* The principal materials are listed below.

- (1) *Asbestos-cement* compositions, mainly for high heat resistance, particularly for parts exposed to arcs;
- (2) *Concrete*, cast or moulded, for inductors and switchgear where strength and fire-resistance are needed;
- (3) *Porcelain*, mainly for out-door use and other cases where dust and moisture collect readily, also special grades for high temperatures;
- (4) *Steatite*, for uses similar to those of porcelain;
- (5) *Special ceramics* for radio capacitors, sparking plugs, etc.;
- (6) *Fire-clay* for holding electric heating elements;
- (7) *Glass* for out-door insulators, lamp bulbs, valves and high-frequency insulation;

- (8) *Mica-glass* composition for high-temperature applications requiring good electrical properties, especially at high frequency.

### 7.7.8 Methods of moulding and forming materials

#### 7.7.8.1 Organic materials

The principal methods of manufacturing parts from the organic materials are as follows.

*Forming* of laminated and other sheet materials in open moulds or other forming tools with moderate pressure, the material being made plastic by a suitable liquid or, more usually, by heat. Such forming is generally restricted to relatively simple shapes such as channels, cones, tubes, collars, spools and wrappings. Heat is usually applied during the forming operation, and the material sets either by cooling, heat-treatment in the mould, or subsequent drying, baking, etc. (e.g. vulcanisation).

*Moulding under pressure* in closed metal moulds ('compression moulding'), using a powder, dough, treated paper, treated fabric or other form of moulding material and heat treating during or subsequent to moulding.

*Injecting* material, made plastic by heat or other means, into moulds under pressure and setting by cooling, or heat processing.

*Extruding* plastic material as for injecting but not into moulds, the shape being determined by the orifice or die through which the material is extruded and the setting being generally due to cooling, but may be followed by a further process such as vulcanisation.

*Casting* a liquid or molten material into moulds (without pressure) and conversion to a solid condition by cooling or heating (thermosetting materials), or by the action of chemicals with or without heat.

*Coating* with polymers in powder form, spread on heated metal components by several methods including electrostatic fields or fluidised bed techniques. Thick coatings with good electrical properties can be applied overall. Conversion to the solid is by cooling with thermoplastic materials, or by further heat treatment for thermosetting materials. Some polymers can be applied to surfaces (which need not be metal) in the form of dispersions in a suitable liquid carrier, followed by curing by heating.

Properties of typical organic moulding compounds are listed in Table 7.23.

#### 7.7.8.2 Inorganic materials (ceramics, etc.)

The methods used for producing articles from the inorganic materials are, briefly, as follows.

*Asbestos-cement compounds* Made from asbestos and other minerals, e.g. powdered silica, mixed wet with lime or Portland cement and moulded *cold* by compression moulding. After removal from the mould the parts are cured in live steam.

*Concrete* The large mouldings for inductors are made of high-grade concrete, made from specially selected Portland cement, sand and aggregate, the wet mixture being poured and 'puddled' into suitable moulds and, after preliminary setting, the parts being cured in live steam.

*Porcelain* Made from china clay (*kaolin*), ball clay, quartz and felspar, finely powdered and mixed with water. Small parts (e.g. tumbler switch bases) are made by the *dry process*

(or *die pressing*), in which a slightly damp mixture is compressed in steel moulds. Many high-voltage parts, particularly large pieces such as transformer bushings, are made by the *wet process* from a wet plastic mixture, shaped on a potter's wheel and turned on a lathe. Others, such as overhead line insulators, are made by pouring a *creamy* mixture into plaster moulds in which partial drying occurs. Parts formed by the foregoing processes are then dried and usually coated with glaze, after which they are fired in a kiln at temperatures such as 1200–1400°C.

**Steatite** Consists of powder soapstone (talc) die pressed dry or moulded wet, similar to porcelain, and finally fired at about 1400°C.

**Special ceramics** A number of ceramics are made, similar to porcelain and steatite, from such materials as rutile (a form of titanium dioxide)—having low losses and high permittivity, and suitable for high-frequency capacitors—and aluminium oxide, mainly for sparking plugs. A ceramic composed of barium titanate has exceptionally high permittivity.

**Fire-clay refractory ceramics** Made from special grades of clay, usually die pressed and fired, somewhat as in the case of porcelain.

**Glass** Made from powdered silica mixed with metallic bases (soda or potash) and a flux (e.g. borax). The mixture is fused at temperatures of the order of 1200–1400°C, and

the molten mass 'blown' into moulds, or forced into moulds under pressure, the parts being removed when cool.

Developments have been made in which the glass instead of remaining in its usual super-cooled liquid state is devitrified, with the result that a fine-grain structure develops and the mechanical properties are much improved. These new materials are known as glass ceramics and can have specially controlled properties. In particular the coefficient of thermal expansion can be selected from high positive to negative values.

**Mica glass composition** Produced from powdered mica and glass, heated to a semi-molten condition and moulded in steel moulds by compression or injection at high pressure.

Properties of typical ceramics and other inorganic formed or moulded compositions are summarised in *Table 7.23*.

## 7.8 Composite solid/liquid dielectrics

Combinations of solids and liquids are widely used for electrical insulation. The solid normally consists of sheets of paper or of polymer film with an insulating liquid, typically a mineral oil, as the liquid component of the composite. Sometimes a synthetic oil is used instead of a mineral oil, especially when polymer films are used as the solid component. Particular applications of composite insulation are power cables, transformers, bushings and capacitors. The solid provides mechanical separation between the conductors and the liquid gives high electric strength with a low dielectric loss.

### 7.8.1 Breakdown mechanisms in composite dielectrics

The construction of composite dielectrics usually starts with the solid material in tape form that is wound around one of the conductors. Several layers of tape are used and there is a small gap between adjacent tapes, with the gaps staggered between layers (*Figure 7.5*).

The most widely used composite insulation system has the spaces between the tapes filled with a mobile insulating liquid. The system that is used in many power engineering applications such as transformers and oil-insulated switchgear is paper and mineral oil. The dielectric constant of paper and mineral oil is very similar, approximately 2.5, but very different from that of air. It follows that if there are air bubbles in the system there is a much higher electric field in the air bubbles than in the rest of the insulation. Bubbles may become trapped in the gaps between the tapes. The air in such bubbles will break down at a much lower applied voltage than the rest of the insulation, producing additional gas and eroding the solid insulation in contact with the bubble perimeter. This can eventually lead to breakdown of the complete insulation structure.

### 7.8.2 Oil/paper systems

This insulating system is excellent for high electric strength over long periods of time, provided the insulation is free from significant partial discharges. It is therefore essential

that gas bubbles are prevented from forming. This is done by applying a vacuum to the insulation to remove dissolved gas where this is possible, and in insulation systems such as high-voltage power cables by applying several atmospheres pressure to inhibit bubble formation.

In laboratory-scale tests it was found that increasing the pressure of the oil from one atmosphere to 14 atm increased the electric stress that could be applied before partial discharges could be detected from 47 kV/mm to 69 kV/mm, or from 60 kV/mm to 90 kV/mm when a thicker oil was used. There is always a problem in relating the results of laboratory investigations to the design of practical apparatus because of the reduction in strength obtained as the volume of the insulation increases. In extreme cases the breakdown strength may be halved by two orders of magnitude increase in volume under stress.

In a series of tests on samples of oil/paper insulation of reasonable size the 50 Hz strength always exceeded 40 kV/mm and the 1/50  $\mu$ s impulse strength was always greater than 90 kV/mm. The presence of moisture in the paper will give a 40% reduction in breakdown strength when the moisture content is increased from zero to 8%. The impulse strength of oil-impregnated paper increases as the thickness of the paper tapes decreases. In one set of tests the impulse strength was 130 kV/mm for 0.13 mm thick tapes and 160 kV/mm for 0.03 mm thick tapes.

The proven long-life-times of oil/paper systems mean that this insulation is the normal choice for insulating power transformers, cables and power-factor-correction capacitors.

## 7.9 Irradiation effects

Electrical equipment is being used increasingly in situations where it will be exposed to the effects of nuclear and other types of radiation, often at high energy levels. Such radiation can change the characteristics of many materials and may cause severe deterioration; on the other hand, radiation can have beneficial effects, especially by causing synthetic polymers to cross-link. Particular cases are the irradiation of polyethylene and other thermoplastic materials giving new products with improved properties, especially resistance to heat and mechanical failure; the vulcanisation of rubber; the polymerisation of plastics; the curing of resin and varnish films and the manufacture of heat-shrinkable films and sleeveings.

### 7.9.1 Type of radiation

The more common forms of radiation encountered are: neutron and  $\gamma$  from nuclear reactors, neutron and  $\gamma$  from isotopes and electrons and X-rays from particle accelerators. The unit of absorbed radiation is the rad ( $=400$  erg/g) or the megarad ( $=40^8$  erg/g of material). The megarad is equivalent to 10 kJ/kg.

Although the effects of radiation on materials are cumulative and, therefore, dependent on the total dose, the dose rate (generally expressed as megarads per hour) may have some further effect. This point must be considered when experimental work is being carried out. Fortunately, it has been found that changes in most materials due to irradiation are practically independent of the type of radiation encountered. Hence, various sources of irradiation may be used for experimental work and those normally employed are:

- (1) 'hot' fuel elements and other parts of nuclear reactors;
- (2) radioactive isotopes (e.g. cobalt 60);

**Figure 7.5** Tape arrangement for composite insulation

Polyisobutylene	20		

- (3) Van de Graaf electron accelerator; and  
 (4) microwave linear electron accelerator.

The most convenient is the linear accelerator, in which a small-diameter beam can be made to scan the parts to be irradiated with uniformity of dosage. The physical conditions—temperature, ambient atmosphere (air, carbon dioxide, nitrogen, etc.), and humidity—must be carefully selected and controlled.

## 7.9.2 Irradiation effects

The effects of radiation are usually assessed in the first place by visual examination, as many materials discolour, crack, disintegrate or melt, while flexible or soft materials may become hard and brittle.

More advanced work relies on the determination of changes in measured properties after certain periods of irradiation. Results of tests on unirradiated samples are compared with those on similar samples after subjection to known energies for different times. Non-destructive tests (loss tangent, permittivity, resistivity, changes in weight and changes in dimensions) are particularly useful because they can be repeated on the same specimen as a function of the total dose. Other tests used to determine the effects of irradiation are electric strength; tensile, shear and impact strength; elongation; hardness; flexibility; and water absorption.

In general, organic insulating materials deteriorate mechanically and electrically as the result of irradiation, the mechanical properties usually being impaired at a greater rate than electrical ones. These results are mainly due to chemical changes which occur in the materials consequent upon certain rearrangements of their molecular structure, usually with the evolution of one or more gases, such as methane, carbon monoxide, carbon dioxide or

hydrogen. The probable life-dose for typical insulating materials is given in *Table 7.24*. The dose figure is that at which marked deterioration is observable, there is a 50% reduction in mechanical and electric strength, or some similar factor. The life-dose is approximate: it depends on the actual formulation of the material and irradiation conditions such as dose-rate and ambients.

### 7.9.2.1 Gases

The spark-gap breakdown voltage of air is reduced by about 20% under intense nuclear radiation. A gas having good radiation stability is sulphur hexafluoride (SF<sub>6</sub>), whereas halogenated hydrocarbons slowly polymerise with evolution of corrosive products, and other gases, such as perfluoropropylene, polymerise rapidly to form liquids when irradiated.

### 7.9.2.2 Liquids

The viscosity of hydrocarbon oils increases and most liquid dielectrics polymerise when irradiated, the electrical properties being lowered considerably. Gases are usually evolved by liquids during irradiation and can create difficulties due to increase of pressure in containers of capacitors, transformers, etc. Silicone oils polymerise to form elastomers, those of high molecular weight yielding elastomers of low tensile strength, but the solids produced from the low molecular weight (e.g. 300–20 000) oils crumble on handling.

### 7.9.2.3 Semi-fluid and fusible materials

Silicone compounds made from fluids with mineral fillers react to irradiation in the same manner as the fluids; they rapidly harden and then gel. Petroleum greases are affected

similarly. Dimethyl silicone fluids of low viscosity are to be preferred for use where doses do not exceed about 100 Mrad.

#### 7.9.2.4 Organic solids

Most of the organic solid insulating materials in general use are synthetic resins or are based upon such resins and similar plastics. The performance of the materials in the form in which they are used under irradiation conditions depends largely upon the resistance of the basic materials to the effects of radiation. Cellulose derivatives, such as cellulose acetate, have poor resistance, mechanical deterioration being rapid; hence lacquers, adhesives and moulded or extruded parts made from them also deteriorate rapidly under irradiation. On the other hand, diphenyl silicone and products made from this resin, have relatively good resistance. The combination of mineral materials, whether as powdered or fibrous fillers or as sheet reinforcement (e.g. woven glass cloth), with the organic base materials usually results in products having superior radiation resistance.

#### 7.9.2.5 Synthetic resins: thermoplastic

Of the thermoplastic synthetic resins *polystyrene* is one of the most stable. Styrene copolymers are generally poorer in resistance to effects of radiation, and high-impact-strength polystyrene loses some of its impact strength when irradiated. A good deal of work has been done on the effects of irradiating *polyethylene*, the principal change being the elimination of its melting point due to cross-linkage: this can be beneficial. Some increase in tensile strength occurs at first but, with continued irradiation at high dosages, the tensile strength decreases and the material ultimately becomes brittle and cheesy. The high-density varieties are slightly better. *Nylon* behaves somewhat similarly when irradiated, cross-linkage occurring with consequent increase in tensile strength in the case of sheet, but rapid reduction of strength occurs in nylon fibres, with decrease of elongation and impact strength.

Of the *vinyl polymers* and *copolymers*, polyvinyl carbazole has good resistance to radiation; *polyvinyl chloride* (PVC) has radiation resistance equivalent to that of polyethylene but liberates hydrogen chloride when irradiated; *vinyl chloride acetate* has a lower radiation resistance than PVC, softening and turning black at low dosages.

Irradiation of *polyethylene terephthalate* in fibrous form causes rapid loss in strength, and the films become brittle and darken. *Cellulose plastics* such as cellulose acetate deteriorate mechanically to a serious extent by low dosages, but electrical properties of the latter are not appreciably affected. *Acrylic resins* also have comparatively low radiation resistance.

The thermoplastic resins most seriously affected by radiation are the fluorooethylene polymers such as polytetrafluoroethylene and *monochlorotrifluoroethylene*, the latter being superior. Decrease of tensile strength and elongation of these is rapid and they become very brittle with only moderate dosages.

#### 7.9.2.6 Synthetic resins: thermosetting

Of the amino resins, the *melamine formaldehyde* type is slightly superior to the *urea formaldehyde*, but with cellulose fillers both deteriorate rapidly and become brittle when irradiated. The radiation resistance of *epoxy* resins is above the average for plastics but it depends largely on the hardener

used. *Epoxyphenolic* resins are better than ordinary epoxies and phenolics for radiation resistance. *Phenolic* and *polyester* resins without fillers have low resistance but this is increased considerably by the addition of fillers, especially minerals such as asbestos.

*Silicone resins* are more resistant to radiation than silicone fluids and elastomers and do not rapidly deteriorate physically, the major electrical properties of most resins being maintained even after subjection to high dosage.

#### 7.9.2.7 Solid materials: inorganic

In general, inorganic materials are much more resistant than organic materials to irradiation. The principal effects are to cause colour changes and to induce conductivity in glasses, ceramics, fused silica and mica, followed by disintegration of natural mica irradiated by high dosages at elevated temperatures (e.g. 150°C). Synthetic mica seems to be more resistant than the natural form to mechanical and electrical degradation. Built-up mica products made from flake mica or reconstituted mica paper are affected according to the bonding medium—which is usually organic. Wires insulated with swaged magnesium oxide have shown high resistance to radiation at a temperature of 815°C.

## 7.10 Fundamentals of dielectric theory

### 7.10.1 Basic definitions

An *ideal dielectric* is a material or medium which has no free electrons so that no conduction can take place. It is an ideal insulator. Electrically it can be represented as a pure capacitor

*Real dielectrics*, however, have some free electrons but much less compared with conductors. Their equivalent circuit can be represented by an RC parallel circuit.

Dielectrics have two main electrical applications:

- Insulation*: to isolate live conductors or conductors of different potentials.
- Energy storage*: some dielectrics can store large amounts of energy when an electric field is applied to them.

### 7.10.2 Types of dielectrics

Dielectrics can have three forms: gas, liquid and solid.

In *gases*, the atoms/molecules do not interact but can contain free electrons which are responsible for the conduction process. Conduction mechanisms due to positive and negative ions as well as charged molecules are also found in some gases.

In *liquids dielectrics*, there is some interaction between molecules, and they are also known to contain impurities in real applications. This makes the conduction process essentially ionic in nature with the addition of contributions due to charged particles.

*Solid dielectrics* have more complex conduction mechanisms (such as thermal, tunnelling, hopping) governed by free electrons, holes and ions.

Solid dielectrics can be either:

- Glasses*: are amorphous materials which have no three dimensional atomic ordering over distances greater than 2 nm (atoms are tenths of nm across).
- Crystals*: these have long range ordering which could lead to a single crystal if the ordering is consistent throughout the solid material.

Figure 7.6 Electronic polarisation

In general, no solid or liquid is completely structureless. Ionic solids do not form glasses but covalent solids form glasses (e.g. polymers) e.g. MgO is an ionic solid (non glass) and SiO<sub>2</sub> is a covalent solid (glass).

### 7.10.3 Polarisation in dielectrics

When an insulating material is subjected to an electric field, a limited displacement of charge takes place at the atomic, molecular and bulk material levels. This charge displacement is known as polarisation.

- Electronic polarisation:** in atoms, positive ions are surrounded by electron clouds. Since the electrons are very light, they respond rapidly to the action of an applied electric field. Figure 7.6 shows a schematic of an atom being polarised due to the action of the field  $E_0$ .
- Molecular polarisation:** within a molecule, the ionic bond is deformed when an electric field is applied resulting in increase of the dipole moment of the lattice:

Molecular polarisation can be:

- Simple ionic** where a simple separation of centre takes place.
  - Distorted ionic** takes place when large ions are distorted by other close ions in addition to the simple ionic polarisation.
- (c) **Orientational polarisation:** in liquids and gases, whole molecules move into line with the acting electric field. Under weak static fields, the alignment is usually not complete. In solids, interfacial polarisation occurs at electrodes and at crystallites interfaces. In addition, in

the presence of an interface with materials of different electrical properties (permittivity and conductivity), space charge polarisation occurs. Figure 7.7 shows the various scenarios of orientational polarisation.

### 7.10.4 Quantification of dielectric polarisation

For a vacuum-filled parallel-plate capacitor, the surface charge density  $Q_0$  is defined as  $Q_0 = \epsilon_0 V/d$  where  $V$  is the applied voltage,  $d$  the separation distance between plates, and  $\epsilon_0$  relative permittivity of free space ( $\epsilon_0 = 8.854 \text{ pF/m}$ ).

If the vacuum insulating medium is replaced by a dielectric material of relative permittivity  $\epsilon_r$ , the new surface charge density will be  $Q_{ds} = \epsilon_r \epsilon_0 V/d$ .

Thus, resulting in an increase of surface density  $\Delta Q_s = Q_{ds} - Q_0 = (\epsilon_r - 1) \epsilon_0 V/d$ .

This quantity is known as the dielectric polarisation  $P$ . In this case, the expression can be written as  $P = (\epsilon_r - 1) \epsilon_0 V/d = (\epsilon_r - 1) \epsilon_0 E = D_d - D_0$ .

With  $D_d$  is the electric flux density in the dielectric case.

$D_0$  is the electric flux density in the vacuum case.

### 7.10.5 Properties of dielectric materials

Dielectrics can be grouped according to their structure and the way they react to the action of an electric field.

- Non-polar dielectrics:** These consist of molecules that do not possess a permanent dipole moment, they are known as simple dielectrics. When an electric field is applied to simple dielectrics, it induces dipoles and orients them in the direction of the field.
- Polar dielectrics:** If a material has molecules with permanent electric dipole moments, in the absence of an external electric field, then it is called a polar dielectric e.g. Water and NaCl. Within these materials, the individual molecular dipoles are usually randomly oriented due to thermal agitation. The application of an external electric field will result in the alignment of the individual dipoles in the direction of the field. In general, polar dielectrics

Figure 7.7 Orientational polarisation cases

**Table 7.25** Examples of polar and non-polar dielectrics

Dielectric type	Examples	Relative permittivity
Non-polar	Transformer oil	2
Mildly polar	Chlorinated diphenyl	6
Strongly polar	Nitrobenzene	$\geq 20$
	Polypropylene carbonate	
	Water	
	Ethanol	
	Hydrogen cyanide	

have low values of relative permittivity and only small concentrations of permanent dipoles. Table 7.25 gives examples of some polar and non-polar dielectrics.

- (c) *Paraelectric dielectrics*: By contrast to simple dielectrics and polar dielectrics, paraelectrics contain a strong dipole in each unit cell with relative permittivity values more than 20 and up to 10 000.
- (d) *Ferroelectric dielectrics*: By analogy to ferromagnetism, ferroelectrics contains domains (of about  $1\mu\text{m}$ ) where permanent dipoles are oriented in the same direction. When an external electric field is applied to a ferroelectric material, the domains are aligned in the direction of the field. However, they are known to exhibit non-linear polarisation with applied field. Ferroelectrics have a relative permittivity, which increases with temperature until the 'Curie temperature' after which the permittivity decreases, and the domains cease to exist. The material becomes then paraelectric (see typical plot in Figure 7.8). Ferroelectrics exhibit hysteresis of polarisation as a function of the applied electric field (see typical curves on Figure 7.9). Therefore, the permittivity of the ferroelectric must be quoted for a given field value,  $E$ , a temperature  $T$ , and the 'history' of the material. Table 7.26 gives examples of some ferroelectric materials.
- (e) *Piezoelectricity*: When a ferroelectric material is subjected to an electric field at paraelectric temperatures (see Figure 7.8 and Table 7.26) and then cooled, the domains in the material will align permanently. Mechanical shearing stress when applied to such materials can cause charge displacement, known as piezoelectricity. This property is also found in most crystals having an anisotropic structure e.g. quartz (simple dielectric which has no domains).
- (f) *Electrets*: Any dielectric can contain electric charges at atomic or molecular level that can be oriented by an

**Figure 7.8** Typical dependence of permittivity on temperature in ferroelectrics

**Figure 7.9** Hysteresis in ferroelectric polarisation versus electric field

**Table 7.26** Examples of ferroelectric materials

Ferroelectric material	Symbol	Curie temperature ( $^{\circ}\text{C}$ )
Potassium dihydrogen phosphate	$\text{KH}_2\text{PO}_4$	-151
Lead titanate	$\text{PbTiO}_3$	487
Barium titanate	$\text{BaTiO}_3$	10 and 120
Cadmium titanate	$\text{CdTiO}_3$	-210
Lead niobate	$\text{PbNb}_2\text{O}_6$	570

external electric field. If after cooling, the charges are immobilised, the dielectric will behave as an electrical equivalent of a permanent magnet. This is known as an electret (thermoelectrets in this case). An electret loses its volume charge exponentially but with a very large time constant (order of 100 years). Standard capacitors have time constants from few seconds up to six months (e.g. polystyrene).

### 7.10.6 Example of ferroelectric material: Barium titanate and its applications

Barium titanate is one of the most important ferroelectrics. It is formed from the reaction of a mixture of  $\text{BaCO}_3$  and  $\text{TiO}_2$  heated at  $1250^{\circ}\text{C}$ . The product is powdered and then worked by means of common ceramic techniques. Admixtures of other oxides are employed to modify the dependence of permittivity on temperature. Its high permittivity is exploited in ceramic capacitors for the range 500–10 000 pF for electronic equipment. Its piezoelectric property is used in transducer effect since it can be fabricated in a variety of complex shapes. The hysteresis in polarisation is used in timing control or carrier-frequency modulation of a voltage control.

**Figure 7.10** Typical relative permittivity,  $\epsilon_r$ , dependence on frequency

Figure 7.11 Typical loss tangent variation with frequency

### 7.10.7 Frequency response of dielectrics

Most materials are polarisable in several ways, producing complex frequency dependence. At the highest frequencies, only the electronic polarisation will 'keep up' with the applied field. At frequencies where permittivity varies rapidly, there is a peak in the dielectric loss. *Figures 7.10 and 7.11* show typical variations of permittivity and loss angle with frequency.

## 7.11 Polymeric insulation for high voltage outdoor applications

### 7.11.1 Materials

Traditional insulators are made of ceramic, either porcelain or glass. The design of these insulators for high voltage applications evolved from telegraph wire experience. These insulators are known to perform reliably in service for several decades. However, their bulky nature, poor pollution performance due to hydrophilic surfaces and susceptibility to vandalism raised a need for better materials.

Non-ceramic insulators (NCI), also commonly known as polymeric or composite insulators, are made of a compound of materials having one of several polymers as a base. Two main materials have been used extensively on outdoor high voltages power systems: silicone rubber and Ethylene propylene diene monomer (EPDM). Their combination (EPS) has been proposed to solve particular problems of surface properties and material strength. The main advantages of these materials are their light weight (since the insulator is made from a fibre rod with a polymeric outer sheath) and more importantly their surface hydrophobicity which inhibits the formation of continuous wet paths along the insulator surface. This is particularly advantageous under pollution condition when outdoor insulators suffer from dry-bands followed by localised discharges across the dry bands.

Room temperature vulcanised (RTV) coating is used to enhance porcelain insulators pollution performance by spraying/applying a thin layer of silicone rubber on the porcelain surface giving it a hydrophobic surface similar to that of silicone rubber insulators. RTV coatings contain typically 5% (by mass) cyclic LMW polydimethyl siloxanes.

IEC 1109:1992 Standard describes acceptance test procedures for composite insulators and IEC 507:1991 specifies artificial pollution tests procedures for high voltage insulators to be used on a.c. systems. However, these latter procedures are particularly suited for porcelain and glass insulators. At present, no standard procedure exists specifically for polymeric insulators. One difficulty is related to surface pollution

because the hydrophobicity of polymeric insulators makes the conventional technique not suitable. Various methods have been suggested to obtain a uniform and repeatable pollution layer on polymeric surfaces. These include surface abrasion, kaolin spraying, multiple layer spraying and the use of small quantities of wetting agents, such as Triton X-100 as used in BS 5604:1986 (same as IEC 587:1984). International Standard IEC815:1986 gives guidance on the selection of insulators for high voltage applications taking into account the insulator shape and pollution severity.

### 7.11.2 Hydrophobicity loss and recovery

Extensive laboratory tests and field experience have shown that these materials can lose their hydrophobicity following a number of individual stresses or their combination. In particular, discharge activity on the insulator surface is found to reduce the hydrophobicity significantly. However, silicone rubber is found to recover its hydrophobicity after a certain time (which is still not well quantified) without the damaging stress. This process of recovery is thought to be due to the diffusion to the surface of low molecular weight (LMW) molecules and/or the changes in orientation of the methyl groups of the polymer.

### 7.11.3 Degradation ageing factors of polymeric insulator surfaces

Despite their excellent pollution performance, polymeric insulators are found to experience faster degradation on their surface compared with conventional insulators. Although such degradation depends on insulator material and design, a number of factors have been identified as affecting the surface properties of polymeric insulators. Some of these are described in the following processes.

#### 7.11.3.1 Electrical process

The electric field distribution along a high voltage insulator unit is not uniform with the highest field regions located at the end terminals. In addition, the regions around the cores have higher electric fields than the shed areas. Under operating service conditions, the insulators are subjected to pollution that modifies the field distribution, reducing the magnitude at the end terminals. However, the wetting process is also non-uniform. The regions at the end terminals (especially at the top end) will wet more and at a faster rate than the regions under the sheds. Such combination of slow wetting and high field magnitudes encourages the initiation of discharges in these 'under-shed' core regions. With continuous intense discharging, the surface loses its hydrophobic properties. Furthermore, the discharging process generates ozone and nitrogen oxides which, when combined with water, produce nitrous and nitric acids. These acids attack the end fittings and make the polymer surface brittle forming a crazed pattern which can lead to splitting of the polymer sheath.

Surface currents on polluted insulators combined with the dry band discharging lead to tracking and erosion of the polymeric surface. Tracking and erosion resistance is improved by adding Alumina Trihydrate (ATH) as a filler to the polymer. After ageing, insulators with such materials exhibit a chalky white appearance caused by the diffusion of the ATH from the bulk to the surface.

### 7.11.3.2 Mechanical process

Direct mechanical stress on insulators can be tensile, compressive or cantilever loading. These stresses can lead to insulator failure by damaging the fibre reinforced plastic (FRP) core. Mechanical stresses usually affect the insulator in combination with other stresses.

Indirect mechanical stress is the form of surface tears caused by the release of stresses trapped during the manufacturing process. This provides arcing regions which would lead to tracking and erosion. Formation of fissures is also possible due to vibrations and the existence of material interfaces in the insulator unit.

Brittle fracture of the FRP rod has been observed under service conditions with insulator mechanical loads below the specified load. Various causes were suggested including faults from the manufacturing process, and water ingress combined with mechanical stress which transports hydrogen ions in solutions with a pH value of 3 or 4.

### 7.11.3.3 UV radiation

Outdoor insulators are exposed to sunlight, hence, ultra-violet (UV) radiation. UV radiation causes photo-oxidation and scission of molecular bonds in polymeric materials. Photo-oxidation is caused by ionisation of the surface molecules and attraction of the oxygen when the photon energy is sufficient. If the energy of the photon is higher than that of the bonds between the molecules or the polymer chains in the backbone of a single polymer, scission occurs.

Silicone rubber has a high resistance to damage by UV radiation because the siloxane (Si-O) bonds are of high energy. However, the hydrocarbon groups in the polymer can be damaged. UV resistance is usually increased by the use of carbon-based fillers which have the disadvantage of affecting the insulating properties of the material.

Intense UV exposure can lead to reduction of the silicone polymer on the surface of the material accompanied by an

increase of the filler. Such surface depolymerisation was found to accelerate loss of hydrophobicity and increase of surface leakage current.

### 7.11.3.4 Chemical processes

Chemical attack occurs due to pollution products and following discharge activity on the insulator surface. Examination of field-aged insulators has found formation of uniform thin pollution layers on the surface. Sea or coastal pollution contains salts, while inland pollution comprises dust, industrial particles and agricultural fertilizers. When wetted, these pollution products react with the polymer under the action of the applied field. In tropical climates, micro-organism growth was found on insulator surfaces which was found to enhance the surface leakage current. The current increase warms the insulator surface, which further encourages the growth of the bacteria population. Partial arcs destroy the organisms but leave biological remains in the form of a slimy surface.

### 7.11.3.5 Water ingress processes

Water ingress in polymeric insulator occurs in three ways a) ingress through poor seals at end fittings, b) ingress through surface defects/damages, or c) through absorption of water into the polymeric material itself.

Corrosive chemicals and/or ionisable contaminants carried by the water affect the mechanical strength of the FRP rod and this is known to cause brittle fracture.

Water absorption causes depolymerisation as well as polarisation of the interfaces between the polymer and the fillers. More importantly, it increases the permittivity and loss tangent while it decreases the dielectric strength. As a consequence, heavy erosion and shed puncture can occur following moisture ingress.

## 8.1 Ferromagnetics

The choice of materials having ferromagnetic properties is very wide. Other than iron, a number of elements such as nickel and cobalt as well as some manganese alloys are ferromagnetic.

It has so far been impossible to obtain absolutely pure iron, in the true sense, even under laboratory conditions; but iron in which the impurities have been reduced to a mere trace has been found to have a maximum relative permeability of 50 000 and a very low hysteresis loss. However, even if it were possible to produce an iron of this degree of purity commercially, its low resistivity would be a disadvantage with alternating fluxes because of eddy currents.

The common impurities in iron are carbon, manganese, silicon, copper, sulphur, phosphorus and oxygen and the general effect of these impurities is to reduce the permeability and to increase the hysteresis loss. Sulphur, phosphorus and oxygen are particularly injurious and the presence of these has to be reduced to the lowest possible level. The presence of small amounts of silicon up to about 5% is beneficial. Small amounts of manganese are not injurious, but when the manganese content reaches 12%, a particularly non-magnetic steel is obtained. To neutralise the effect of impurities and to confer special properties, iron is alloyed with other elements, of which the following are the most important: nickel, cobalt, silicon, chromium, tungsten, molybdenum and vanadium.

The magnetic properties of ferromagnetic materials depend not only on their chemical composition, but also on the mechanical working and heat treatment they have undergone. For practical purposes magnetic materials fall into two main groups, high permeability or soft magnetic materials and permanent magnets or hard magnetic materials.

There are a number of groups of soft magnetic materials including soft iron, mild steel, silicon steels, nickel irons and ferrites. In static d.c. applications mild steel is the main bulk material, but where better properties are required with greater magnetic permeability, soft iron is used. Silicon steel is the bulk material for low frequency alternating fields and the nickel irons are used for more specialised applications with the soft ferrites being used at higher frequencies because of their higher resistivity.

There are four main classes of permanent magnet materials: steels, Alnicos, hard ferrites (also called ceramics) and rare earth alloys. Of these the steels are almost obsolete because of their inferior properties and the ferrites have gradually taken over from Alnico as the main bulk material, mainly due to their cost advantage. The rare earth alloys SmCo and NdFeB because of their superior properties have created new interest and have found a great many new applications. They have enabled considerable weight savings to be made in many instances.

## 8.2 Electrical steels including silicon steels

### 8.2.1 General

Electrical steels form a class of sheet material used for the flux-carrying cores of transformers, motors, generators, solenoids and other electromechanical devices. Almost always alternating magnetisation is employed and the material is designed to keep power losses due to eddy currents and magnetic hysteresis to a minimum.

#### 8.2.1.1 Eddy current losses

Minimisation of eddy currents is achieved by using thin laminations. The e.m.f. generated in a lamination is proportional to the cross-section of the lamination for a given peak magnetic flux density and frequency; while the path length (and resistance) varies only slightly for a given lamination width, so that lamination of the core reduces the  $V/R$  ratio for the eddy currents (see Figure 8.1).

The current is proportional to (area of cross-section)/(path length).

$$\text{For (i) in Figure 8.1 this is } \frac{ab}{2b+2a} \approx \frac{ab}{2b} = \frac{a}{2}$$

$$\text{and for (ii) this is } \frac{2ab}{2b+4a} \approx \frac{2ab}{2b} = a$$

Power rises as  $I^2 R$  so that loss per unit volume rises rapidly as the sheet thickness increases. By increasing the resistivity of the steel, eddy currents may be further restrained and this is usually done by adding silicon as an alloying element. Silicon additions range from zero up to some 3.25%.

Over this range the resistivity may vary from about 12 to about  $48-50 \Omega\text{-m} \times 10^{-8}$ .

The addition of silicon has the effect of reducing the saturation flux density of the steel so that a larger core cross-sectional area is needed to carry a given magnetic flux.

#### 8.2.1.2 Hysteresis losses

Magnetic hysteresis is another source of power loss which can be reduced by the addition of silicon as an alloying element. While the area of the very low frequency  $B-H$  loop is often taken as a measure of hysteresis loss, effects which impede magnetic domain wall motion alter with frequency. At 50 or 60 Hz the overall loss mechanism is a complex mixture of macro eddy currents relating to lamination thickness, micro eddy currents associated with the movement of the internal domain walls and energy dissipative hysteretical effects due to impediments to free domain wall motion. Such impediments may be non-metallic inclusions, grain boundaries or regions of stress within the crystal lattice of the material.

Table 8.1 gives an outline of the principal types of electrical steel produced in the UK, and some of their properties and applications.

As the percentage of added silicon increases, the steel becomes more difficult and expensive to process. Thinner material is more costly because it requires more rolling and processing. The key points of a material specification are given in Table 8.1.

Primary grading is by power loss in watts per kilogram at a peak magnetic flux density of 1.5 or 1.7 T and 50 Hz (60 Hz in the USA).

Figure 8.1  $V/R$  ratio for eddy currents

**Table 8.1** Selection of electrical steel grades produced by Cogent Power Ltd—typical properties

Grade identity	Thickness (mm)	Typical specific total loss* (W/kg)	Typical specific apparent power* (VA/kg)	Nominal silicon content (%)	Resistivity ( $\Omega\text{-m} \times 10^{-8}$ )	Stacking factor	$\hat{B}_{\dagger}$ (T)	Typical applications

## 8.2.2 Ancillary properties

### 8.2.2.1 Specific apparent power

Specific apparent power (in volt-amperes per kilogram) gives an indication of the r.m.s. ampere-turns which must be available to maintain a given state of alternating magnetisation, e.g. a peak value of 1.5 T at a specified frequency. Most of the current drawn is 90° out of phase with the supply voltage and so is non-dissipative, but copper or aluminium windings of sufficient cross-section must be used to keep copper losses low in the face of the current demanded.

### 8.2.2.2 Permeability

There are many varieties of permeability, but for electrical steels those of most interest are  $\hat{B}_{1000}$ ,  $\hat{B}_{2500}$ ,  $\hat{B}_{5000}$ , and  $\hat{B}_{10000}$ , that is the peak value of magnetic flux density attained under the influence of an applied field of 1000, 2500, 5000 and 10 000 A/m, respectively.

### 8.2.2.3 Surface insulation resistance

This is a measure of the quality of the surface insulating coating (expressed in ohm-metres squared) used to restrain the flow of current between laminations.

### 8.2.2.4 Stacking factor

This is the ratio of the height of a stack of laminations calculated from the volume of metal present to the measured height of the stack of laminations under a specified clamping pressure, for the same cross-sectional area of material. The stacking factor is expressed as a percentage and typical figures range from 96% to 98%.

### 8.2.2.5 Ductility

This is expressed as the number of 180° bends the material can sustain over a specified radius without cracking

(typically >10 bends over a radius of 5 mm). Full details of specifications are given in: BSEN 10726, 10165, 10106 and 10107.

### 8.2.3 Chemistry and production

Electrical steels are produced by a complex process of casting, hot rolling, cold rolling and heat treatment. The end product must be very low in carbon and sulphur and free from non-metallic inclusions—that is metallurgically very ‘clean’.

The magnetic properties are much improved if the grain size of the metal can be enlarged, up to a maximum of some 1 cm diameter for some grades and considerable metallurgical skill is employed to procure an end product that is chemically appropriate, metallurgically clean and of optimum grain size.

### 8.2.4 Physical form

Electrical steels are normally sold in coil form in coil weights up to several tonnes and widths up to 1 m wide, or in sheets cut to lengths of up to 3 m. Thickness normally ranges from 0.23 mm up to 0.65 mm (1.6 mm if high tensile grades are included). Strip can be supplied fully finished in a state of final anneal and carrying an insulating coating or semi-finished so that users can cut or punch the material and apply a final heat treatment and perhaps coating before building into a core. Electrical steels are susceptible to stress and mechanical damage so they must be handled with care and, if appropriate, re-annealed to recover properties damaged by stress. Appropriate heat treatments are normally an anneal at 800°C in a neutral atmosphere (non-oxidising) or a decarburising anneal at some 900°C in wet hydrogen.

When supplied as slit, narrow strip steel can be used to wind ‘clockspring’ cores directly without need for punching.

### 8.2.5 Coatings

The insulative coatings applied to electrical steels fall into two main classes: organic and inorganic. Organic coatings are inexpensive but cannot be used if further annealing is to be applied to the steel.

Inorganic coatings are resistant to annealing and some may be formed during the processing of the steel for the development of its magnetic properties.

Coatings having both organic and inorganic components can be used, so that the organic component which aids punching may disappear on anneal but a useful inorganic residual coating remains.

### 8.2.6 Grain orientation

The grains in electrical steel of the so-called ‘non-oriented’ type are, for the most part, randomly arranged so that the magnetic properties of sheet are broadly isotropic. This is convenient for many applications where flux must flow in varying directions in the steel.

However, if the grains are specially oriented so that an easy direction of magnetisation of the crystal lies along one direction of the sheet (normally the production rolling direction) then the magnetic properties in this direction are much enhanced at the expense of those at other angles to the rolling direction.

This, so-called, ‘grain orientation’ requires a costly and complex regime of rolling and heat treatments and the high-temperature anneal stage of production produces a glass film on the surface of the steel which acts not only as an insulating coating but also as a further means of enhancing magnetic properties. When steel bearing a glass coating cools from a high temperature the steel contracts more than the glass so that at room temperature the glass coating is holding the steel in a state of tension. This tension improves the magnetic properties of the steel, so that the material at its best functions as a composite system of a precisely grain oriented steel substrate held in a state of beneficial tension by a very thin (some 1–2 µm) layer of glass which also acts as an interlaminar insulant. A final phosphate coating is usually applied to complete the insulation and tensioning process.

### 8.2.7 Test methods

The test methods for electrical steels are fully described in BSEN 60404-2: 1998 and BSEN 10280: 2001 and in IEC standards 60404-2 and 60404-3. These tests seek to simulate the service conditions of electrical steels.

One of the best-known test methods is the Epstein test in which a set of strips of steel each 30.5 cm long and 3 cm wide are arranged in four limbs with double lapped corners to form a hollow square. Four double sets of windings enclose the strips and these are energised to produce a situation analogous to that in a small transformer at operating levels of magnetic flux density and under ‘no load’ conditions. Careful measurements of magnetic properties are carried out using a precision wattmeter and ancillary instrumentation.

There is a growing trend towards the use of single plates some 50 cm square for tests, and increasing use of such plate tests will reduce the labour involved in the lengthy Epstein test.

Cogent Power Ltd produces specialist test equipment for the measurement and quality control of electrical steel as do some instrument makers.

Steel producers offer a customer advisory service which in the case of Cogent Power Ltd is offered as well as the services of their Standards Laboratory which holds United Kingdom Accreditation Service (MKAS) approval for power loss testing at Newport in South Wales.

### 8.2.8 Various

Electrical steels cover a wide range of applications, some are made to have especially high strength for use where heavy mechanical loads arise. Some are of specially precise grain orientation where very low power loss and the highest permeability are vital. Some are simple but inexpensive for use in applications where cost and ease of manufacture of the final article may be paramount.

Electrical steels used inside nuclear reactors must behave well under conditions of high temperature and neutron flux.

Wherever alternating magnetic fields must be managed efficiently and economically, electrical steels of one variety or another can assist.

## 8.3 Soft irons and relay steels

### 8.3.1 Composition

The primary aim of soft irons is to be a close approximation to pure iron. Efforts are made to keep contaminant elements to a low level—particularly carbon and sulphur.

Carbon levels of 0.005% are advantageous, but expensive to produce, and material of intermediate quality can be obtained with carbon ranging from this low level up towards 0.05% and higher. At 0.1% carbon the material becomes a common 'mild steel' and while it can still be processed to have useful magnetic properties it is no longer a specialist material. Sulphur levels are kept as low as possible and <0.01% is a good aim.

### 8.3.2 Applications

Soft iron (or 'relay steel' as it is often called) is used largely for the magnetic circuits of electromechanical relays and solenoids, for the pole pieces of d.c. magnets and parts of the magnetic circuits of small generators. Quite a considerable amount of soft iron is used in the construction of particle accelerators for nuclear research where huge magnets are required to guide accelerated particle beams.

### 8.3.3 Physical forms

Soft irons come in four main physical forms:

- (1) flat rolled, mainly in the thickness range 0.3–2.0 mm;
- (2) round rod in the diameter range 2.0–20 mm;
- (3) thick plate from 2.0–25 mm thick; and
- (4) solid block up to 100 mm to 150 mm thick.

### 8.3.4 Metallurgical state

To achieve the best magnetic properties the material should be free from non-magnetic inclusions, have large grains and be free from internal stress.

### 8.3.5 Magnetic characteristics

The primary grading property of soft iron is coercive force—that is the magnitude of reverse field required to demagnetise the steel fully after a previous magnetisation to a

Figure 8.2

Figure 8.3 A simple electromechanical relay

Figure 8.4 Shearing of the  $B$ - $H$  loop

specified value of magnetic flux density. This is shown as the distance  $PQ$  on the  $H$  axis of the  $B$ - $H$  loop in Figure 8.2.

Coercive force is important as it indicates the amount of hysteresis which a material exhibits.

In an electromechanical relay (Figure 8.3) the magnetic circuit has quite a large air gap in it when the relay armature is in the relaxed 'open' state. When 'closed' the air gap is less but still of finite size (often set by a non-magnetic stop pip). It is well known that the magnetic reluctance of the air gap in a magnetic circuit produces 'shearing' of the  $B$ - $H$  loop of the circuit material (see Figure 8.4). The coercive point  $X$  stays the same under loop shear, but the remanent point  $Y$  moves to  $Y'$ . It is apparent that material having a 'thin' loop with a small  $H_c$  will show a greater fall in remanence for a similar amount of 'shear' than will a material of high  $H_c$  and having a 'fat' loop. For this reason coercive force is used as a quality guide for material which ideally should have as low a hysteresis as possible.

Besides coercive force, permeability is important. Depending on the application the low-, mid- or high-field permeability may be important and strict specifications may be placed on the magnetic induction (tesla) achieved for a given applied magnetic field strength.

### 8.3.6 Grades and specifications

BS6404:8.10: 1994 is the UK Standard for grades of soft iron. Traditionally, a chemical specification has been used for the

supply of relay steels and soft iron, but this can lead to wide variations of magnetic properties within a batch which meets the chemical specification.

Typically, steel is offered to a magnetic specification within five coercive force grades:

- (1)  $<40$  A/m
- (2)  $<60$  A/m
- (3)  $<80$  A/m
- (4)  $<120$  A/m
- (5)  $<240$  A/m

(There is still much use made of the CGS unit, the oersted, (Oe) for soft iron grading). Material supplied to a magnetic guarantee is much more satisfactory to the relay designer and quality control engineer.

### 8.3.7 Heat treatment

It is important that iron should be in a fully annealed stress-free state in its final form in a magnetic circuit. Most material is punched, sheared, upset or machined in one way or another during fabrication, all of which induces high stress. An appropriate heat treatment of a piece—part will allow the material to give the best performance in service.

Optimum heat treatments are best worked out in conjunction with the steel supplier. Broadly, a  $950^{\circ}\text{C}$  anneal in a neutral atmosphere followed by a slow cool over several hours is satisfactory.

Where material is fairly thin (up to 1 or 2 mm) the final heat treatment can, with advantage be decarburising so that lowest coercive force is obtained as residual carbon is removed. Decarburising anneals employ furnace atmospheres of wet hydrogen and, again, require specialist advice.

### 8.3.8 Ageing

A final anneal takes residual carbon into solution and some of this may precipitate over a period of years leading to increases in coercive force as domain wall motion becomes impeded by carbon precipitates. Ageing may be minimised by keeping carbon content low and by use of special stabilising additions to the steel. When necessary, modern irons can be made ageing-free.

### 8.3.9 Test methods

British Standard BSEN 6404-4: 1997, now being amended, deals with test methods appropriate to relay steels. It covers the more lengthy procedures in which a welded ring is used as sample (or stamped rings from sheet), or the use of a d.c. permeameter with flux closure yokes. BS 6404: Part 7 (1986) gives details of the Vibrating Coil Magnetometer with which it is possible to obtain a coercive force reading in a few seconds. This is a very simple procedure compared with the more lengthy permeametric methods which require ballistic galvanometers, etc.

Cogent Power Ltd have pioneered the production of the Vibrating Coil Magnetometer for sale to industry in conjunction with the National Physical Laboratory.

IEC Standards 60404-4 and 60404-7 are equivalent to BS 6404 Part 4 and BS 6404 Part 7 respectively. Study of the UK and IEC Test Standards is of the greatest assistance in understanding how to grade soft irons for quality.

### 8.3.10 Other applications

Where relays must operate at the highest speeds it is necessary to raise the electrical resistivity of the magnetic circuit. This is necessary so that flux can penetrate the core iron rapidly. A low electrical resistivity gives rise to very vigorous induced eddy currents which oppose flux penetration to the centre of the material. The use of lamination is not often suitable so resistivity can best be raised by the addition of silicon, up to some 3% as required. This produces a four-fold increase in resistivity.

Thin iron is often used for screening. This may be applied to cables to reject outside interference or to load them inductively. Whole areas may be screened with iron enclosures where steady field or field-free conditions are essential. For this purpose screens consisting of layers of iron and air are the most effective.

## 8.4 Ferrites

In the context of electromagnetism, ferrites may be defined as magnetic materials consisting of compounds of metallic oxides and containing ferric ions as the main constituent. They usually have the structure of polycrystalline ceramic materials, but for some special applications the single crystal form is used. Ferrites are used in a wide variety of applications in electronic and communication engineering.

In the crystal lattice of ferrites the metal ions are separated by oxygen ions and this results in high electrical resistivities which suppress eddy currents and their usually undesirable effects. Another important consequence of the presence of oxygen ions is that the magnetic moments of the metal ions on the two constituent sublattices have anti-parallel alignment so that the net available magnetisation is the difference between the magnetisations of the sublattices (ferrimagnetism). This, together with the dilution due to the presence of the non-magnetic oxygen ions, inherently limits the saturation flux density of ferrite materials to about 0.4–0.6 T (compared to about 2 T for some magnetic alloys).

The usual manufacturing process consists of the following steps; mixing of raw materials (oxides, carbonates, etc.) in the required proportions, calcining at about  $1000^{\circ}\text{C}$ , crushing, milling, powder granulation, forming to the required shape by pressing the powder in a die or by extrusion, and finally sintering the piece parts at about  $1250^{\circ}\text{C}$  for up to 12 h in a controlled atmosphere. During sintering, crystallites of the required formulation are formed by solid-state reaction and this process is accompanied by a shrinkage of linear dimensions of between 10 and 25%. The product is a black brittle ceramic piece part having a density of about  $4800\text{ kg/m}^3$ . Any subsequent shaping operations, such as pole face finishing, have to be done by grinding (and sometimes lapping).

Ferrites may be broadly divided into the magnetically soft category, those having high permeability and low losses, and the magnetically hard category, those having permanent-magnet properties. The hard ferrites are described later.

### 8.4.1 Magnetically soft ferrites

Magnetically soft ferrites have the cubic crystal structure of the mineral spinel. In ferrites, this structure is characterised by a very low magnetocrystalline anisotropy which results in the ferrite having a very low coercivity, high permeability and low magnetic power losses at frequencies extending up to 300 MHz, depending on composition. The chemical formulation is represented by  $\text{MeFe}_2\text{O}_4$  where Me is most

commonly a combination of manganese and zinc with some ferrous iron (abbreviated to MnZn ferrite), or nickel and zinc (NiZn ferrite). Minor constituents (additives or substitutions) are often included in order to enhance particular properties.

Ferrites are usually manufactured in the form of specific core shapes such as rings and a wide variety of pot-, E-, and U-shaped cores. Except for rings, the complete cores are usually assembled from pairs of half cores, the mating surfaces having been ground flat and sometimes lapped to ensure a low-reluctance joint. Where the application requires the core to contain an air gap in order to modify the properties of the wound assembly, one of the pole faces in the magnetic circuit is ground back by a specific amount during manufacture.

#### 8.4.1.1 Properties

The properties of a ferrite material are strongly influenced by the composition, the presence of minor constituents and the details of the manufacturing process. For example, increasing the proportion of zinc lowers the Curie point and affects the saturation flux density. In MnZn ferrites the presence of a small proportion of the iron in divalent form critically controls the temperature coefficient of the permeability and influences the bulk resistivity and the magnetic losses. By varying these and other factors, a wide range of ferrite grades can be made, each specifically matched to a particular application. Typically a manufacturer's range of ferrite grades may extend to over fifty different specifications.

All ferrites exhibit a ferrimagnetic (or spin) resonance frequency at which the permeability falls to a very low value and the magnetic losses peak. For soft ferrites in general, the product of the low frequency initial permeability and the ferrimagnetic resonance frequency is approximately a constant (Snoek's law). So a high-permeability ferrite has a low cut-off frequency; where low losses are required at higher frequencies, ferrites having lower permeabilities must be used, see *Figure 8.5*.

Generally, the MnZn ferrites have the higher permeabilities and lower losses in the frequency range up to about 2 MHz; their bulk resistivities lie between about 0.05 and 20  $\Omega\text{m}$ . The NiZn ferrites have lower permeabilities (dependent on the Ni/Zn ratio) and higher losses (relative to the MnZn ferrites) below about 2 MHz. However, they maintain their useful properties to much higher frequencies. Their resistivities are about three orders of magnitude higher than those for MnZn ferrites and so are virtually free of eddy current effects.

The initial permeability,  $\mu_i$ , is the permeability at very low field strengths. High values of  $\mu_i$  are desirable in principle, but Snoek's law dictates that the optimum initial permeability falls as the frequency characterising the application rises. If an air gap is inserted in the magnetic circuit of a core, the permeability apparent to a winding on that core is reduced to the effective permeability,  $\mu_e$ . At the low flux densities appropriate to signal applications, the magnetic loss in ferrites is expressed in terms of a loss factor defined as the tangent of the loss angle divided by the initial permeability,  $(\tan\delta)/\mu_i$ . The loss tangent of a gapped core equals the loss factor multiplied by the effective permeability. In many applications the flux density is low enough for the hysteresis

**Table 8.2** Typical properties of some magnetically soft ferrites (at 25°C unless otherwise stated)

Parameter	Conditions			Ferrite classification				Units
	$f$ (kHz)	$B$ (mT)	Misc.	(i)	(ii)	(iii)	(iv)

**Figure 8.5** The inductive component of the permeability,  $\mu'_s$ , and the corresponding loss component,  $\mu''_s$ , as functions of frequency for three typical ferrites. (a) is an MnZn ferrite having an initial permeability of 2000 and intended for high performance inductors at frequencies up to about 0.3 MHz, (b) is an MnZn ferrite having a permeability of about 700 and is intended for inductors operating at frequencies of 0.3–0.7 MHz and (c) is an NiZn ferrite with a permeability of 130, applicable to inductors intended for the low MHz band

loss to be negligible. The main loss is then represented by the residual loss. This is low over the lower frequency region but rises rapidly as the frequency of ferrimagnetic resonance is approached. Figure 8.6 shows the residual loss factor as a function of frequency for three typical ferrites: (i) is a low loss MnZn ferrite, (ii) is a high permeability MnZn ferrite intended for signal transformers, and (iv) is an NiZn ferrite with a permeability of about 130. Other properties of these typical ferrites are listed in Table 8.2

The temperature dependence of the initial permeability is important for inductor applications. As a material property it is usually expressed as a temperature factor  $\Delta\mu_i/(\mu_i^2\Delta\theta)$ , where  $\theta$  is the temperature. If a core is gapped so that it has an effective permeability,  $\mu_e$ , then the temperature coefficient of effective permeability (and therefore of the inductance of a winding on the gapped core) is  $\mu_e$  times the temperature factor. So the temperature coefficient of inductance can be determined by the choice of the gap length. For an inductor used in filter applications, the negative temperature coefficient of the tuning capacitor can thus be compensated to achieve very high combined temperature stability.

In applications involving MnZn ferrites, the finite conductivity of the material gives rise to some eddy-current loss in the core. This loss depends on the size and shape of the core and, although small in relation to the total core loss at low frequencies, it can become significant at frequencies above about 50 kHz, depending on the ferrite resistivity and the size of the core. The low-amplitude hysteresis loss in a ferrite is expressed in terms of a coefficient,  $\eta_B$ , such that the hysteresis loss factor  $(\tan \delta_h)/\mu_i = \eta_B B$ , where  $B$  is the peak flux density. The hysteresis coefficient of a ferrite determines the Total Harmonic Distortion (THD) generated by a core made in that material, e.g. for a pulse transformer.

**Figure 8.6** Typical residual loss factors as functions of frequency. (For material classifications see Table 8.2)

In modern digital networks THD is a critical parameter in that it can cause bit errors. Special MnZn ferrites with high permeability and very low hysteresis loss have extremely low THD levels and are to be recommended for such applications.

In power applications the important material property is the power loss per unit volume, i.e. the power loss (volume) density. The principal component of this is the magnetic loss which is defined as the loss due to all causes other than the eddy currents generated in the bulk of the core. The magnetic loss (volume) density  $P_M = k f^m B^n$ , where  $k$  is the loss coefficient and  $n$  is the Steinmetz exponent. The values of  $k$ ,  $m$  and  $n$  depend on the composition and microstructure of the ferrite and are temperature dependent. For MnZn ferrites intended for power applications,  $n$  usually lies between 2 and 3 (typically 2.5). The exponent  $m$  is unity at low frequencies, rises to typically 1.5 at 100 kHz and continues to rise as the ferrimagnetic resonance frequency is approached. These data apply both to sinusoidal and symmetrical square-wave excitation (in the latter case the flux waveform in the core is approximately triangular).

As the frequency of operation increases, the flux density must be reduced to keep the power loss within the limits imposed by thermal considerations. For MnZn ferrites operating at frequencies approaching 1–2 MHz, the rising value of  $m$  in practice imposes a cut-off frequency for the power application of these materials. To extend the range of MnZn ferrites to the highest possible frequencies, lower permeability grades have been developed. Lowering the permeability raises the frequency of the ferrimagnetic resonance and this, in effect, lowers the value of the exponent  $m$ . Figure 8.7 shows the loss curves for two typical high-performance power ferrites and illustrates the improvement in the higher frequency performance that can be achieved by such means. The ferrite composition is usually chosen so that the minimum in the power-loss/temperature curve occurs at the typical operating temperature of the core, for example 85°C. To evaluate the total loss density it is necessary to add the eddy-current loss density to the magnetic loss density. The eddy current loss density, which is specific to a given core, may be expressed approximately by  $P_F = \pi f^2 B^2 A_e / \varsigma$  ( $4\rho$ ), where  $A_e$  is the effective cross-sectional area of the core and  $\rho$  is the bulk resistivity of the ferrite at the operating temperature. At low frequencies, the eddy-current loss can be relatively small, but at frequencies above about 50 kHz it becomes an increasingly significant fraction of the total.

**Figure 8.7** Magnetic loss (volume) density,  $P_M$ , for two MnZn ferrites intended for power conversion applications. The solid curves are typical of power ferrites for switching frequencies in the range 50–500 kHz. The broken curves show the properties of lower permeability power ferrites designed for the frequency range 0.5–2 MHz. Courtesy of Drs. J. W. Waanders, *Philips Components*

For a conventional transformer core, the temperature rise normally limits the total core loss density to about 100–400 kW/m<sup>3</sup>, the larger figure relating to the smaller cores. The maximum allowable core loss density will set a limit on the flux density for a given frequency and this will enable the minimum number of turns required on a given core to be evaluated. The actual core loss is obtained by multiplying the total core loss density by the effective volume of the core as quoted in the data sheet for the core. In addition to providing loss data on their grades of power ferrite materials, some manufacturers quote the core loss in watts at given frequencies and flux densities for specific cores in their product range.

In the development of electronic power supplies, the priority is size reduction which leads to increasing throughput power densities. To accommodate this trend, switching frequencies are increased, the losses in the ferrites are reduced by material development and the power loss densities in the switching transformers are increased. To achieve higher loss densities in the transformers without exceeding a safe operating temperature, the trend is to use flat or planar geometries that can dissipate heat more easily. Such flat designs, which may be only a few millimetres high, are more compatible with pcb technology, can use windings based on printed circuit practice and can allow power loss densities as high as 700 kW/m<sup>3</sup>.

For the lower frequency power applications where the design is saturation rather than loss limited, it is important that the saturation flux density of the ferrite should be as high as possible at the operating temperature. This allows a high value of peak flux density to be used and minimises the required number of turns. Except in saturable reactor applications, a flux density excursion into the saturation region must usually be avoided, even under the worst overvoltage conditions, since it causes a steep rise in magnetising current that can damage the associated semiconductors.

#### 8.4.1.2 Applications

Magnetically soft ferrites are used extensively as cores for inductors and transformers in industrial and consumer

electronics. Referring to *Table 8.2*, the data in the first three classifications indicate typical properties of MnZn ferrites. The first is a low-loss ferrite intended for cores in high quality inductors used at frequencies up to about 300 kHz, such as inductors in filters for telecommunication applications. These cores are usually made in the form of cylindrical or square pot cores with an air gap to provide a specific effective permeability. There is usually provision for adjusting the inductance over a range of about  $\pm 10\%$ . Such components combine potentially high  $Q$ -factors (300–1000) and good stability with temperature and time. The evolution from the early analogue to the present digital electronics has greatly reduced the proportion of ferrite cores required for such inductor applications.

The second column in *Table 8.2* is representative of ferrite grades having high initial permeabilities and intended for cores used in low-power wide-band and pulse transformers. They are usually made in the form of rings and a wide range of E-core and pot-core shapes, some having low profiles compatible with pcb technology. The demand for wideband and pulse transformers increased dramatically with the introduction of digital networks such as Internet, and this in turn promoted the development of special high permeability ferrites having very low third harmonic distortion levels.

The third column refers to ferrites developed specifically for power applications. Initially the main application was the line scan (and high voltage) transformer in the domestic television receiver. The enormous growth in integrated circuit electronics led to a corresponding growth in the need for high frequency switched-mode power supplies. This stimulated the development of ferrite materials and cores specifically for this purpose. Cores for use in power conversion are now second only in production volume to ferrite yokes used in cathode ray tube deflection systems. Originally switching frequencies were between 25 and 50 kHz, but the trend towards more compact power supplies and the attendant trend towards the use of resonant power conversion has progressively pushed these frequencies up towards 1 MHz and beyond. *Figure 8.7* shows the magnetic loss data for two typical power ferrites, illustrating the development of improved performance at higher frequencies. When switching frequencies exceed about 3 MHz, even the best MnZn ferrites are unsuitable due to their increasing eddy current and ferrimagnetic resonance losses. NiZn ferrites, at the higher permeability end of their composition range, then offer superior performance.

Cores developed for power applications are generally variations of the E-core or U-core shape and many different designs are available. With the higher frequency applications, power loss densities become very high and this makes flat (low profile) geometries preferable, as described in Section 8.4.1.1.

The largest use of ferrites, by weight, is for yokes in cathode ray tube deflection systems. Most line deflection frequencies are relatively low so magnetic loss has not been a significant parameter in the design. However, in response to the need for better image definition, the line frequencies in domestic television receivers and, more particularly, in computer monitors are increasing; 100 kHz and even higher is quite common. Power losses are therefore becoming important in this application.

In addition to the uses outlined above, magnetically soft ferrites are employed in a variety of other applications, e.g. as rods for radio receiver antennas and tuning slugs in radio frequency coils. Ferrites with relatively square hysteresis loops are used for magnetic amplifiers in power control. With the increased use of electronic equipment and the stricter EMC regulations, electromagnetic interference

(EMI) suppression has become an important application area for soft ferrites. Special ferrites have been developed to meet the requirements. In particular, ferrites in which the permeability and magnetic losses combine in such a way that the core presents an impedance that remains high over a broad frequency band. Above 1 GHz, ferrites having hexagonal crystal structures, such as those used for permanent magnets, are being introduced into the EMI suppression application. Traditionally, massive ferrite toroids have been and still are used as coupling cores in large particle accelerators. To conclude this very brief overview of the great range of ferrite applications, two very contrasting products can be included. High permeability ferrites, often in single-crystal form, are used in large quantities for magnetic recording heads in all types of analogue and digital recording equipment, and ferrites having the property of absorbing EM waves are produced as tiles, powders and granules for coating the surfaces of rooms and buildings to attenuate the reflection or transmission of EM energy at frequencies from hundreds of MHz to tens of GHz.

#### 8.4.2 Microwave ferrites

Ferrites having special formulations are used in the non-reciprocal components (or gyrators) in microwave systems. This application of ferrites at microwave frequencies depends on the fact that the axis of the spinning electron (the magnetic element of the crystal lattice) will, if disturbed, precess with a rotational direction dependent only on the direction of the static magnetic field aligning the spins, and at a frequency that depends only on the static field strength. An electromagnetic wave, having positive circular polarisation relative to the static field direction and a frequency equal to the precession frequency, will couple to the spin precession to induce a resonance. There is no corresponding coupling or resonance for a negatively polarised wave. So a ferrite that is saturated by a static magnetic field and thus constitutes an array of aligned spins, will have properties that depend on the sense of the polarisation of an incident electromagnetic wave. Devices based on such material conditions will exhibit discrimination as to the directional properties of such a wave. This phenomenon gives rise to a family of waveguide and stripline devices used in microwave systems, such as unidirectional attenuators (isolators) and energy-routing components (e.g. circulators).

To meet the diversity of requirements found in microwave applications, many different magnetic oxides have been developed. Some are based on spinel (cubic) ferrites such as nickel ferrite, MnMg ferrite and NiCuCoMnAl ferrite. Magnetic oxides based on the garnet structure are extensively used in many applications, examples are yttrium iron garnet and gadolinium iron garnet each having a variety of substitutions to obtain the required properties.

### 8.5 Nickel-iron alloys

The nickel-iron alloys, ranging in composition from 30 to 80% nickel are the most versatile of soft magnetic materials. The design engineer can select from a wide range of available properties such as saturation flux density, permeability, coercive force and loss. The alloys can be subdivided into four main groups. Properties of a typical range of alloys are given in *Table 8.3*.

#### 8.5.1 30% Nickel

The 30% nickel-iron alloy has a Curie temperature of the order of 60°C and exhibits a large linear change of permeability with temperature over the range -30°C to +40°C. This alloy property can be utilised in the form of a shunt to provide compensation for the change in the characteristics of a material, such as magnetic performance or conductivity, with temperature. Typical examples of such usage are watt-hour meters, speedometers and microwave circulators. The 31% and 32% nickel-iron alloys have Curie temperatures of 100°C and 150°C respectively and were developed for use in devices operating at higher temperatures.

#### 8.5.2 36% Nickel

The alloy has a lower saturation flux density (1.2 T) and permeability than the 50% alloy but its lower cost and high resistivity make it an attractive alternative. The main applications are relays, high-frequency transformers and inductors. The alloy is also employed in devices, such as inductive displacement transducers, where its very low coefficient of expansion,  $1 \times 10^{-6}/^{\circ}\text{C}$ , is a great advantage.

#### 8.5.3 50% Nickel

This alloy has the maximum saturation in the nickel-iron range (1.6 T) and is used where a higher permeability and/or a better corrosion resistance than that of silicon-iron is required. Another advantage of the alloy is its high incremental permeability over a wide range of polarising d.c. fields. Applications include chokes, relays, small motors and synchros.

Special processing techniques enable a wide range of properties to be developed in this alloy. A cold reduction, in excess of 99%, produces a cube texture in the annealed strip and a square hysteresis loop. Applications utilising this property are magnetic amplifiers, inverters and pulse transformers. Annealing in a magnetic field, below the Curie temperature, can also alter the magnetic characteristics. If the field is applied in the conventional manner, both the initial and maximum permeabilities are substantially increased. When the field is applied in a transverse direction a very flat hysteresis loop with a low remanence is produced. These properties are ideal for thyristor firing circuits where a unipolar pulse is required and the transformer only operates between remanence and saturation.

#### 8.5.4 80% Nickel

The high permeability and low coercivity of this group of alloys is due to the fact that both the magnetostriction and crystalline anisotropy are essentially simultaneously zero at this composition. Until the discovery of the cobalt-boron metal glasses and the nanocrystalline alloys with a similar combination of properties, the 80% nickel-iron alloys were unique for their ultra-high permeability performance.

The commercial alloys have additions of small percentages of molybdenum, copper or chromium to give improved magnetic performance over the binary alloy. Applications include sensitive relays, pulse and wide-band transformers, current transformers, current balance transformers for sensitive earth leakage circuit breakers and magnetic recording heads. Magnetic shielding is also a major area of application either in the form of fabricated

cans or screens for transformers and cathode ray tubes. Annealed tape is also used in the manufacture of shielded cables.

## 8.6 Iron–cobalt alloys

The addition of cobalt to iron results in an increase in saturation, up to a maximum flux density of 2.45 T at 35% cobalt. The high cost of cobalt, relative to that of iron, restricts the widespread use of these alloys, although they are widely employed in the aircraft and associated industries. Their high Curie temperature and magnetostriction are also of special importance. Properties of a typical range of alloys are given in Table 8.4.

### 8.6.1 24/27% Cobalt iron

The ductility drops very considerably when the addition of cobalt exceeds 27% and compositions in this area are chosen for applications such as magnet pole tips where a combination of good ductility, ease of machining and high magnetic saturation flux density is required. The permeability, coercive force and loss characteristics are, however, inferior to the 50% cobalt alloy.

### 8.6.2 50% Cobalt iron

The optimum combination of magnetic properties is obtained in the 50/50 cobalt–iron composition. The ductility of the binary alloy is so low that it is not possible to fabricate the alloy to any extent. The addition of 2% vanadium greatly increases the ductility and fortunately, from the eddy current loss viewpoint, also substantially increases the resistivity. The 49/49/2 Fe/Co/V alloy has been extensively used for stators and rotors in lightweight electrical generators for many years. Other applications include lightweight/small-volume transformers, special relays, diaphragms, loudspeakers and magnet pole tips.

With Curie temperatures in excess of 900°C, this group of alloys is often the only choice for designers of equipment which incorporates soft magnetic materials that are required to operate at exceptionally high temperatures.

A typical example of such an application is in the construction of the magnetic pumps used to pump liquid metal in the production of automobile engine castings.

The demand for increased electrical power in civil aircraft has forced designers to consider changing from the conventional constant frequency type of electrical generator to variable frequency or variable speed, constant frequency, machines. Higher centrifugal forces are exerted on the rotors of these machines, which operate at greatly increased speed. High strength cobalt–iron alloys have therefore been developed to meet these and other applications, such as magnetic bearings.

## 8.7 Permanent magnet materials

The properties of a permanent magnet material are given by the demagnetisation curve (Figure 8.8) the second quadrant of the  $B$ – $H$  hysteresis loop. This extends from the remanence  $B_r$  to the coercivity  $H_{cb}$ . It can be shown that when a piece of permanent magnet material is put into a magnetic circuit, the magnetic field generated in a gap in the circuit is proportional to  $BHV$ , where  $B$  and  $H$  are the corresponding points at a point on the demagnetisation curve and  $V$  is the volume of permanent magnet material. This means that, to obtain a given field with the minimum volume of magnet material, we require the product  $BH$  to be a maximum. The magnet is then designed so that its  $BH$  value is as close as possible to the  $(BH)_{max}$  value. It is also useful to use the  $(BH)_{max}$  value, which represents the useful available energy, to compare the characteristics of materials. Generally, the material with the highest  $(BH)_{max}$  will be chosen but this has to be weighed against such considerations as cost, shape, manufacturing problems and stability.

When the magnet is fully magnetised in a completed magnetic circuit with no gap, the working point is the remanence  $B_r$ . When a gap is made in the circuit the magnet will be partly demagnetised and its working point will fall to, say the point P. If now a further demagnetising field is applied to the magnet corresponding to  $H_1H_2$  the flux density will be reduced to  $B_2$ . If this extra field  $H_1H_2$  is removed the field will recoil along the narrow loop QR to the point R. The corresponding flux density is  $B_3$ . This narrow loop is called the recoil loop and its slope is  $\mu_r/\mu_0$  where  $\mu_r$  is the

**Table 8.4** Iron–cobalt alloys

Alloy	Saturation flux density (T)	Initial permeability	Maximum Permeability	Coercive force (A/m)	Remanence (T)	Resistivity ( $\mu\Omega\text{m}$ )	Curie temperature ( $^{\circ}\text{C}$ )	Yield strength (Mpa)
24% Co (24 Permendur)* (Hiperco 27)*	2.34	250	2000	150	1.5	0.2	950	280

\*Carpenter Technology (UK) Limited.

Figure 8.8 Demagnetisation curve and recoil loop

relative recoil permeability and  $\mu_0$  is the magnetic constant ( $=4\pi \times 10^{-7}$ ). This is an important consideration in dynamic applications such as motors, generators and lifting devices where the working point of the magnet changes as the magnetic circuit configuration changes. It is also important when considering premagnetising before assembly into a magnetic circuit. If  $\mu_r$  is nearly equal to unity, as it is for ferrites and for rare earth alloys, then the magnets can be premagnetised before assembly into a magnetic circuit without much loss of available flux. However, if  $\mu_r$  is considerably greater than unity, care must be taken to magnetise the magnet in the assembled magnetic circuit.

The dotted curve in Figure 8.8 is the  $J$ - $H$  curve where  $B = \mu_0 H + J$ . For materials with  $B_r$  much greater than  $\mu_0 H_{CB}$ , e.g. Alnico, the two curves are almost identical, but for ferrites and rare-earth alloys where  $B_r$  and  $\mu_0 H_{CB}$  are close in numerical value the curves become quite different. The  $J$ - $H$  curve has only a gentle slope from  $B_r$ , this indicates that the magnetisation in the material is nearly uniform. A new parameter the intrinsic coercivity  $H_{CJ}$  is introduced. This intrinsic coercivity  $H_{CJ}$  is a measure of the difficulty or ease of demagnetisation. As the value of  $H_{CJ}$  is increased the more will the material resist demagnetisation due to stray fields, etc. However, as a field of at least three times  $H_{CJ}$  must be applied to the magnet for magnetisation, difficulties may be encountered in attaining the full magnetisation if  $H_{CJ}$  is too high.

Magnets in the three main groups Alnico, ferrites and rare-earth alloys are generally made anisotropic with the properties in one direction considerably better than in the other directions. This best direction is called the preferred direction of magnetisation. The curves and parameters applied to such a material refer to the properties in this preferred direction. To choose between these three materials for a particular application, Alnico must be used where magnetic stability is a requirement and this will apply in any type of instrument application. Ferrite will be used where cost is the main consideration and rare-earth magnets will be used if the highest possible strength is required or if miniaturisation is needed.

### 8.7.1 Alnico alloys

A wide range of alloys with magnetically useful properties is based on the Al-Ni-Co-Fe system. They are characterised by high remanence and available energy and moderately high coercivity. They are very stable against vibration and have the widest useful temperature range (up to over 500°C) of any permanent magnet material. They are however mechanically hard, impossible to forge and difficult to machine except by grinding and special methods such as spark erosion.

The commonest alloys contain 23–25% Co, 12–14% Ni, about 8% Al, a few per cent of Cu and sometimes small additions of Nb, Ti and Si, with the balance being iron. They are cooled at a controlled rate in a magnetic field applied in the direction in which the magnets are to be magnetised. The properties are much improved in this direction at the expense of those in the other directions. There is finally a fairly prolonged and sometimes rather complicated heat treatment at temperatures in the range 550–650°C. With the aid of the electron microscope it has been shown that after this treatment the magnets have a two-phase structure consisting of fine elongated magnetic particles separated by a non-magnetic phase, this structure being oriented by the magnetic field applied during cooling.

The field cooling is more effective in producing anisotropic properties if the magnets are cast with a columnar structure. Casting the alloy into a very hot mould placed on a cold steel plate produces this columnar structure. The moulds are usually made from exothermic material and the molten alloy is poured into this mould. This is a rather expensive process and there are limitations on the lengths and shapes of magnets that can be made into this columnar form.

The coercivity of Alnico can be improved by a factor of 2 to 3 by increasing the cobalt content to 30–40% and adding 5–8% Ti with possibly some Nb. For the best properties it is necessary to hold these alloys for several minutes in a magnetic field at a constant temperature, accurately controlled to  $\pm 10^\circ\text{C}$ , instead of the usual field cooling process. This meticulous heat treatment as well as the high cobalt content makes these alloys expensive and they are only used where the higher coercivity is required. Columnar versions of these alloys can also be made but they are very brittle and are only used for very specialised applications.

The Alnico alloys can be produced as castings of up to 100 kg and down to a few grams in weight but it is found more economical to produce the smaller sizes of 50 g and less by the sintering process. It is always advisable to contact the manufacturers before any design is considered.

### 8.7.2 Ferrite

The permanent magnet ferrites (also called ceramics) are mixed oxides of iron (ferric) oxide with a divalent metal oxide usually either barium or strontium. These ferrites have a hexagonal crystal structure, the very high anisotropy of which gives rise to high values of coercivity, e.g. 150–300 kA/m (compared with about 110 kA/m for the best Alnico alloys). The general formula is  $\text{MO} \cdot 5.9(\text{Fe}_2\text{O}_3)$  where M is either Ba or Sr. These ferrites are made by mixing together barium or strontium carbonate with iron oxide in the correct proportions. The mixture is fired in a mildly oxidising atmosphere and the resulting mixture is milled to a powder of particle size of about 1  $\mu\text{m}$ . The powder is then pressed in a die to the required shape (with a shrinkage allowance), anisotropic magnets are produced by applying a magnetic field in the direction of pressing. After pressing the

compact is fired. This compound is a ceramic and can only be cut using high speed slitting wheels. Ferrite magnets are produced in large quantities in a variety of sizes for different applications. Flat rings are made for loudspeakers ranging up to 300 mm in diameter with a thickness of up to 25 mm. Segments are made for motors with ruling diameters from 40 to 160 mm and rectangular blocks are made for separators with dimensions of up to 150 mm  $\times$  400 mm  $\times$  25 mm. These blocks can be built up into assemblies or cut down into smaller pieces for a variety of applications. In each of these cases the preferred direction of magnetisation is through the shortest dimension. Generally the magnetic length does not exceed 25 mm and if a longer length is required, this is built up with magnets in series.

The great success of permanent ferrites is due to the low price per unit of available energy, the high coercivity, the high resistivity and the low density. The isotropic grades are the least expensive to manufacture and may be magnetised into complex pole configurations; they are used for a wide range of relatively small sized applications. The largest application in terms of market volume is for magnets for motors which use high coercivity anisotropic ferrite in the form of an arc-shaped segment. These segments are magnetised radially and a pair of segments surround the armature and provide the stator field. The application for these d.c. motors is particularly in the automotive industry, e.g. for windscreen wipers, window movers, blowers etc. Another large volume application is for loudspeakers where the

high remanence grades are used. Other applications of anisotropic hard ferrites include magnetic chucks, magnetic filters and separators.

### 8.7.3 Rare earth cobalt

The  $\text{SmCo}_5$  alloy was the first of the rare-earth permanent magnet alloys. The alloy powder is prepared by chemically reducing the rare earth oxide powder together with cobalt powder. The resulting powder is compacted and pressed almost invariably in a magnetic field to produce anisotropic magnets. The properties are due to a very strong magneto-crystalline anisotropy related to its hexagonal crystal structure. The range of sizes which can be produced is from about 1 mm cubes up to blocks of 50 mm  $\times$  50 mm  $\times$  25 mm, the short dimension being the preferred direction.

A more recent development is  $\text{Sm}_2\text{Co}_{17}$  which is the generic title for a series of binary and multiphase alloys with a number of transition metals replacing some of the cobalt. These alloys have a number of advantages over  $\text{SmCo}_5$  alloys, they include a higher remanence  $B_r$  and energy product  $(BH)_{\max}$ , greater temperature stability and lower material costs. This potential lower cost is however offset by the difficulties of production including a long heat treatment and inconsistency of properties. The good temperature stability, the best for the rare-earth alloys, makes it attractive for some applications.

**Table 8.5** Characteristics of permanent magnet materials\*

NdFeB bonded	Walkman motors and earpieces Small motors for hand tools, toys etc. Holding devices

### 8.7.4 Neodymium iron boron

The basic alloy is Nd<sub>15</sub>Fe<sub>77</sub>B<sub>8</sub>; it came out of efforts to produce high energy magnets which do not contain cobalt and from interest in amorphous alloys produced by very rapid cooling from the melt. When alloys of the appropriate NdFeB composition are recrystallised, a material with very good permanent magnet properties is obtained. The crystal structure of this alloy is tetragonal, the long axis being the preferred magnetic direction. The alloy powder can be produced by ball milling or by reduction of the neodymium oxide using calcium. However, a more popular development is to reduce the particle size of the alloy by contact with hydrogen. In this HD (hydrogen decrepitation) process, the hydrogen is absorbed with considerable expansion of the alloy causing it to break down into powder. The hydrogen is then pumped away. This is followed by jet milling to reduce the size of the powder to the optimum size. The resulting powder is then pressed in a magnetic field to produce an anisotropic compact and sintered. Throughout the processing the powder is kept either under a protective atmosphere or under vacuum to protect the neodymium from oxidation.

The advantages of magnets made from this alloy are that they have higher remanence  $B_r$  and  $(BH)_{\max}$  than the SmCo alloys and they are also cheaper because Co and Sm have been replaced by Fe and Nd. The disadvantages are that they are subject to corrosion and to a rapid change of magnetic properties with temperature, particularly coercivity changes. Coating the magnets with polymer or metal films, depending on the application can prevent corrosion. The elevated temperature properties can be improved by additions of small amounts of dysprosium, gallium, niobium or vanadium. These last two elements may also give improved corrosion protection.

A further development of the HD process is the HDDR (hydrogen, disproportionation, desorption and recombination) process. This can produce very fine powder after a heat treatment under vacuum. This powder is suitable for the production of anisotropic magnets by pressure or for mixing with a polymer to produce bonded magnets.

### 8.7.5 Bonded materials

Each of the above materials can in the powdered form be mixed with a bond pressed to shape and cured either cold or in an oven. The bonds can be rubber, polymer or plastics and they may be flexible or rigid. The flexible rubber bonded ferrites have found wide application in holding and display devices and the best quality anisotropic material is used in small motors. Alnico and rare earth cobalt are also made in the bonded form, they have the advantage of a uniform level of properties and freedom from cracking. Bonded magnets are not so good as the cast or sintered materials, at best the  $(BH)_{\max}$  is about 50% of the solid forms.

For bonded NdFeB magnets the powder is very often made in the form of flake. Rapidly quenched melt spun ribbon is produced by ejecting molten NdFeB alloy through a fine orifice onto a rapidly rotating water cooled wheel. The ribbon is crushed into fine flake. The bonded magnets are produced by mixing the annealed flake with epoxy resin, pressing the mixture into the required shape and subsequently oven curing. The moulding procedure may be either injection moulding or compression moulding. Injection moulding is the best for bulk production but compression moulding provides better magnetic properties. This MQ1 flake material is isotropic and is used for a wide range of applications including hand held tools, holding devices and motors. Powder produced by the HDDR process mentioned above may be better for some applications as a higher  $(BH)_{\max}$  is possible than with the flake.

### 8.7.6 Other materials

There are a number of other permanent magnet materials with minority applications. This is often because they can be mechanically formed to shape, which is not possible for Alnico, ferrite or rare-earth alloys. It must be emphasised that these other materials are only available in a limited range of sizes and shapes.

Steels, which were the original permanent magnets, are now almost obsolete because their properties are inferior to those of the materials mentioned above. They do, however, find applications in hysteresis motors where lower coercivities are required.

CrFeCo is an alloy which can be rolled and drawn into wire, it has properties similar to those of Alnico. The alloy FeCoVCr can be drawn into wire, which produces the anisotropy. Platinum cobalt (PtCo) which has a very high coercivity was much used in the early days of space research. For most applications it has now been replaced by rare-earth alloys. However it is still used for medical and other applications where resistance to corrosion is required.

### 8.7.7 Properties, names and applications

The range of properties for each class of material is given in Table 8.5. These ranges include deliberate variations in properties obtained by small changes in composition and heat treatment.

Permanent magnets have for many years been used for a wide range of applications. The ferrite (ceramic) magnets provide cheap magnets which are used for small motors and many other applications in the automobile industry. The ferrites are also used as ring magnets for radio and hi-fi loudspeakers and are prepared as blocks which can be cut up for a wide range of applications. The very great improvement in the available properties provided by the rare-earth magnets has focused interest on permanent magnet motors and the associated electronic equipment. In recent years there has been a movement from the SmCo alloys to NdFeB alloys but for some applications Sm<sub>2</sub>Co<sub>17</sub> is preferred because of its better corrosion resistance and elevated temperature properties. Table 8.6 lists the important applications of the various permanent magnetic materials.

## 9.1 Introduction

The three major uses of electricity in industry are motive power, lighting and in the provision of heat for processes. The latter is perhaps the most interesting since it covers such a wide variety of products ranging from metals, glasses and ceramics to textiles, paper, food and drink. The processes covered involve aspects of the whole frequency range from d.c. to ultraviolet and power levels from a few watts to many megawatts (*Table 9.1*). With the changes away from 'smoke stack' industries some electroheat processes have decreased in importance but others involved in the newer higher value operations are widely accepted.

## 9.2 Direct resistance heating

Direct resistance heating is used in the iron and steel industry: for heating rods and billets prior to rolling and forging; for ferrous and non-ferrous annealing; either alone or in combination with other fuels for melting glass; in electrode boilers, for water heating and steam raising; and in salt baths, for the surface heat treatment of metallic components.

### 9.2.1 Metals

The resistivity of several common materials is shown in *Table 9.2*, and *Figure 9.1* shows the variation in resistivity with temperature of some of these. The relatively high resistivity of steel allows billets of up to 200 m<sup>2</sup> to be heated efficiently, provided that the length is several times greater than the diameter. The heating time is of the order of seconds to a few minutes, so that heat losses (e.g. radiation from the surface and thermal conduction through the contacts) are small. The efficiency of the process can be of the order of 90% or better. The workpiece resistance is normally low, and for these efficiencies to be achieved the supply resistance must be much lower. The low resistivity of copper and similar materials implies that the length/diameter ratio should be considerably higher than 6 if the process is to be successful, and with these materials the more common application is the annealing of wire and strip. In all cases the cross-sectional area of the current-flow path must be uniform, otherwise excessive heating, with the possibility of melting, will occur at the narrower sections. With the normal 50-Hz supplies non-uniform current distribution caused by skin effect leads to higher heating rates at the surface, but this is counteracted by increased surface heat loss.

**Table 9.1** Electric heating processes

<i>Technique</i>	<i>Frequency range</i>	<i>Power range</i>
Direct resistance	0–50 Hz	0.01–30 MW
Indirect resistance	50 Hz	0.5–5 kW
Oven, furnace	50 Hz	0.01–1 MW
Arc melting	50 Hz	1–100 MW
Induction heating	50 Hz–450 kHz	0.02–10 MW
Dielectric heating	1–100 MHz	1–5000 kW
Microwave heating	0.5–25 GHz	1–100 kW
Plasma torch	4 MHz	0.001–1 MW
Laser CO <sub>2</sub>	30 THz	0.1–60 kW
Infra-red	30–400 THz	1–5000 kW
Ultraviolet (mercury arc)	750–1500 THz	1 kW

**Figure 9.1** Variation of resistivity with temperature (relative to 0°C) of aluminium, copper, nickel and iron

**Table 9.2** Resistivity of typical metals

<i>Metal</i>	<i>Resistivity (μΩ-cm)</i>
Copper	1.6
Aluminium	2.5
Nickel	6.1
Iron	8.9
Mild steel	16.0
Stainless steel	69.0

A typical supply circuit is shown in *Figure 9.2*. The high-current transformer will usually have off-load tapplings to take account of the major changes in workpiece resistivity that occur over the heating cycle. The reactance of this transformer and its associated connections should be minimised and the whole arrangement must be designed to withstand the magnetic forces at the high currents involved which, in the larger units, can be in excess of 100 kA. Although this is a resistance-heating application, the inductance of the circuit may result in a power factor as low as 0.4 at the start of the process, and power-factor-correction capacitors are often incorporated.

A high contact resistance between the supply and the workpiece leads to excessive voltage drop and local overheating. Large-volume contacts behave as heat sinks with

**Figure 9.2** Electric circuit for direct resistance billet heater

the possibility of cold ends, and welding of the contact to the bar may occur. Allowance needs to be made for the longitudinal thermal expansion during heating. One commercial arrangement uses a number of hemispherical contacts of copper alloy at each end of the bar, applied by hydraulic pressure. Liquid contacts have been employed for the continuous heating of wire and strip. Sliding or rolling metal-metal contacts are also used.

Process control can be achieved on the basis of a simple timed cycle with the transformer tapings adjusted during the cycle to maintain the required current. A refinement involves weighing the billet before the process is started and using this information to adjust the cycle time to give the required temperature. Other installations are controlled by an optical pyrometer to monitor the surface temperature and feed back a signal to the control system. Wire and strip heating installations usually employ throughput speed as the control variable.

The direct resistance heating of bar or billets is a one-phase load that is switched at frequent intervals. This results in voltage unbalance at the point of common coupling and in transient voltage disturbances. The load can be phase balanced by inductive and capacitive components. In large units the switch-on disturbances may be compensated by a soft-start arrangement.

### 9.2.2 Glass

Glass at temperatures above  $1100^{\circ}\text{C}$ , has low viscosity and a resistivity low enough (Figure 9.3) for direct resistance heating at acceptable voltages to be considered.

In the UK, electricity is used in mixed melting units where, typically, electrodes are added to a fuel furnace to increase the output for a relatively low capital outlay. Current is passed between electrodes immersed in the molten glass. These electrodes must withstand the high temperatures involved and the movement of molten glass across their surface, and must be protected from exposure to the atmosphere. Contamination of the glass by pick up of electrode material must also be avoided and either molybdenum or tin oxide electrodes are used with current densities of the order of  $1.5\text{ kA/m}^2$ . A one-, two- or three-phase electrode system may be employed; the two-phase connection uses Scott-connected transformers. The three-phase arrangement is preferred for phase balance and low cost, and also produces electromagnetic forces in the glass which, together with the thermal forces, lead to significant movement in the melt. Provided that it is not excessive, the movement improves quality and melting rate.

Figure 9.3 Variation of resistivity with temperature of glasses

Existing electric furnaces have usually followed a traditional design pattern with a rectangular tank, but circular designs have now been developed which are claimed to give improved stirring in the melting zone.

The power input to the furnace, and hence the melting rate, is controlled by varying the input voltage by use of tapped transformers or saturable inductors. An alternative method is to change the effective surface area of the electrodes by raising them from the melt.

### 9.2.3 Water

The generation of steam and hot water by passing current between electrodes in water is now common practice. As with molten glass, the conductivity is dependent on the ions that the water contains, but in many districts it is sufficient to use normal tap water. Electrode boilers range in size from a few kilowatts up to 20 MW. The larger capacity units operate at high voltages up to 6 kV, and the water is sprayed on to the cast-iron electrode. The heating rate is regulated by moving a porcelain shield over the jets to divert the water. Output control in the smaller units is achieved by varying the surface area of the electrode in contact with the water, either by vertical movement of the electrodes or, more simply, by changing the water level in the boiler. It is important to ensure that the conductivity of the water is maintained at the appropriate value: too low a conductivity reduces the power, while if the resistivity is too high the result is a deposition of insoluble salts on the electrodes. In large units the conductivity and pH are continuously monitored and their values automatically controlled.

### 9.2.4 Salt baths

Salt baths can be used for heat treatment of metal components. The heated salt reacts chemically with the surface layer of the workpiece to give the required surface properties. At temperatures above about  $800^{\circ}\text{C}$  direct resistance heating as opposed to the use of sheathed elements or external heat sources is the only usable method. Although the salt is a good conductor when molten, the bath must be started up from cold by using an auxiliary starting electrode to draw a localised arc. The electrodes have to withstand the corrosive effects of the salt and are manufactured from graphite or a corrosion-resistant steel alloy. The currents involved can be up to 3 kA at voltages of 30 V. Both one- and three-phase units are available.

### 9.2.5 Other fluids

In recent years the principles of electrode boilers have been extended to the heating of a number of other fluids, under the generic term of *ohmic heating*. Units having a heating capacity of up to 200 kW operating at voltages up to 3.3 kV have been used to heat foodstuffs containing solid particulates (with characteristic dimensions of up to 25 mm) to temperatures of  $140^{\circ}\text{C}$ , thus cooking and sterilising the foodstuff in a single very rapid (in some instances a few tens of seconds) operation, which preserves the quality and taste of the food for subsequent packaging and unrefrigerated storage with a shelf-life of many months.

The potential of the technique for heating other fluids which tend to foul conventional heat-transfer systems, but without the expense of microwave or r.f. generators, has also been exploited in the heating of clarified sewage and sewage sludge to maintain process temperatures during the treatment at sewage works, and as a possible method of pasteurising the final effluent from the works.

The technique also lends itself to the heating of highly corrosive conducting liquids, provided materials can be identified for the electrodes and heater enclosure which are capable of withstanding the conditions in the heater for reasonable periods of time, without introducing unacceptable levels of contamination into the liquid stream.

### 9.3 Indirect resistance heating

In this method, electricity is passed through a suitable conducting material or element which then transfers its heat by conduction, convection and/or radiation to the target material or process. The element becomes the hottest component of the system and the factors which determine the choice of element materials depend on the nature of the heat transfer process employed and the physical and chemical characteristics of the process environment.

All such elements have the following characteristics:

- (1) they are electrically conducting materials;
- (2) they are supplied with electricity via a suitable contact, cold end or terminal block, and leads;
- (3) they need mechanical support;
- (4) they are solid materials; and
- (5) they have properties enabling an economic operating life for the environment or process chosen.

#### 9.3.1 Metallic elements

Traditionally, metallic elements take the form of wire, strip or tape. This calls for reasonable ductility in the manufacturing process. For a given operating temperature, the element life tends to decrease with decreasing cross-section of element caused by progressive oxidation of the surface or reduction in mechanical strength and so, in practice, an optimum element thickness for economic life exists for each application. The choice of metal composition will depend upon the operating temperature required, the material resistivity, the temperature coefficient of resistance, high temperature corrosion resistance, mechanical strength, formability, and cost. Metallic elements can be manufactured to close tolerances and, provided the material is in the fully annealed, slowly cooled condition, will have nominal resistivities within  $\pm 5\%$ .

Whilst many metals and alloys are used as element materials, the most common for industrial applications are alloys based on nickel–chromium, iron–nickel–chromium alloys, or iron–chromium–aluminium alloys. All depend on an adherent non-spalling, self-sealing oxide layer forming on the surface of the alloy. Further oxidation is limited by diffusion of reacting species through this oxide layer. The iron–chromium–aluminium alloys rely on an alumina film developing on the surface, whereas the nickel–iron–chromium alloys depend on chromium oxide. Generally, the iron–chromium–aluminium alloys can operate at higher temperatures than the nickel–chromium based alloys, but are not as readily fabricated. The most exotic metals (platinum, tantalum, molybdenum, etc.) are used for special laboratory or high temperature vacuum work. *Table 9.3* summarises some of the characteristics of these materials.

When used in a freely radiating state, the elements need to be supported on ceramic tubes, pins or correctly insulated metallic pins. If ceramic supports are chosen, it is important that they have sufficient mechanical strength to prevent sagging and have a sufficiently high electrical resistance at the working temperature to prevent excessive leakage current. Elements can also be supported in grooves in bricks, partially or fully embedded in ceramic fibre vacuum formed blocks or

cast refractory blocks. It is important to reduce the furnace wall loadings to suitable levels when employing these techniques, and that the electrical loadings, often quoted in terms of watts per square centimetre of element surface, and the geometry of the element and supports comply with the element manufacturer's recommendations.

Advice and literature on this subject is readily available from suppliers.

#### 9.3.2 Sheathed elements

The elements may be protected from the working environment by the use of a suitable insulation layer separating the element from an outer sheath. In many domestic appliances, for example cooker rings, immersion heaters and kettle elements, a purified magnesium oxide powder separates the helical element coils from copper, stainless steel or nickel based alloy sheath material. In these cases the element is often rated in terms of watts per square centimetre of sheath. Such mineral insulated elements are also used in industrial applications as cartridge heaters, radiant panels and immersion heaters.

Thin strip or band heaters are available which use a mica insulation between the element and the sheath.

Higher rated industrial units employ a protective metallic or thermally conducting ceramic sheath insulated from the elements by an air gap created by suitable ceramic supports and spacers. As before, careful consideration should be given to selection of materials for use in each application regarding the heat transfer, electrical and mechanical properties and corrosion characteristics.

#### 9.3.3 Ceramic elements

Silicon carbide, molybdenum disilicide, lanthanum chromite and hot zirconia are examples of ceramic materials which have sufficient electrical conductivity to act as element materials. The silicon carbide and molybdenum disilicide elements depend on a protective, self-sealing silica layer on the surface. These materials tend to be brittle and have to be handled with care, but they can achieve much higher temperatures and surface loadings in air than can conventional metal elements. They also can have unusual temperature coefficients of resistance as shown in *Figure 9.4*. Note that the values shown in this figure are for illustrative purposes only. The actual resistivity will depend on purity, grain size and method of manufacture. Careful selection of element size, shape and working resistance is required in practice, and advice regarding the choice of element, support, insulation and electrical supply characteristics should be sought.

Graphite is another recognised non-metallic element material which, of course, should be operated in the absence of oxygen or gaseous oxygen compounds such as steam and carbon dioxide.

Ceramic elements generally consist of a hot zone either created by a thin section or a spiral cut supported by two or more cold ends which are either thicker in cross-section or which have been impregnated with a metallic phase to lower the resistance locally. Examples, together with their metallic counterparts, are shown in *Figure 9.5*. Ceramic elements must be free to expand and contract in their support system, otherwise tensile failure may occur.

#### 9.3.4 Terminals and leads

The means of connecting the elements to the electrical supply is a very important design requirement and the correct choice of location, materials and joining method can

maximise reliability. The temperature of the joint should be kept as low as possible. This can be achieved by using large terminations of high thermal conductivity arranged such that the contact resistance is low and any heat generated in this region can be dissipated correctly. Materials with a good electrical conductivity and high oxidation resistance at the expected temperature are recommended. Several types of nickel alloy can be employed for high-temperature connections, and aluminium braid, held in place with special clips, is used to connect to the cold ends of ceramic elements.

For terminals exposed to wet conditions it is important to ensure adequate corrosion resistance and this should include consideration of avoiding electrochemical corrosion couples by choice of incompatible alloys as well as the danger of electrical shorting across the terminals themselves.

Leads should be of low resistance and should have sufficient section to dissipate any joule heating ( $I^2R$ ) incurred.

Note that the use of thyristor-control systems may require the use of leads and cables up-rated to cater for harmonic currents.

### 9.3.5 Aggressive environments

Carbon and sulphur are harmful to nickel based alloys, and chlorine or molten chloride or liquid metal splashes can damage both nickel and iron-chromium-aluminium based alloys. Element materials which rely on a self-sealing oxide for protection may be damaged by reducing atmospheres and the maximum operating temperature of the elements for such conditions, or the element surface electrical load ( $\text{W}/\text{cm}^2$ ), may be reduced accordingly. Protective tubes or sheaths may be used for such environments. However, this may impose an additional space requirement in the process and should be considered during the design stage.

Immersion heater sheath materials should be matched to the process environment too. *Table 9.4* lists some of the materials commonly used for this purpose.

### 9.3.6 Infra-red heaters

Infra-red is one of the most widely used electrical process heating techniques in industry, finding applications in all sectors. The intensity distribution of radiation with wavelength from an infra-red source varies with its temperature. Proportionately more of the power is radiated at shorter wavelengths as the temperature of the source is increased (*Figure 9.6*). Typical input power densities to different types of infra-red sources are given in *Table 9.5*, with many

of the comments given earlier in Section 9.3 applying also to their use for infra-red heating. The lower temperature infra-red sources (long and medium wave) are normally used for heating and drying non-metallic materials as these generally absorb at the longer wavelengths. Short-wave heaters are used where higher product temperatures are required (e.g. metal heat treatment), high intensities and through heating of suitable materials.

Efficient use of infra-red radiation for heating is assisted by matching the spectral output of the infra-red source to the reflective and absorptive properties of the product in the infra-red range. Materials considered to be good absorbers of infra-red radiation, because they are opaque, can show a significant degree of reflection, particularly at short wavelengths. Materials of thick section which show a considerable degree of transparency to some infra-red wavelengths, can advantageously be through heated by choosing an infra-red source producing most of its output at these wavelengths.

Control of infra-red heating can be effected in a number of ways. Infra-red heaters are generally of low power rating (less than 10 kW). Thus an infra-red heating installation will often use many heaters which can either be switched on/off individually or in groups, or the voltage/current to each or groups can be adjusted. As control of heating systems increases, contact or remote (pyrometers) temperature sensing of the product is used, with information fed back to the control system for the heaters. One aspect of altering the power input to an infra-red heater is that its temperature, and hence its spectral output, will be changed which can have implications for the efficient heating of those materials which show a variation in infra-red absorption with wavelength.

## 9.4 Electric ovens and furnaces

Electric ovens and furnaces are used for a great variety of different processes, ranging from sintering ceramic materials at temperatures up to 1800°C to drying processes close to ambient temperature at power ratings varying from a few kilowatts to more than 1 MW. A substantial part of the electric heating load is taken by electric ovens and furnaces of conventional design used for heat treatment (*Table 9.6*) and similar processes at temperatures up to about 1100°C.

### 9.4.1 Heating-element construction for ovens and furnaces

The materials used for resistance heating elements have been listed in *Table 9.3*. Forms of construction of furnace heating

elements are shown in *Figure 9.5*. Metal resistance heating elements for furnaces are normally in the form of wire, strip or tube. Heavy-section low-voltage high-current elements are made with an alloy casting or with corrugated or welded tube. Helically wound wire heating elements are manufactured with wire-to-mandrel diameter ratios of between 3:1 and 8:1, limited by collapse of the helix. The helix is then expanded so that its length is about three times the close-wound length. Coiled-wire or strip heating elements may be inserted in ledges or grooves supported at intervals by nickel alloy or ceramic pegs. The end connections of the heating elements, normally made of a material different from that of the element to reduce attack from oxidation and chemical reaction with the refractories, have a lower resistance to reduce heat dissipation where the leads pass through the furnace wall; this lower resistance is achieved by making the diameter of the ends greater than that of the heating zone or by using a material of high electrical conductivity.

Silicon carbide rod or tubular heating elements are mounted vertically at the side or arranged to span the roof of the furnace. The cold ends of these rod elements are impregnated with silicon or made by joining end sections of higher conductivity. The hot zone of a tubular element is obtained by cutting a helix so that the current path length is increased and the cross-section is reduced which increases the resistance. Single-ended double-spiral and three-phase rod heaters can be suspended vertically from the roof of the furnace.

Molybdenum disilicide is normally available only in the hairpin or W-form of construction for suspending vertically or supporting in a horizontal plane. The heating zone is of reduced cross-section to increase the resistance. Graphite in the form of machined rods or slabs, or as tubes, is used in muffle furnaces.

### 9.4.2 Ovens

An oven is usually defined as having an upper temperature limit of about 450°C. Ovens, using natural or forced convection, are widely employed for drying and preheating plastics prior to forming, curing, annealing glass and aluminium baking and a host of other applications. Coiled nickel-chrome wire or mineral-insulated metal sheathed heating elements are distributed around the oven so as to obtain as uniform a temperature distribution as possible. Heat transfer rates may be increased by using a fan to circulate air over the heating elements onto the workpiece, the air being recirculated through ducts. An important advantage of convective ovens is

**Table 9.6** Heat-treatment processes

Metal	Treatment process	Temperature range (°C)
Aluminium and alloys	Annealing	250–520
	Forging	350–540
	Solution heat treatment	400–500
	Precipitation hardening	100–200
	Stress relief	100–200
Copper	Annealing	200–500
Brass	Annealing	400–650

	Hardening	950–1050
Cast iron	Annealing	500

**Figure 9.7** Infra-red conveyor ovens. (a) Horizontal conveyor; (b) Vertical conveyor

that the operating temperature is normally the element temperature and the maximum temperature is never exceeded as the process is self-limiting, which prevents overheating if the material is left in the oven too long. This is particularly important for temperature-sensitive materials such as plastics.

High heating rates can be achieved by direct radiation from heating elements in infra-red ovens. The oven walls are made of sheet metal which reflects the radiation, and vapour is easily removed. Two forms of continuous infra-red ovens are illustrated in *Figure 9.7*, the low thermal mass and weight allowing a light-weight structure and a very high power density. The high-intensity lamps employed have a low thermal inertia and can be switched to a low level of stand-by power, full power being used only when the workpiece is inside the oven. Infra-red heating processes are advantageous when only the surface layer is required to be heated, for example when curing coatings, so that the overall efficiency may be very high compared with other methods which heat also the substrate.

### 9.4.3 Furnaces

Furnace construction depends on the application. Some examples of batch furnaces for heat treatment are shown in *Figure 9.8*. The heating elements are arranged around the sides of the furnace and, where very uniform heating is required, also in the roof, door and hearth. Radiation from the heating elements and from the refractory lining occurs, so that the internal surface of the furnace approximates to a black-body enclosure.

Forms of work handling used with batch furnaces include bogie or car-bottom hearths and elevated hearths raised into the furnace on hydraulic rams to facilitate loading and unloading. The box furnace is normally used at temperatures where radiation is dominant. Where it is necessary to avoid exposure to air during the quenching process, the sealed quench furnace is used. Forced convection furnaces allow high heating rates and with careful design, good temperature uniformity can be achieved; but usually these are limited to maximum temperatures of 700–900°C. In the pit furnace, capable of operating at higher temperatures, radiation is the dominant mode of heat transfer and, by using a retort, the process can be carried out in a controlled atmosphere.

The bell furnace may be used as a hot-retort vacuum furnace. By reducing the pressure inside the bell, very low partial pressures of oxygen are obtained. Since heat losses by convection are greatly reduced at low pressures, the bell can be raised when the required temperature is reached, one bell then being used to heat several retorts.

The rectangular bell furnace is a form of box furnace that allows unimpeded access to the furnace hearth. It is useful for heat treating large components such as mill rolls or fragile items such as ceramics. The cold-retort vacuum furnace allows very high temperatures to be achieved. It is used for heat treatment and brazing in controlled low-pressure atmospheres using vacuum interlocks to achieve high throughputs. The hydrogen muffle furnace is used for sintering alumina at 1700°C, zone refining where a precise temperature profile is required, and the continuous annealing of wire and strip in controlled atmosphere by use of an open-ended muffle.

Continuous furnaces use a conveyor mechanism enabling in-line processes to be carried out combining heating and cooling at a controlled rate (*Figure 9.9*). Some examples of different conveyor mechanisms are illustrated in *Figure 9.10*. The choice depends on the nature of the process and the size of the workpiece. Applications range from bright annealing of fasteners to normalising steel billets.

## 9.5 Induction heating

Induction heating makes use of the transformer effect. The workpiece is placed in the alternating magnetic field of a coil. The field produces eddy currents in the workpiece, which is heated as a result of  $I^2R$  losses. The induced current density and consequent heating effect is always non-uniform; it depends on the magnitude and frequency of the inducing field and the physical properties of the workpiece. The current density in the workpiece is a maximum nearest to the surface adjacent to the coil conductors and, in the case of a solid workpiece in an enclosing coil, is zero at the centre. The distribution of heating in the body of the workpiece can be controlled by choice of frequency. If the frequency is high, most of the heat is developed in a thin layer, while lower frequencies give a more uniform distribution. Hysteresis loss heating also occurs in ferrous metals; it is normally small compared with the eddy-current effect but it is applicable in heating metal powders at high frequencies. Induction techniques are used for both through heating and surface heating of metallic materials at frequencies in the range 50 Hz to 1 MHz. They are used for melting and also, at very high frequencies, in the manufacture of semiconductor materials, and the hot working of glass.

The eddy-current power  $P$  per unit length of a cylindrical workpiece of diameter  $d$ , resistivity  $\rho_s$  and absolute

Figure 9.9 Conveyor furnace and typical temperature profile

permeability  $\mu$ , induced by an alternating field of strength  $H$  (r.m.s.) and frequency  $f$  is

$$P = H^2 \frac{\pi \epsilon}{2} \left( \frac{d}{\delta} \right)^2 \rho Q \quad (9.1) \Leftarrow$$

where  $\delta$  is the skin depth of the induced current

$$\delta = (\rho / \pi f \mu)^{1/2} \quad (9.2) \Leftarrow$$

$Q$  is a factor depending on skin depth and the shape of the workpiece, and is plotted in Figure 9.11 for a cylinder in terms of a normalised (dimension/skin depth) parameter. Values of  $\delta$ , based on room-temperature resistivities and assuming, where appropriate, a relative permeability of 100 (i.e.  $\mu = 100 \mu_0$ ), are given for a number of materials in Table 9.7. The relative permeability is a function of the applied magnetic field strength and can be as low as 10 in high-intensity heating applications. For design purposes, the value of resistivity appropriate to the average temperature of the workpiece is used. High frequencies (i.e. small skin depths) are needed if workpieces of small dimensions are to be heated.

### 9.5.1 Power sources for induction heating

There is still an economic advantage in being able to use power at the frequency of the mains supply rather than converting to a higher frequency. However, the increased power rating of solid-state converters, their reducing cost/unit power, ease of control and the fact that they present balanced loads to the supply system, means that each application must be carefully assessed. Loads which can be effectively heated at 50 Hz include slabs, large billets and cylinders, and process vessels. Depending on the load rating, the power input is controlled by either an off-load tap changing transformer or an autotransformer. Power-factor correction is usually provided on the primary side of the heater supply transformer, and phase-balancing networks are used to correct the imbalance of large single-phase loads. Voltage transients on the supply network are minimised by the use of soft-start arrangements when switching large loads.

	(b) 34	20	7.6	2.4	0.36

\* (a) Below Curie temperature ( $\mu_r = 400$ ,  $\rho_{\text{sat}}$  at 20°C). (b) Above Curie temperature ( $\mu_r = 4$ ,  $\rho_{\text{sat}}$  Curie temperature).

Power supplies for frequencies above that of the mains supply are now almost invariably based on solid-state converters. Some large installations previously utilised static frequency triplers to provide a 150 Hz supply for through heating slabs prior to rolling, derived from three one-phase saturated transformers with secondaries connected in open delta (Figure 9.12). Harmonics generated in the tripler are filtered by an arrangement of inductors and capacitors. A 20 MW installation of this type is operated in Canada.

Higher frequencies give faster heating rates and, because of skin-effect phenomena, enable the effective induction heating of a smaller cross-section of workpiece. Power at these frequencies, before the advent of the thyristor, was obtained from rotating machines designed to produce power at frequencies up to 10 kHz. They are normally vertically mounted and, in the larger sizes, water cooled. Conventional starting equipment is used for the induction motor. Output power is controlled by varying the d.c. excitation of the alternator field either manually or with an automatic voltage regulator. They have a fixed frequency output and present a balanced load to the supply; the efficiency is comparatively low and falls with decreasing load and increasing frequency. These machines are noisy and were often installed in sound-reducing enclosures.

The availability of high-power thyristors capable of operating at frequencies up to 50 kHz has opened up a new field to the designers of medium-frequency heating equipment. Sources based on these devices are commercially available with power outputs up to about 6 MW at the lower frequencies. The major applications are through heating and melting, and this source has the advantage over the machine of a flexible operating frequency. The efficiency is around 90%,

**Figure 9.12** Three-phase transformer with open delta secondary for generation of the third harmonic

even on partial load. The operating principle is familiar: the rectified 50 Hz supply is chopped by thyristors and fed into a resonant load circuit formed by the resistance and inductance of the loaded work coil together with a tuning capacitor. The firing pulses may be applied at a pre-set frequency; alternatively, the control signal may be derived by feedback from the load circuit. Principal variants of this basic arrangement are commonly referred to as *voltage source*, *current source* and *variable mark/space ratio generators*. A fourth variation, the cyclo-converter, converts the 50 Hz supply directly to the higher frequencies without the intermediate d.c. stage.

At frequencies above 50 kHz, the power source uses a vacuum triode feeding into a tank circuit of which the load forms a part (Figure 9.13) either directly or through a coupling transformer. Water-cooled inductors are used in the tank circuit and, in all but the smallest ratings, the valve is also water cooled. Conventional industrial valves have been and still are used for this application in ratings of up to 500 kW operating in the class C mode with conversion efficiencies greater than 50%. Even higher efficiencies are obtained with the magnetically beamed triode, which has an inherent low grid dissipation. This valve is robust and offers more flexible control than the conventional unit, owing to the lower grid power requirements which enable semiconductor control circuits to be used. Closed-loop control of the process variables, i.e. power and temperature, is possible.

An important version of the triode based r.f. generator uses a high efficiency coupling transformer in the triode circuit, with the tuning capacitors connected directly across the work coil. This 'aperiodic' generator can operate over a wide frequency range, supplying remote workstations at a higher efficiency than the more conventional oscillator.

## 9.5.2 Load matching

The matching of the loaded work coil to the source is extremely important in the successful application of induction heating processes. The impedance of the work coil depends on the geometry and physical properties of the workpiece, the frequency of operation, and the geometry and number of turns of the coil. A matching transformer may be required if the correct impedance cannot be achieved by selection of coil turns. The rating of the power source is minimised by tuning the reactive component of the load impedance with capacitors. These may be connected in series or parallel directly with the load coil, or on the primary side of the matching transformer, depending on the coil voltage and type of power source.

The load impedance will change during a heating cycle which might necessitate re-tuning or re-matching to the source.

## 9.5.3 Coil design

Coil designs depend on the operating frequency and the application. The basic objectives are to produce the

**Figure 9.13** Basic oscillator circuit for r.f. induction heaters

required magnetic field strength over that section of the workpiece to be heated and to insulate the coil both to prevent electrical breakdown and to reduce heat transfer from the workpiece to the coil. The heat generated by the  $I^2R$  loss in the coil usually requires some form of forced cooling, and it is customary to use hollow water-cooled copper tubular conductors. The current distribution in the coil conductors is non-uniform. It is frequency dependent, and affected by the proximity of adjacent conductors, the presence of the workpiece and the geometry of the winding.

Although most units employ only one layer of winding, there is now widespread use of multilayer windings for the heating of non-ferrous billets at supply frequency. With the correct choice of conductor cross-section, multilayer coils offer significant energy savings in these applications.

#### 9.5.4 Through heating of billets and slabs

Induction heating is used extensively for the through heating of both ferrous and non-ferrous metal billets prior to rolling or forging. The billets, of circular or rectangular cross-section, are either heated individually or passed in line through a series of induction coils. The frequency of the current, the power input and the length of time in the coil are chosen to give the required throughput rate with an acceptable temperature distribution over the cross-section of the workpiece. A compromise is sought between high heating rates produced by high frequencies, and an acceptable skin depth. A typical example is a 350 kW, 1 kHz unit for heating steel transmission forgings to a temperature of 1150°C; the energy consumption is of the order of 400 kWh/t and the heating time can be less than 5 min. Heaters with power outputs of up to 6 MW are readily available and, although the frequency for most applications is in the range 50 Hz to 3 kHz, higher values (up to 50 kHz) are occasionally employed. The efficiency of the process is a function of the coil design and the coupling between it and the workpiece. In some instances a tapered coil has been used to allow for the changing parameters of the workpiece material as the temperature increases during the process. The workpiece resistivity at the final working temperature may be four or five times that at 20°C and, in the case of ferromagnetic materials, the relative permeability will fail to unity when the Curie temperature is reached.

Metal slabs are also heated by induction processes. One of the largest single installations is in the USA, where a 200 MW, 60 Hz power supply heats large steel slabs prior to rolling, at a maximum rate of 600 t/h. Average energy consumption is reported as 340 kWh/t for a 22 t slab. A more recent installation in Sweden rated at 37 MW heats 15 t slabs, for rolling, at the rate of 85 t/h. Thin slabs, from continuous casting machines or at an intermediate rolling state, are heated at medium frequency.

#### 9.5.5 Strip heating

The heating of continuous-strip materials by the conventional induction method requires the use of frequencies above 10 kHz and efficiencies are low for non-ferrous materials. A preferred technique is the transverse flux method where, for example, efficiencies above 70% can be achieved heating thin aluminium strip at 250 Hz. The strip is passed between two flat inductors comprised of windings in a laminated iron, or ferrite, core which form a series of magnetic poles. The flux passes transversely through the sheet and currents are induced in the plane of the sheet. The winding and pole arrangement must be designed to give uniform heat distribution over the moving strip. Installations rated

at 1.8 and 2.8 MW are operating in Japan and Belgium, respectively, for the heat treatment of aluminium strip.

Development is also being carried out on the travelling-wave induction heater, which utilises a three-phase winding operating at 50 Hz similar in construction to that of a linear motor with the secondary (workpiece) held stationary. Applications of interest are the heating of metal cylinders and tanks; this technique could also be used for the heating of sheets and slabs.

#### 9.5.6 Surface and localised heating

Induction heating at high frequencies (up to 500 kHz) is used extensively in the engineering manufacturing industries for the hardening of bearing surfaces, welding and brazing and similar surface heat treatment processes. The workpiece is placed in a coil (*Figure 9.14*) designed to cover the area to be heated. Heating takes place within a few seconds and, owing to the high frequencies, is confined in the earlier stages to a thin surface layer. The heated area is then cooled rapidly, so that the required surface hardening effect is obtained while still leaving the centre ductile. Contoured shapes can be heated, as can the internal surfaces of tubes, etc., with suitably designed coils. Flat spiral coils are used for the treatment of localised areas in sheet materials. An extension of the application is to soldering and brazing in which case the field distribution is modified by the use of a field intensifier, a suitably shaped piece of magnetic material such as a ferrite core. The technique is also used for seam welding of steel tubes from flat strip, bent into shape and the two edges welded. The field and, therefore, the heat is concentrated at the two surfaces which are to be welded. In this latter application high throughput rates are achieved by using power sources with ratings as high as 1 MW at 450 kHz.

#### 9.5.7 Semiconductor manufacture

Since the energy from the heating coil can be generated in the workpiece without any heat transfer medium, the whole process can be carried out in a vacuum chamber. This is particularly useful in the manufacture of semiconductor materials. In one technique the material is placed in a conducting crucible in the vacuum space and is heated by induction. Semiconductor materials can also be heated directly by induction without the need for the crucible: in this case very high frequencies up to 4 MHz are used.

#### 9.5.8 Indirect induction heating for non-metals

Induction heating is generally used to heat the 'work' directly, that is the induced currents flow in the electrically conducting object being heated. However, there is an important and growing series of applications where induction heating is used to heat a vessel or container from which heat is transferred by conduction to a non-metal product. Some examples include:

**Figure 9.14** Coils for surface hardening by induction heating: (a) cylindrical coil for shaft hardening; (b) pancake coil for heating flat surfaces; (c) hair-pin coil for localised heating; (d) current concentrator

- (1) induction heating of a vessel containing a solid or liquid;
- (2) induction heating of a pipe through which a liquid flows;
- (3) induction heating of a chemical reactor vessel; and
- (4) induction heated extruders.

These techniques often employ the same coil arrangements as have been discussed elsewhere, but there are some recent developments using novel induction techniques.

An example of such a novel technique is ROTEK, a rotary kiln heated by an unusual form of induction heating and used for drying or calcining granular solids which flow continuously through the revolving kiln drum. The kiln lining and agitating/lifting flights are made from stainless steel or Inconel and heated by the passage of a very large electric current flowing from end to end; this current is too large (perhaps 20 kA or more) to be fed through sliding contacts and the drum therefore forms a single-turn secondary of a ring transformer with a bar primary which passes through its centre (see *Figure 9.15*). The bar primary is fed from a low-voltage transformer and the efficiency of the device as a heater is very high. Because the ring core can be thermally insulated, the operating temperature can be well above the Curie point and, with an Inconel drum, temperatures exceeding 1000°C can be achieved.

## 9.6 Metal melting

### 9.6.1 Introduction

Before considering the types of electric furnaces used today for melting metals, it is useful to review the options available for converting electrical energy into thermal energy contained within the melt. Essentially two approaches are possible. The most direct approach is to employ Joule heating within the metal to be heated. This approach is used in the coreless induction furnace and the channel induction furnace.

The alternative approach is to convert the electrical energy into a heat flux on the metal surface. This can be done in a number of ways. The thermal energy can be derived from an electric arc (either at the metal surface or sufficiently adjacent to it), from an electric plasma (which may or may not be transferred to the surface of the metal) or from the Joule heating of a resistor adjacent to the metal. The resistor may be molten slag on the metal surface, or a crucible containing the metal, or resistance elements adjacent to the metal or its containment crucible. Electron beam and laser heating techniques are not, as yet, widely used for bulk melting operations, although they are finding increasing application on a small scale, for example in the local melting required for fusion welding.

**Figure 9.15** ROTEK: (a) operating principle; (b) cross-section of actual machine

In recent years medium frequency coreless induction furnaces have become widely used for a vast number of ferrous and non-ferrous applications. Resistance-heated furnaces have also become firmly established for melting and holding furnaces in the aluminium and zinc casting industries.

### 9.6.2 Arc furnace

The electric-arc furnace is largely used for the melting of steel scrap to produce liquid steel. Essentially, it consists of a squat cylindrical vessel, refractory lined, with a movable domed refractory roof, as shown in *Figure 9.16*. The furnace is usually charged from a drop bottom bucket. Each of the three graphite electrodes, which pass through holes in the roof, is fed from one phase of the three-phase furnace transformer via flexible cables and bus tubes connecting onto the electrodes. The metal charge forms the star point of the furnace transformer.

Heat-transfer efficiency is high when the arcs are surrounded by solid charge which absorbs the largely radiant energy of the arcs. As the charge melts, the arcs radiate onto the surrounding refractories (which are nowadays largely replaced by water-cooled panels, to reduce overall operating costs), and the thermal efficiency deteriorates because of this. Conversion efficiency of electrical energy into heat in the steel of around 94% is attained.

Electromagnetic stirring may be incorporated by using a non-magnetic steel shell and incorporating a low-frequency stirring coil below the furnace bath. The entire structure, including electrodes, masts, etc., is normally mounted on a hydraulically operated rack and pinion enabling it to be tilted in one direction for pouring and in the reverse direction for slagging. The roof structure is pivoted so that it can be swung aside (with the electrodes raised) for charging. The electrodes can be slipped in the clamp to allow for electrode wear.

The electrode arms can also be raised and lowered individually by hydraulic or winch systems and the electrode height above the melt is controlled by feedback signals derived from the arc voltage and current.

The substation for a large arc furnace is normally adjacent to the furnace itself and contains the furnace transformer, which normally has a star connected primary and an input voltage of 33 kV. The transformer must withstand very large electromechanical forces produced by the high short-circuit currents; it is oil cooled and has terminations brought out to which the flexible cables are connected. The furnace power is

varied by on-load tap-changing. Electrical contact to the electrodes is made by a large copper pad contained in the electrode clamp connected in water-cooled bus-bars which rise and fall with the furnace electrodes. Various configurations have been adopted to ensure that the geometry remains as nearly symmetrical as possible, independent of the bus-bars, to minimise out-of-balance currents. The furnace electrodes are normally connected in delta, and where very high currents are used, the delta is closed at the electrode clamp in order to minimise the effects or reactance in the transformer secondary circuit.

As an electrical load, the arc furnace is less than ideal. The arc can vary between extinction, at zero current, to the short-circuit condition, caused by scrap contacting the electrode. Physical movement of both the solid charge pieces and the melt, when formed, causes variation in the arc length which can fluctuate many times within a second, and superimposed on these effects is arc-length variation caused by the mechanical vibration of the electrode and its supporting structure.

These effects prevent a constant high power level being delivered by each of the phases, and this results in:

- (1) reduced melting rate attained for a given transformer capability;
- (2) the occurrence of current fluctuations which are reflected back into the supply system, these occurring especially in the early stages of the melting operation;
- (3) voltage fluctuations at the point of common coupling to other electricity users; and
- (4) acoustic noise generation from the furnace.

A typical large steelmaking arc furnace is of around 100 t melt capacity and powered at perhaps 50 MVA. No other available electric furnace can match the sort of melting capability attainable from such a single unit, and the furnace, therefore, is likely to remain the only electrical alternative for the tonnages currently required by the steel industry.

#### 9.6.2.1 Submerged-arc process

The submerged-arc process is not essentially an arc process as heating occurs also by direct resistance with, perhaps, some limited heating from arcs and sparks during interruption of the current path. The principal applications are for reducing highly endothermic ferroalloys of high melting point, such as ferromanganese, nickel, chrome, silicon, tungsten and molybdenum, which are subsequently remelted in arc furnaces to produce special alloys. Fused oxides may also be produced via the submerged arc route.

The design of a submerged arc furnace depends on its application. In principle, it is a dish-shaped vessel (*Figure 9.17*),

Figure 9.16 Arc furnace

Figure 9.17 Submerged-arc smelting furnace

brick lined, as with the arc furnace. But there the similarity ends: the dish and the roof are axially fixed, although the roof, together with the electrodes, may rotate. The furnace is charged through ports in the roof, and molten metal and slag flow from the furnace continuously. The electrodes are of the Soderberg type, formed *in situ* by pouring a mixture of pitch and tar plus anthracite into a steel tubular shell. The process is carried out several metres above the furnace, and as the electrode is lowered, it bakes, so driving off the volatile binding. By the time it enters the furnace it is a solid mass. Electrodes capable of carrying very high currents up to 120 kA, can be produced in this way.

#### 9.6.2.2 Vacuum arc furnace

The vacuum arc furnace (Figure 9.18) is used primarily for remelting metals of very high quality, including titanium, tantalum, niobium, hafnium, molybdenum, tungsten, zirconium, and for refining some steel and nickel alloys. Ingots of up to 100 t can be produced. The furnace operates at low pressure, down to about 0.01 Pa, and very effective degassing of the droplets of molten metal (which have a high surface area) occurs. The ingot forms a molten 'skull' which freezes in contact with the copper mould, thus eliminating contamination from refractory linings and the relatively low volume of liquid present minimises thermal stresses and piping at the ends. Impurities either evaporate or collect in the molten pool on the ingot surface. The electrode is either prefrabricated or melted first in a vacuum induction furnace; the arc is d.c. and operates with a current of 10–25 kA and a voltage of 20–30 V. A low voltage is used to prevent the arc attaching to the walls of the vessel, and an additional field coil, which interacts with any radial component of arc current, tends to help the stabilising effect and produces a strong stirring action.

#### 9.6.2.3 Electroslag refining

Electroslag refining (Figure 9.19) is directly competitive with vacuum arc processes for materials not unduly reactive in air. A high degree of refining can be obtained, since the

Figure 9.19 Electroslag refining furnace

droplets of molten metal penetrate through the molten slag, enabling desulphurising to be carried out and oxide inclusions to be removed. The process, like the vacuum arc furnace, forms a molten pool on the solidifying ingot and has similar advantages.

The electroslag refining process is essentially one of resistance heating, since it relies on electrical conduction in the molten slag. Single- or three-phase operation (using three electrodes over one ingot) is possible. The operating voltage is kept in the range 40–60 V to prevent formation of arcs, and currents of up to 3 kA are used. Operation is controlled by limiting the voltage and keeping the electrode immersed in the electrically conducting slag in order to avoid drawing an arc. The slag depth and composition are carefully controlled to maintain its electrical conductivity and to allow it to refine the molten metal droplets. Cylindrical and slab ingots can be produced: typical ingot diameters are 350 mm (single-phase) and 900 mm (three-phase), with a melting rate of 180–360 kg/h at 360 kVA (single-phase) or up to 6 MVA at 180 V and 18 kA (three-phase). Large ingots can be produced by switching electrodes during refining.

#### 9.6.2.4 Electron-beam furnace

Electron beams are used for welding, melting and the production of evaporated coatings. The beam is obtained from a heated filament or plate and is accelerated in an electron gun by a high electric field produced by one or more annular anodes. Electrons on the axis of the gun pass through the final anode at very high velocities (e.g.  $8.5 \times 10^7$  m/s at 20 kV). The electron gun and chamber are kept at a low pressure of around  $10^{-3}$  Pa and, as little energy is lost from scatter or production of secondary electrons, practically all the kinetic energy of the beam is converted to heat at the workpiece. Thus the conversion efficiency of electrical energy input to thermal energy in the workpiece is very high. The electron-beam furnace (Figure 9.20) utilises a cooled ingot mould in the same way as the vacuum and electroslag furnaces.

Ingots, slabs, tubes, castings, pellets and powder can be produced. One system, shown in Figure 9.20, comprises one, two or three guns arranged around a consumable electrode. Individual power ratings up to 400 kW are possible, which enables total power inputs of up to 1.2 MW and melting rates of 500 kg/h to be obtained.

### 9.6.3 Coreless induction furnace

The coreless furnace essentially consists of a refractory crucible encircled by a solenoid coil excited from a single-phase

Figure 9.18 Vacuum arc furnace

Figure 9.20 Electron-beam melting furnace

a.c. supply (Figure 9.21). The fluctuating axial magnetic field linking the charge within the crucible causes  $I^2R$  heating within it. The power induced in the charge depends on the physical properties of the material, the magnitude and frequency of the flux linking it and its geometrical shape. For efficient energy transfer to the load, the cross-section of the current paths must be greater than three times the penetration depth of the electromagnetic wave in the material.

This penetration depth  $\delta$  is given by equation (9.2). Thus, to melt individual components of charge contained in the crucible, the components must have dimensions lying across the coil axis of  $3\delta$  or the voltage generated between the individual components must be sufficiently high to establish current paths of sufficiently large diameters within the bulk of the charge.

Depending on the resistivity of the material being melted, the coreless furnace converts electrical energy to heat in the charge at an efficiency of between 60 and 85%. It is useful to note that, for most furnace designs, the total circuit reactance is far greater than the resistance (by as much as an order of magnitude) and the largest reactive component is

Figure 9.21 Diagrammatic view of a coreless induction furnace

caused by the separation of the coil from the metal charge. The change in the reactance of the charge causes the total circuit reactance to change by about 30% when melting typical iron scrap charges. In addition, lining wear or build-up of slag or dross on the walls of the crucible typically alter the total circuit reactance by a further 30%. It is also seen that, as the frequency of the supply increases, there is a reduction in the circuit power factor. The furnace efficiency, however, is independent of frequency, although it is improved by a high charge permeability such as when melting ferromagnetic materials, e.g. steel scrap.

Water cooling of the induction coil is required to remove the  $I^2R$  losses from it—the resulting steep thermal gradient through the crucible wall then improves its integrity in maintaining a separation of the melt from the induction coil. Normally, the coil is manufactured from a thick-walled high-conductivity copper tube, and the design is a compromise between mechanical, electrical and hydraulic requirements. The coil, in the most common modern designs is wound with electrical insulation and the turns are separated using studs, fastened to each turn and arranged in vertical rows, held in place by hardwood pillars. This coil assembly is then restrained vertically and radially by the furnace structure.

For small furnaces, the furnace body can be made from high-strength insulation boards or aluminium side-panels interconnected by non-metallic components, but for larger furnaces (say over 1 t iron capacity) the furnace body is made from a steel frame or from rolled-steel plate. In this case, an electromagnetic screen must be interposed between the coil and its supporting structure. This improves the power factor and coil efficiency compared to the unscreened smaller furnace design, but the lamination packs introduce a small iron loss component.

In recent years, the capital cost of coreless melting furnaces has been significantly reduced in real-money terms, for a given melting rate. This has been due to the development of high-power-density furnaces fed at medium frequency via the solid-state inverter.

Inverter power sources are designed to allow the output frequency to alter to maintain tuning to the natural frequency of the coil system. Thus, capacitor switching is eliminated and the power applied to the furnace is dependent solely on the limits of current and voltage within the inverter, these being chosen to allow substantially constant power input to be achieved throughout the melting of a cold charge, the load conditions of which will change during the total melt cycle.

Inverters used are of the a.c. to d.c. type, and conversion efficiencies of mains to medium-frequency power of over 95% are achieved. Two circuit designs compete in the furnace market, both being capable of giving similar melting efficiencies. These are the current-fed inverter (parallel inverter) and the voltage-fed inverter (series inverter).

The current-fed inverter operates at a leading output power factor and follows the load resonance of the circuit, control of power being by phase-angle control of the inverter rectifier stage. The voltage-source inverter operates slightly below the resonant tank frequency, and power control is achieved by moving the operating frequency away from the resonant condition, allowing a fixed rectification input stage to be used.

The load characteristics imposed on the supply are determined by the rectifier input stage, the harmonics generated being determined by the pulse number of the rectifier. For six-pulse inverters, the predominant harmonics are the fifth and seventh, and for 12-pulse the eleventh and thirteenth, respectively.

Six- or 12-pulse input stages are used, depending on the supply requirements. Individual rectifiers are rated up to

2 MW, and for higher ratings units are connected in parallel. The voltage-source inverter presents a fixed input power factor to the supply but the current-fed inverter, which uses a controlled rectifier input stage, has a load-dependent input power factor. Inverter bridges up to 1 MW from four devices are used and, to achieve higher ratings, devices are connected in series or parallel. Circuit protection is important for long-term inverter reliability, the current-source inverter being easier to protect because of the absence of the high stored energy which must be dissipated in the voltage-source inverter.

The magnetic field reacting with the induced currents in the melt causes forces to be applied to the liquid metal in the furnace, resulting in a surface stirring action which can be advantageous in assisting with dissolution of alloy additions or newly added charge materials. The magnetic pressure creates a metal surface which is dome shaped and the height of this dome (also termed the meniscus), ultimately sets a limit to the power density which can be tolerated. The limiting power density is sometimes empirically taken as linearly related to  $(\text{frequency})^{1/2}$ .

For molten iron, the limit to power density is around 300 kW/t for a mains-frequency furnace, although the meniscus lift can be dampened by using a larger ferrostatic head above the power coil. By comparison, power densities of up to 750 kW/t are acceptable when using medium frequencies, in the range 180 Hz to 10 kHz. However, metal surface movement markedly increases at the lower frequencies, benefiting assimilation of alloys and light materials. Thus, where this is a significant factor, frequencies of around 250 Hz or even lower are preferred. As lower frequencies are chosen, the voltage generated between individual charge pieces becomes less (for a given furnace power and size), since this is related to the voltage per turn of the furnace coil, which is proportional to  $f^{3/4}$ . Thus, the lower frequency furnaces are more dependent on the characteristics of the charge pieces than furnaces of higher frequency, and hence choice of frequency has to be a compromise, at least for a given furnace rating and size, and should take into account the required surface stirring action.

Since the first application of large, high-power-density medium-frequency coreless furnaces in the UK (around 1980), the iron-foundry trade has chosen this type of furnace for virtually all new electric melting schemes.

In common with the iron-foundry sector, the lower cost, greater flexibility, and higher power density advantages of modern medium-frequency induction furnaces have tended to eliminate mains-frequency furnaces from consideration for the majority of coreless melting applications in the non-ferrous metals sector.

The low heat requirements to melt lead and zinc generally militate against induction melting, whereas the high melting temperatures of copper alloys are not as efficiently met by other fuel types. Undoubtedly aluminium is the metal which is melted in the widest range of furnaces employing the widest range of fuels and melting practices. There has been significant growth of induction furnaces particularly for recycling in furnaces varying from 0.5 to 8 t capacity.

In the foundry sector several variations of the basic coreless furnace can be found. For example, in furnaces of up to 1 t capacity melting copper and its alloys, parallel-sided clay graphite or silicon carbide crucibles may be used in preference to conventionally refractory-lined furnaces, although consideration must be given to the heat generated directly in these graphite-based materials, particularly the more highly conducting carbon bonded silicon carbide types. This is of special importance in free-standing crucible furnaces generally in the form of push-out or, more recently, by drop coil

designs. These furnaces have been rapidly accepted by the foundry sector because of the ability to melt small batches of metal very quickly, e.g. 60 kg in 13–14 min. At the end of a melt, crucibles can be removed from the vicinity of the power coil and carried directly to the casting mould. Inter-melt contamination is avoided by using different crucibles for each alloy type.

#### 9.6.4 Channel induction furnace

During the 1970s, the channel furnace became accepted as a melting unit for cast iron, and this acceptance was largely due to the improved refractory technology allowing useful levels of power to be applied. Up until then, in iron foundries, the furnace had mainly found application for metal holding.

Electrically, a mains-frequency solenoid coil encircles one leg of a lamination pack and the resultant alternating magnetic field induces Joule heating in a loop of molten metal which surrounds the coil, this metal loop acting as a single-turn secondary of the transformer (*Figure 9.22*). The close coupling between the induction coil and the metal loop provides a higher natural power factor than occurs with the coreless induction coil, and the metal loop provides a higher natural power factor than occurs with the coreless induction furnace. The efficiency of converting electrical energy into heat in the metal is therefore also higher, being above 95%. The molten-metal loop needs to be continuous, and it is not allowed to solidify in case this continuity is broken during contraction. The loop is contained by refractory, enclosed usually within a rigid-steel inductor box, and this can be separated from the main furnace body to allow refurbishment of the inductor box refractory. To mechanically support the refractory between the loop and the induction coil, a bushing, which may be a water-cooled jacket, is interposed (electrically divided into two). The cooling system is designed to produce a steep thermal gradient in the refractory, so improving its integrity.

For melting cast iron, the furnace normally consists of a vertical cylindrical bath having the inductor box attached to its base. The refractory in the main bath is able to be heavily thermally insulated.

The melting power can be applied continuously during the whole of the charging period, and this provides a very consistent and repeatable melting routine.

**Figure 9.22** Diagrammatic view of a channel induction furnace

The use of channel furnaces for aluminium melting has been constrained by problems of oxide build up in the loop necessitating special designs to allow easy cleaning. In recent years European furnace companies and research workers alike have attempted to produce high-power designs of up to 1.3 MW per inductor with freedom from loop blockage for bulk melting applications, thus utilising the high electrical efficiency of the furnace to minimise melting costs.

### 9.6.5 Resistance furnaces

Electric radiant-heating techniques for metal melting are most widely employed in the zinc and aluminium foundry sectors with only minor penetration into the higher melting point copper base alloy market. In general, resistance heating is used where metal demand patterns are not appropriate to induction furnaces and hence should not be considered as a competitive technique. For example, furnaces for aluminium range from bale-out-crucible furnaces of 25 kg capacity to well insulated box-like receivers of over 10 t capacity.

Resistor elements may be in the form of wire (e.g. iron-chromium-aluminium alloys) which can be mounted in various configurations, or for higher temperature applications silicon carbide rods either of conventional or spirally cut tube section.

A particular advantage of electric resistance heating is superior metal temperature control, achieved by feedback to the power supply. The simplest power supply comprises direct on-line switching of, for example, a three-phase 415 V mains supply feeding a star-connected element configuration, control being achieved by means of a contactor. Although this is acceptable for wire elements, time-dependent resistance changes of silicon carbide elements (ageing) usually demand voltage regulation which can be effected by a tapped transformer. At power inputs of 50 kW it often becomes more economical to use thyristor circuitry controlling power by means of phase-angle control or burst firing. In the former case, the resulting waveform is not purely sinusoidal and harmonics can be developed at odd integer values of the fundamental (third, fifth, seventh, etc.). A three-phase open delta system (or six-wire load) is usually favoured for silicon carbide element furnaces for two reasons:

- (1) to minimise the presence of triple harmonics in the supply lines; and
- (2) to allow independent control of each phase load in the event of, for example, partial load failure.

In this configuration, harmonics create r.m.s. current levels in excess of those normally expected for a purely resistive load and, therefore, cable sizes need to be increased.

Burst firing does not generate the type of harmonics described above, but can cause flicker on tungsten filament lamps discernible to the human eye. This is due to particular combinations of voltage fluctuation caused by load 'steps' or bursts, and their frequency. Undue voltage fluctuation is minimised by careful selection of supply cable impedance. Thyristor control may also be used in preference to direct on-line switching in situations where close temperature control is required.

Crucible furnace designs comprise a steel shell containing insulating material, heating elements and a carbon based crucible located in the central chamber (*Figure 9.23*). The highest ratings are around 120 kW, giving a maximum melting rate of 230 kg/h (aluminium) in a 600 kg capacity furnace. Crucible furnaces exist in both tilting and bale-out configurations, and great strides have been made to improve performance figures in the light of competition between

**Figure 9.23** Diagrammatic view of a resistance crucible furnace

manufacturers and from other fuels. For example, a typical 180 kg capacity bale-out furnace has a holding requirement of about 4 kW with advantages of automatic start-up, good working environment and close temperature control.

Bath-type furnaces, using roof-mounted elements radiating onto a refractory lined bath of metal, are available for a wide range of metal melting and, more commonly, metal storage applications. The rate of heat transfer to the melt is limited by the low emissivity of the melt surface, a factor which, conversely, is of considerable advantage in reducing heat losses during normal bale-out applications. Since heat transfer is also proportional to bath surface area, significant melt rates are achieved only with high-capacity furnaces. Typically, the metal content is around eight times the optimum hourly melt rate achieved when these large structures have reached thermal equilibrium.

For bulk storage and dispensing applications, good thermal insulation techniques have led to the development of integrated systems in which low-power mineral-insulated elements operate around 2–3 kW/t of metal capacity.

Immersion heating using silicon carbide or wire elements in silicon carbide based tubes provides an alternative high-efficiency heating mode for lower melting point metals.

## 9.7 Dielectric heating

Processing of non-metals by the conventional heating techniques of convection, conduction and radiation is often limited by the physical characteristics of the materials such as thermal conductivity and temperature sensitivity. Furthermore, since all these modes of heating depend on the transfer of heat through the product surfaces there is inevitably a temperature gradient between the surface and the centre, a problem which increases as the thickness of the product increases. In many operations this is undesirable, leading as it does to process inefficiencies and product degradation. Dielectric heating which covers both the r.f. and microwave parts of the electromagnetic spectrum can, in many circumstances, alleviate these problems by virtue of its 'volumetric' or at least deep penetration form of heat transfer. The industrial applications of dielectric heating are many and varied ranging from drying of textiles and the welding of plastics to the thawing of meat and the heating of rubber extrusions. Dielectric heating depends on a number of polarisation effects, the most commonly described one being dipole orientational polarisation (*Figure 9.24*). This is very important at microwave frequencies, but of relatively little significance at the lower, radiofrequencies.

**Figure 9.24** Dielectric properties of water: variation with frequency and temperature. Arrows indicate change with increase of temperature

The dominant mode in the r.f. range is space charge orientation, which in turn is dependent on the ionic conductivity of the material being processed. Therefore, for a particular material it is possible in theory to choose the most appropriate frequency from those available in the industrial, scientific and medical (ISM) bands (*Table 9.8*). In reality, many products can be processed by either r.f. or microwave and the choice of which can be made on other considerations such as the engineering required to make a satisfactory enclosure compatible with the process line requirements. The heat transferred per unit volume of product is given by

$$P = \pi f \varepsilon_0 \varepsilon'' E^2 \quad (9.3) \leftarrow$$

where  $f$  is the frequency (MHz),  $E$  is the electric field strength (V/m), and  $\varepsilon_0$  is the loss factor or relative permittivity.

**Table 9.8** Frequency allocation for industrial, scientific and medical purposes (existing allocations, 1980)

Frequency (MHz)	Frequency tolerance ( $\pm$ )	Area permitted
0.007	10 kHz	USSR
13.56	0.05%	World-wide
27.12	0.6%	World-wide
40.68	0.05%	World-wide
42, 49, 56, 61, 66	0.2%	Great Britain
84, 168	0.005%	Great Britain
433.92	0.2%	Austria, Netherlands, Portugal, W. Germany, Yugoslavia, Switzerland
896	10 MHz	Great Britain
915	13 MHz	North and South America
2375	50 MHz	Albania, Bulgaria, Hungary, Romania, Czechoslovakia, USSR
2450	50 MHz	World-wide, except where 2375 MHz is used
3390	0.6%	Netherlands
5800	75 MHz	World-wide
6780	0.6%	Netherlands
24150	125 MHz	World-wide
40680		Great Britain

The loss factor, i.e. the product of the dielectric constant and the loss tangent, varies with a number of parameters including frequency, moisture content and temperature. The relationships are often quite complex as, for example, in drying where as the temperature of the material rises the moisture content will start to fall. However, one of the major applications of dielectric heating, moisture profile correction, takes advantage of the relative values of loss factor between areas of high and low moisture concentration. These are such that preferential heating and drying of the wetter areas takes place with resulting product quality improvements. *Table 9.9* gives an indication of the loss factor of a number of materials for a range of frequencies; some are quoted at a number of different temperatures. Interpretation of such data needs to be undertaken with care. In the case of water the effect of having any level of ionic material present (as in most 'real' water), will substantially increase the loss factor at r.f. but have relatively little effect at microwave frequencies.

In common with all high-voltage equipment, it is necessary to prevent access to live components and in this case it is also necessary to contain the electric field for both operator safety and to avoid interference with other users. Both considerations are dealt with by enclosing the equipment in a metal case, which may have interlocked access doors for batch operations and attenuating ducts for continuous processes.

### 9.7.1 RF dielectric heating systems

The available systems for producing and transferring RF power to dielectric heating or drying applicators can be divided into two distinct groupings; the more widespread *conventional RF heating equipment*, and the more recent *50  $\Omega$  RF heating equipment*. Although conventional RF equipment has been used successfully for many years, the

**Table 9.9** Typical loss factor and frequency relation

ever tightening EMC regulations, and the need for improved process control, is leading to the introduction of RF heating systems based on 50  $\Omega$  technology.

#### 9.7.1.1 Conventional RF heating equipment

In a conventional system, the RF applicator (i.e. the system which *applies* the high frequency field to the product) forms part of the secondary circuit of a transformer which has the output circuit of the RF generator as its primary circuit. Consequently, the RF applicator can be considered to be part of the RF generator circuit, and is often used to control the amount of RF power supplied by the generator. In many systems, a component in the applicator circuit (usually the RF applicator plates themselves) is adjusted to keep the power within set limits. Alternatively, the heating system is set up to deliver a certain amount of power into a standard load of known conditions, and then allowed to drift automatically up or down as the condition of the product changes. In virtually all conventional systems, the amount of RF power being delivered is only indicated by the d.c. current flowing through the high power valve (usually a triode) within the generator.

A typical conventional RF heating system is shown schematically in Figure 9.25.

Figure 9.25 Components of a conventional RF heating system

#### 9.7.1.2 50 $\Omega$ RF heating equipment

RF heating systems based on 50  $\Omega$  equipment are significantly different, and are immediately recognisable by the fact that the RF generator is physically separated from the RF applicator by a high power coaxial cable (Figure 9.26).

The operation frequency of a 50  $\Omega$  RF generator is controlled by a crystal oscillator and is essentially fixed at exactly 13.56 MHz or 27.12 MHz (40.68 MHz is seldom used). Once the frequency has been fixed, it is relatively straightforward to set the output impedance of the RF generator to a convenient value—50  $\Omega$  is chosen so that standard equipment such as high power cable and RF power meters can be used. For this generator to transfer power efficiently, it must be connected to a load which also has an impedance of 50  $\Omega$ . Consequently, an impedance matching network has to be included in the system which transforms the impedance of the RF applicator to 50  $\Omega$ . In effect, this matching network is a sophisticated tuning system, and the RF applicator plates themselves can be fixed at an optimum position.

The main advantages of this technology over the conventional systems are:

- (i) Fixed operation frequency makes it easier to meet onerous international EMC regulations.
- (ii) The use of 50  $\Omega$  cable allows the RF generator to be sited at a convenient location away from the RF applicator.
- (iii) The RF applicator can be designed for optimum performance, and is not itself part of any tuning system.
- (iv) The use of a matching network gives the possibility of an advanced process control system. The positions of components in the matching network give on-line information on the condition of the dielectric load (such as its average moisture content). This information can be used to control the RF power, speed of conveyor, temperature of air in applicator etc. as appropriate.

#### 9.7.1.3 RF dielectric heating applicators

Whether conventional or 50  $\Omega$  dielectric heating systems are used, the RF applicator has to be designed for the particular product being heated or dried. Although the size and shape of the applicator can vary enormously, they mostly fall into one of three main types.

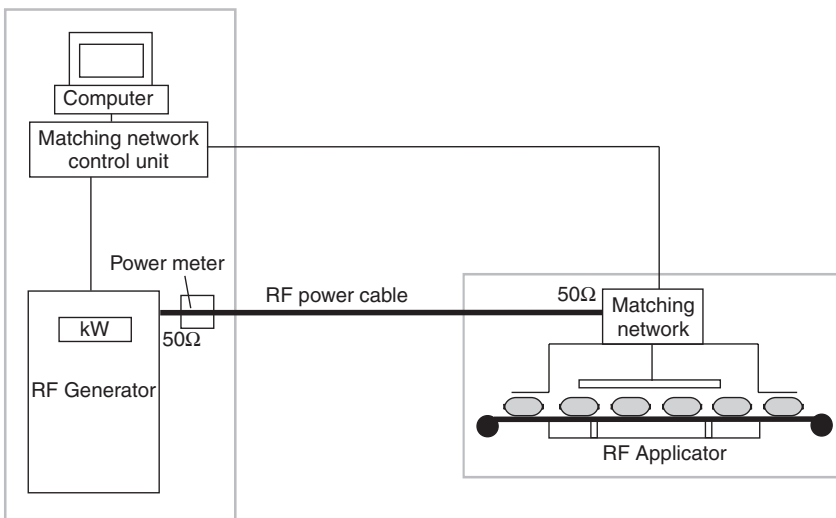

Figure 9.26 The components of a typical 50  $\Omega$  dielectric heating system

**Figure 9.27** Simple through-field RF applicator

**Figure 9.28** Concentric through-field

*'Through-field' applicator* Conceptually, a through-field RF applicator is the simplest, and the most common, design, with the electric field originating from a high frequency voltage applied across the two electrodes which form a parallel plate capacitor (Figure 9.27).

This type of applicator is mainly used on relatively thick products, or blocks of material.

A variation on this is the concentric through-field, shown in Figure 9.28 in which the product to be heated, normally a liquid or fluidised bed, fills the space between the two cylindrical electrodes. The inner electrode is at high voltage, the outer one at earth potential.

*'Fringe-field' applicator* An alternative RF applicator arrangement, often used in drying applications, is known as the *fringe-field* system. In this case, the product passes over a series of bars, rods or narrow plates which are alternatively connected to either side of the RF voltage supply (Figure 9.29).

The major advantage of this configuration is that the product makes a complete contact across the bars, and there is no air gap between the RF applicator and the product. This ensures that there will be a virtually constant electric field in the material between the bars (an important requirement to maximise moisture levelling performance). It also reduces

**Figure 9.29** Fringe-field applicator

the electric field that has to be applied between the electrodes to generate a given power density within the product. The major disadvantage of this arrangement is that only relatively thin layers of product can be used—otherwise there will be an electric field variation throughout the product thickness.

*'Staggered through-field' applicator* For intermediate thickness of products, a modified through-field applicator is often used; known as a *staggered through-field* applicator (Figure 9.30).

This arrangement reduces the overall capacitance of the applicator which, in turn, makes the overall system tuning easier. It also reduces slightly, the voltage that has to be applied across the electrodes to produce a given RF power density within the product.

## 9.7.2 Microwave power sources and applicators

For industrial heating applications using microwaves, the usual power source is the magnetron. At the permitted operating frequency of 2450 MHz, the largest output from a magnetron commonly used, is 5 kW, although 10 kW units are just becoming available. For the other frequency band (896/915 MHz) high-efficiency magnetrons of 60 kW output exist. When higher powers are needed, a number of magnetrons may be fed into one applicator. The most common form of industrial heating oven is the multimode oven, essentially an enlarged version of the familiar domestic oven with, in the case of continuous processing, appropriate product ports, to allow the passage of product yet confine the microwaves within the oven. In such applicators the antenna of the magnetron may be mounted directly into the oven, but more often the microwave power is transmitted from the power supply via metallic pipes (waveguides) to the oven cavity where it is launched into the chamber by a variety of means. Other forms of heating applicator which incorporate, for example, launching horns,

**Figure 9.30** Staggered through-field applicator

leaking wave antennas, or single-mode resonant cavities, are possible.

Industrial microwave heating has been used extensively in the rubber industry for curing and preheating prior to moulding. In the food industry it has been used for tempering, melting, cooking and drying. Recently, microwave vacuum dryers have been developed for drying expensive, high-quality temperature-sensitive pharmaceuticals.

## 9.8 Ultraviolet processes

Inks and surface coatings can be cured at high rates with ultraviolet sources. The coatings are specially formulated, using monomers and photoinitiators, so that very rapid polymerisation is brought about on exposure to ultraviolet radiation. Although this is not strictly a heating process, it has much in common, and is very often in direct competition with infra-red heating for drying or cross-linking; however, the energy usage is normally much lower, since the process requires only the stimulation of an overall exothermic reaction.

The active spectral region covers the range 250–400 nm in the ultraviolet, and visible wavelengths in the range 400–500 nm may also be used. The envelopes of the ultraviolet lamps are usually made from pure silica glass, which has higher transmission than other glass for the shorter ultraviolet wavelengths. Energy radiated from an electrical discharge is not governed by the black-body laws: the

Figure 9.31 Spectral output from a medium-pressure mercury lamp

Figure 9.32 Rod and nozzle type of plasma torch construction

distribution can be confined to a few intense narrow bands of wavelength. A typical output spectrum from a medium-pressure (sometimes called high-pressure) mercury vapour discharge lamp is shown in Figure 9.31. Additional spectral bands can be generated by incorporating metal halide dopants in the lamp fill. Power ratings of these lamps are in the range 2–20 kW over active lengths of 250–1800 mm.

Low-pressure actinic lamps are used for curing thick sections of glass-reinforced polyester resins. These lamps operate at much lower power densities than medium-pressure lamps, a typical power rating being 80 W for an active length of 1.5 m. Suitable phosphors on the internal surfaces of the lamp tubes convert the primary radiated output, which is concentrated at 254 nm, to broad-band emission in the region 300–500 nm. The lamp tubes are made of glass, which has good transmission properties down to about 300 nm.

Both medium-pressure and low-pressure mercury lamps are used to disinfect air and water, and to sterilise surfaces. Wavelengths shorter than 300 nm are required, the action spectrum peaking at about 260 nm. In the case of low-pressure, 'germicidal' lamps the primary radiated output at 254 nm is utilised. The effect achieved is, again, not the result of a heating process, but the consequence of the biologically damaging properties of ultraviolet radiation.

## 9.9 Plasma torches

### 9.9.1 Types of plasma-torch design

A plasma torch is a device that uses an electric arc discharge to generate a thermal plasma, that is, a partially ionised gas in which the degree of ionisation is linked to the temperature of the gas according to the laws of equilibrium thermodynamics. When the temperature of a gas rises above about  $6 \times 10^3$  °C the electrical conductivity becomes sufficiently high to make the gas a reasonable conductor of electricity. Temperatures in the core of an arc may reach  $2 \times 10^4$  °C or higher.

Torches that are used in electroheat applications may be broadly classified into the three families described below.

- (1) *Rod and nozzle electrode types* (Figure 9.32): an arc burns between the end of a rod and the internal surface of a nozzle and gas is blown around the arc and through the nozzle. The current supply is usually d.c., but torches designed for a.c. use are also available.
- (2) *Linear coaxial tube types* (Figure 9.33): the arc burns between the internal surfaces of tube electrodes and gas is blown through the electrodes around the arc. The current supply is usually d.c., but some designs also operate on a.c. The power-handling capacity is improved if arc root motion is induced by the imposition of axial magnetic fields.
- (3) *Electrodeless types, particularly induction-coupled types* (Figure 9.34) and *microwave types*: an induction coupled arc burns in a ring-shaped electric field induced within a coil carrying current typically at a frequency of a few megahertz. The arc plasma is effectively the workpiece in an r.f. induction heater. In microwave torches the arc is maintained by currents driven by microwave fields in a resonant cavity. Peak plasma temperatures in electrodeless torches are typically within the range  $7 \times 10^3$  to  $1.1 \times 10^4$  °C, that is, rather lower than for the electrode types.

If the plasma torch is intended to handle significant power levels, the electrodes must be adequately cooled to dissipate

**Figure 9.33** Linear coaxial tubular electrode types of plasma torch construction. (a) The Hüls type developed from Schoenherr's original early design; (b) A typical 2 MW non-transferred torch; (c) A typical stretched or segmented torch rated at 6 MW or higher

**Figure 9.34** An induction-coupled plasma torch

**Figure 9.35** Electrical connections of plasma torches. (a) Non-transferred; (b) Transferred; (c) Superimposed mode shown transferred to workpiece

the heat transferred at the arc roots. Water cooling is usual and electrode cooling considerations are critical for torch design. Water cooling may also be necessary for other parts of the torch exposed to the arc plasma.

### 9.9.2 Electrical connection of plasma torches

Plasma torches are used in various different types of connection (*Figure 9.35*). In the non-transferred mode the torch behaves as an arc-powered gas heater. In the transferred mode the torch behaves as one electrode for an arc while the workpiece is electrically connected as the other electrode.

A third mode of connection, the superimposed mode, is a hybrid connection requiring the use of an auxiliary a.c. or d.c. power source which may be either transferred (as shown) or non-transferred.

### 9.9.3 Performance

Transferred torches are available for industrial applications at power ratings up to about 7 MW in a single device. State-of-the-art torches are being developed for 12 kA capacity but 6 kA capacity torches are widely available. In most industrial applications voltages up to about 500 V may be accommodated without serious stray arcing but, with care-

ful design, long arcs (1 m or longer) operating at up to about 1 kV are possible. Electrode life-times are dependent on the torch current, the materials of construction and the reactivity of the environment to which they are exposed. Life-times over 100 h are usually necessary for application in major industrial process plant.

The efficiency of transferred torches is very dependent on the specific application. Electrical to thermal conversion efficiencies can reach 95% but, in a practical furnace, the efficiency of conversion to heat transferred to the hearth may fall as low as 50% unless heat losses from the arc plasma column are usefully intercepted. The mechanism of heat transfer is mainly convection.

Non-transferred torches are available in power ratings up to about 100 MW, but for industrial applications a practical maximum rating of about 10 MW is imposed by electrode life-time considerations. Life-times of 1000 h and longer are possible in air or in hydrocarbon gases, provided that the current may be maintained below about 1.5 kA.

The efficiency of non-transferred torches may reach 90% for coaxial tube electrode types when used with high gas

flow rates, corresponding to relatively low gas temperatures of  $3 \times 40^3$  to  $4 \times 40^3$  °C. The efficiencies of rod and nozzle types, which are generally used for lower power ratings up to 100 kW, tend to be lower at about 60% at best.

The major advantage of electrodeless torches is that reactive gases are more easily maintained in a state of high purity than in other torch designs, and that long torch-component lifetimes are achieved. Their efficiency is limited, by the conversion efficiency to high-frequency power, the coupling efficiency into the plasma and heat losses to the containing walls, to the range 40–60% at best.

#### 9.9.4 Plasma furnaces or reactors

The simplest type of furnace or reactor is, in principle, the 'in-flight' reactor in which the input materials are injected directly into the plasma stream, or even into the torch, and the required processes occur with the reactants all suspended in the plasma stream. In-flight reactors generally require the input materials to be gaseous or finely divided because the time available for the process is short, typically of the order of milliseconds.

Transferred plasma torches are commonly used in open bath furnaces. A return electrode is then usually built into the hearth refractories, but three-phase a.c. and bipolar d.c. multiple torch systems have been developed to eliminate the need for the hearth connection. The feed rate of materials to open bath furnaces is usually controlled to prevent the build up of unreacted materials on the surface, but plasma torch operation has also been demonstrated in a submerged mode.

Non-transferred torches are often used in shaft-type furnaces where a hot reaction zone is created close to the point of injection of reactive plasma gases in the base of a packed shaft. Furnaces with rotating shells are also available, particularly for the fusion of pure refractory compounds (Figure 9.36) or when a long residence time is required as in the treatment of some waste materials.

The advantages of a plasma furnace are that the heat input is independent of the process chemistry, so that highly oxidising or fully reducing furnace atmospheres are equally permissible, that furnace operation may be made largely independent of the physical characteristics of the input materials, that furnace gas outflow rates are reduced to levels that allow the treatment of fine powders without excessive carry-over, that very high temperatures may be

**Table 9.10** Applications of plasma heating technology

<i>Application</i>	<i>Plasma system</i>
Welding, cutting, surface heat treatment of metals	Transferred, typically up to 100 kW
Precision cutting of metal foils, cutting non-metals	Non-transferred, from 0.5 kW
Spray coating of refractory metals and ceramics	Transferred or non-transferred, typically up to 100 kW, in-flight reactors
Platinum group metals recovery from scrap vehicle exhaust catalyst	Transferred, 1–2 MW
Steel tundish heating	Major application, transferred 1–3 MW
Consolidation melting and cold hearth melting of reactive metals (e.g. Ti)	Transferred, torch anodic, typically 800 kW
Blast furnace blast superheating	Non-transferred, up to $8 \times 2$ MW
Plasma fired cupolas	Non-transferred, 4 MW and $6 \times 4.5$ MW
Metals recovery from steel-plant dusts	Major application, from transferred 1 MW to $3 \times 4.5$ MW non-transferred (shaft furnace)
Smelting of metal ore fines	Transferred and non-transferred from 1 MW
Acetylene production, process off-gas reforming	Non-transferred, up to 8.5 MW
Titanium dioxide pigment production	Non-transferred, 2 MW oxygen heater
Waste treatment	Emerging major application

achieved limited only by the containment requirements, and that compact high energy density, high throughput systems, are possible.

Some established applications of plasma technology are listed in Table 9.10.

**Figure 9.36** Rotating shell furnace for fusing pure refractory powders and using a non-transferred, superimposed mode torch arrangement

#### 9.10 Semiconductor plasma processing

Plasma processing has been used in the semiconductor industry since the late 1960s when rudimentary processes were introduced for removing photoresist from silicon using an oxygen plasma. This was an extension of an earlier application in the medical field in which an oxygen plasma was used to volatilise organics from biological specimens in order to separate the inorganic residue or 'ash'. The misnomer 'ashing' is still used in the semiconductor industry to describe this resist-stripping process.

The widespread use of plasmas for semiconductor applications stemmed from work carried out in the early 1970s in which fluorocarbon gases were used to generate highly reactive fluorine atoms and  $C_xF_y$  radicals. These species were shown to be capable of etching most of the materials of interest in device fabrication, and the relative etch rates could be controlled by manipulation of the concentration of these species.

More recently, plasma processes have been used for plasma-enhanced chemical-vapour deposition (PECVD) both of insulating films like silicon nitride and also of semiconducting films such as amorphous silicon (a-Si). The use of PECVD  $\text{Si}_3\text{N}_4$  for passivation of integrated circuits (ICs) has allowed plastic packaged ICs to have reliability comparable to hermetically packaged devices.

More novel applications of plasma processing include techniques in which material is grown such as *plasma oxidation*—oxidation of existing material or *deposition* of  $\text{SiO}_2$  and plasma-assisted epitaxy. As yet these techniques are not in widespread use but offer some significant advantages over their conventional counterparts.

The reasons for the increasing use of plasma processes are three-fold.

- (1) *The requirement for low-temperature processing.* Thermal oxidation and chemical vapour deposition are performed at temperatures in the range 800–1000°C, and sometimes higher. These thermal processes consume a considerable amount of energy leading to an increased thermal budget for the fabrication facility. In addition, they introduce unwanted dopant redistribution, thermal warping, dislocations and stacking faults in the semiconductor substrate. Furthermore, when an aluminium layer is used for circuit interconnection, these elevated temperatures preclude the deposition or growth of further insulating layers; as a result the fabrication of multilayer circuits becomes problematic.
- (2) *The need to etch small geometry structures.* As the dimensions of circuits and devices are reduced, conventional solution or wet-chemical etching becomes more difficult, because the surface tension of the solutions tends to cause the liquid to bridge the space between adjacent features, thereby preventing further etching of the underlying film. As wet etching proceeds downwards through a film, it also proceeds laterally because of its essentially isotropic characteristic, thereby undercutting and broadening lines and restricting the minimum dimensions of the device. In contrast, plasma etching is anisotropic, resulting in a very high ratio of vertical to lateral etch rates. Very steep edge profiles are achievable for interconnection layers with minimal undercutting (see Figure 9.37).

(a) Isotropic (wet chemical)

(b) Anisotropic

**Figure 9.37** Etch profiles for isotropic and anisotropic etching. Undercutting beyond the mask edge is minimal in the case of anisotropic plasma etching

- (3) *The desirability of a dry process.* Strong acids can be used to strip resist films and to etch semiconductor wafers, but with the associated disadvantages of lack of control and the need for a large amount of high purity chemicals and deionised water. In contrast, plasma etching is a dry process which takes place in a clean vacuum environment. The sources of heavy metal and sodium ion contamination commonly found in solution are eliminated. The process can be monitored by controlling the flow rate of the reactive gases and plasma parameters, and end-point detection of the process is possible.

### 9.10.1 Basic mechanisms in plasma processing

All plasma processes use a low-pressure gas in the form of a plasma to provide the required chemical species, whether for material removal (etching and ashing) or for material deposition. Free electrons within the plasma processing reactor are accelerated by an applied electric field until they gain sufficient energy to excite some of the parent gas molecules into highly reactive states by collisional processes. The resulting glow discharge, although still mainly composed of neutral ground-state molecules, contains significant numbers of free radicals, ions and other excited species. The degree of ionisation may typically be only of the order of  $10^{-4}$ , but the excited species can be highly reactive, to the extent that reactions either within the body of the plasma, or on exposed surfaces can occur at rates which would only be achieved thermally at temperatures in excess of 1000°C.

These plasma-generation and surface-reaction processes, although widely used, are still not well understood and are very difficult to model. In most systems, however, free radicals are believed to be the major reactant species and ions serve primarily to enhance their reaction rates.

The plasma, due to its degree of ionisation may be regarded as an equipotential volume. Surfaces in contact with the plasma, however, can attain potentials which differ from the plasma potential by amounts which depend upon the configuration of the system and its operating conditions (gas composition, pressure, applied power, excitation frequency, etc.). Because of the higher energies and mobilities of electrons compared to positive ions, electrically isolated surfaces develop a floating potential a few volts below that of the plasma in order to maintain a net charge neutrality. The electric field which maintains this flux neutrality causes a reduction in the electron concentration near the surface, resulting in a plasma sheath, or dark space, where the generation of excited species which decay by photo-emission is much lower than in the bulk of the plasma.

Electrodes in contact with the plasma develop similar plasma sheaths, whose magnitude depends upon the relative areas of the electrodes and the frequency of the RF. Higher frequency = smaller dark space. In most plasma-processing systems the energy is fed into the plasma by capacitive coupling (see Figure 9.38). In a capacitively driven plasma with internal electrodes, a large sheath voltage appears at the smaller electrode and a smaller one at the larger electrode. These voltages are typically of the order of tens or hundreds of volts in practical systems.

The electrode sheaths are usually a few millimetres thick, so that a device wafer with topographical flatness of the order of a micrometre, placed on an electrode does not significantly perturb the field directionality. It is this directionality which gives rise to anisotropic etching in ion-enhanced processes, by enhancing the etch rate in the direction normal to the electrode surface.

**Figure 9.38** Typical configurations for plasma-processing equipment

**Table 9.11** Characteristics of the most common plasma etching configurations

Configuration	Etch profile	Selectivity	Etch rate	Type	Range (T)	Electrode arrangement	Wafer position
Barrel	Isotropic	V. good	Fair	Chemical	$10^{-1}$ – $10^1$	External	Immersed in plasma
Downstream	Isotropic	V. good	Fair	Chemical	$10^{-1}$ – $10^0$	External	Downstream of plasma
Plasma etch	Variable	Fair–good	High	Physico-chemical	$10^{-1}$ – $10^1$	Planar diode	Anode (grounded)
RIE	Anisotropic	Fair	Fair	Physico-chemical	$10^{-3}$ – $10^{-1}$	Planar diode	Cathode (driven)
MRIE	Anisotropic	Fair	High	Physico-chemical	$10^{-3}$ – $10^{-2}$	Planar diode	Cathode (driven)
Triode	Variable	Fair	High	Physico-chemical	$10^{-3}$ – $10^{-1}$	Planar triode	Cathode (driven)
RIBE	Anisotropic	Fair	Fair	Physico-chemical	$<10^{-3}$	Planar triode	Cathode (grounded)

### 9.10.1.1 Plasma etching

A dry etching process (other than physical sputtering) can be described in terms of four sequential steps: generation of the reactive species, adsorption onto the wafer surface, chemical reaction (may be radiation enhanced), and desorption of the reaction products. Any one of these steps may be the rate-limiting step. It is also necessary that the reaction products be volatile in order that the etch products do not contaminate the surface and prematurely terminate the process. For this reason, fluorine or chlorine containing plasmas are used for virtually all inorganic films used in semiconductor applications and oxygen for organics.

**Types of plasma etching processes** The most common plasma etching configurations are shown in Figure 9.38 and their characteristics are listed in Table 9.11. In chemical plasma etching active species are generated in a reactor by an externally excited r.f. or microwave discharge and the wafers are either immersed in the plasma at a floating potential (barrel etching) or located downstream of the plasma in a gas flow (downstream etching). Ion bombardment is minimal in the former and absent in the latter. Etching is due to free atoms

and excited neutrals and is, therefore, isotropic. With an appropriate choice of etch gas the selectivity can be very high because of the absence of physical enhancement but etch rates are relatively low for the same reason. The lack of anisotropy makes this approach unsuitable for very large scale integration (VLSI) patterning applications, but it is widely used for photoresist stripping (ashing).

By far the most widely used means of achieving directional etching is to use systems in which the wafer is physically bombarded by the ions in the plasma as well as exposed to the chemically reactive gaseous and ionic species. In the plasma etch mode the wafers are placed on the larger (grounded) of two electrodes whereas in reactive ion etching (RIE) they are placed on the smaller (driven) electrode and the system is operated at lower pressure. Under these conditions the ion energies bombarding the wafer are of the order of a few tens of electron-volts in the former and several hundred in the latter. RIE therefore tends to be more anisotropic, but this is gained usually at the expense of reduced selectivity (due to the increased ion bombardment) and reduced etch rate (due to the reduced flux density of reactive species at the lower pressure). However, all of these parameters can be optimised for a given application.

Magnetron-enhanced RIE (MRIE) and triode etching are more recent refinements of this class of operation. In the former case free electrons are magnetically confined in the plasma by a magnetic field orthogonal to the electric field. The collision probability is, therefore, increased and the reactant densities can be enhanced by up to two orders of magnitude. This results in higher etch rates than RIE at similar pressures. The reduced plasma impedance results in lower sheath voltages, but the higher flux of low energy ions is more efficient in promoting physically stimulated processes and so anisotropy is still good, with the added advantage of less radiation-induced damage to the device substrate.

In triode systems, r.f. power is applied to a third electrode in such a way that the cathode sheath voltage is controlled independently of the generation of the reactive species. This allows some degree of decoupling over the physical and chemical components of the process, and thus permits anisotropy and selectivity to be controlled.

Reactive ion beam etching (RIBE) describes the process in which a spatially collimated, usually reasonably mono-energetic, flux of one or more ion species is directed at a substrate leading to etching or erosion of that substrate. Ion energies may be controlled independently of the neutral flux by means of extraction grids.

**Choice of etchant** For silicon based materials, fluorinated gases have been extensively used, which include  $\text{CF}_4$ ,  $\text{C}_2\text{F}_6$ ,  $\text{CHF}_3$ ,  $\text{SF}_6$  and, more recently,  $\text{NF}_3$ . The major criterion in selection is to create volatile products with the constituents of the target at reasonable working temperatures. Etching other semiconducting materials such as III–V compounds, has required a slightly different approach as the group III fluorides are involatile at workable plasma parameters. For this reason chlorinated gases have been widely used, such as  $\text{Cl}_2$ ,  $\text{CCl}_2$ ,  $\text{F}_2$ ,  $\text{SiCl}_2$  and  $\text{BCl}_3$ .

#### 9.10.1.2 Plasma enhanced chemical vapour deposition

Chemical vapour deposition (CVD) is a reaction in which two types of gas react at about 1 atm and at high temperature to form a solid phase and a gas phase. Plasma enhanced CVD (PECVD) may be defined as a gas-phase reaction in a low-temperature plasma that forms a similar thin solid film by precipitation onto a substrate. The catalytic effect of the plasma is to accelerate the reaction between the dissociated molecules of the reactant gases. Techniques such as mass spectroscopy and emission spectroscopy allow study of the various reactions within the PECVD process.

The composition and properties of the films vary significantly with substrate temperature and also with the method of generating the plasma. In general, PECVD films are less dense, usually due to the incorporation of hydrogen within the structure. In the case of semiconductors produced by this process, e.g. a-Si, the presence of hydrogen significantly affects both the physical and electronic properties.

Both inductively coupled and capacitively coupled high-frequency power supplies have been used for PECVD, at frequencies ranging from 50 kHz to 13.56 MHz. Of great importance is the power density distribution within the plasma since the life-times of the reactive species are short and must be continually produced in the deposition zone. For this reason the most successful PECVD systems are capacitively coupled and planar in construction—many having developed from the designs of plasma etchers. The introduction of a dilutant gas into the plasma, such as helium, has proved beneficial to film properties. This is

thought to be due to the fact that the helium effectively cools the plasma by reducing the electron temperature and hence reduces damage. Uniformity of deposition in such systems is now better than 3% over 8 in. wafers and the step coverage is very good.

### 9.10.2 Power supplies for plasma production

Four basic types of power supply are used to excite the plasma in most semiconductor plasma-processing equipment. These are: d.c. supplies, high frequency (h.f.) supplies for the range 20 kHz–1 MHz, radiofrequency (r.f.) supplies for the range 1–100 MHz and microwave supplies. The h.f. and r.f. supplies are the most commonly used.

#### 9.10.2.1 H.f. and r.f. power supplies

R.f. power supplies provide an output current and voltage which are alternating with equal but opposite amplitude at a given frequency. The connection to a plasma system is complicated by the fact that the 'plasma load' or r.f. connection to the system cannot be considered as a simple resistive load, but a load with a complex impedance dependent mainly on pressure, applied field and type of gas. The value of plasma impedance can give rise to substantial phase shifts of applied voltage and current resulting in an energy loss in the plasma reactor due to unwanted dissipation.

The output of a generator has a specified termination impedance or output impedance (most commonly 50  $\Omega$  resistive). To achieve maximum power transfer to the plasma the load (plasma) impedance must be equal to the output impedance and this is usually achieved using a  $\pi$ - or L-type impedance matching network. These networks effectively transform the plasma load impedance to that of the output impedance and can be automatically tuned to suit the particular plasma.

For the h.f. case (<1 MHz) the connection of the load to the generator is generally simpler than for r.f. systems since the plasma impedance is more stable, stray capacitances are small and circuit losses insignificant. Such power supplies tend to be used in the inductively coupled mode for PECVD systems. For the r.f. case the most common frequency is 13.56 MHz which is an international allocation for industrial use. For these systems particular care must be taken with the design of components and circuitry. At these frequencies and above, r.f. currents travel in a conductor through its surface and, generally, the penetration (skin depth) decreases as the frequency increases. This means that coils and capacitors, etc., should have highly conducting and large surface areas to reduce losses.

The most widely used r.f. plasma processing system is the parallel-plate configuration with electrodes varying in size from 100 mm to about 1 m, depending on the type and use of the system. It is normal for the base of the chamber to form the substrate holder which is often part of the chamber or a separate earthed electrode. The top (r.f. powered electrode) is usually of a similar diameter, depending on the application, and parallel to the lower electrode. The generator will normally give some visual indication of forward and reflected power and thus allow some degree of control of the generation process.

#### 9.10.2.2 D.c. and microwave power supplies

The d.c. low voltage power supply operates at voltages of 100–800 V and uses a magnetron for plasma confinement. The target or cathode is thus encased in a high density

magnetic field, usually supplied by permanent magnets. This type of supply requires rugged construction as rapid and repeated short circuits can occur from the powered electrode in the plasma system to the positively connected earths at the start of the process. The output current of the supply (typically around 10 A) must also be regulated using closed-loop control, as small changes in the output voltage can create large changes in operating current. A common application of this type of supply is in sputtering equipment.

Plasma excitation by microwaves is also used for semiconductor plasma processing. The frequency of operation is usually 2.45 GHz and most power supplies use a magnetron oscillator with the energy introduced through an isolator into the wave cavity. The microwave circuit is monitored by measuring the power of the incident and reflected waves using a directional coupler. This form of discharge is known as an electrodeless discharge and contamination of the substrate is low. Such supplies are used in etchers, oxidation systems and, more recently, in plasma stream transport systems in which the substrate is placed downstream of the discharge and the plasma transported to it by magnetic flux tubes.

### 9.10.3 Current trends and future developments

It is certain that semiconductor plasma processing will continue to find increasing application throughout the microelectronics industry. In the field of etching most of the current activity in high fidelity pattern transfer is in the area of physico-chemical processes, and particularly in RIE and its refinements. Submicrometre features can already be defined with vertical or bevelled profiles in most of the materials of interest for VLSI applications, but there are still shortcomings in several respects. The enhanced etch rates and lower plasma sheath voltages obtainable with MRIE and triode systems are likely to provide a spur for further developments in these areas. RIBE, because of its flexibility and control over bombardment energy, looks attractive for many applications.

Much research and development is continuing in the field of PECVD of amorphous silicon. Applications of a-Si ICs include solar cells and thin-film transistors for active-matrix liquid-crystal displays. Small flat-screen colour displays to rival the conventional cathode-ray tube are currently available and their use is expected to become widespread in the future.

## 9.11 Lasers

### 9.11.1 Introduction

Laser<sup>1</sup> is a compound word which means 'light amplification by stimulated emission of radiation'.<sup>2</sup> Lasers (or laser devices) basically consist of: (a) a light amplification (or laser) medium; (b) an optical cavity which contains the laser medium; and (c) a pumping source which gives energy to excite atoms or molecules in the laser medium to higher energy levels.

The basic principles involved in producing laser light are shown schematically in *Figure 9.39*. The pumped laser medium has a state of inversion population where a specific upper level has a larger population than the lower level compared to the expected Boltzmann distribution of thermodynamic equilibrium.

Light that passes through such a laser medium is amplified by induced transitions from upper to lower energy

**Figure 9.39** Principles of lasers. (a) Light amplification; (b) Optical cavity; (c) Oscillation by positive feedback

levels. Light that is confined in an optical cavity increases its intensity by multiple reflection between two mirrors and multipassage through the laser medium.

The laser medium may be solid, liquid, or gaseous in the form of a plasma (Section 9.10). Depending on the energy levels of the laser transition, the wavelength of laser light may be in the range from X-rays to millimetre waves.

The properties of laser light, compared with ordinary thermal radiation, can be summarised as follows.

- (1) Laser light is an electromagnetic wave which has a high spatial and temporal coherence.
- (2) Laser light has a high spectral purity which is determined by the resonant curve of the optical cavity and the energy level of the laser transition.
- (3) A beam of laser light has a low divergence, the lower limit of which is determined by diffraction as the divergence angle of  $\lambda/D$ , where  $\lambda$  is wavelength and  $D$  is the beam diameter.
- (4) The high focusability of laser light gives a small focal spot of the order of a wavelength. This gives a high energy or power concentration in space.
- (5) A very short light pulse can be generated by a laser. The pulse width can be compressed to the order of femtoseconds.
- (6) Well-defined polarised light can be generated by introducing a polariser into the cavity.

These characteristic features of lasers have wide application in modern science and industry.<sup>3</sup> Various kinds of lasers are listed in *Figure 9.40* along with their specific wavelengths and performance properties.

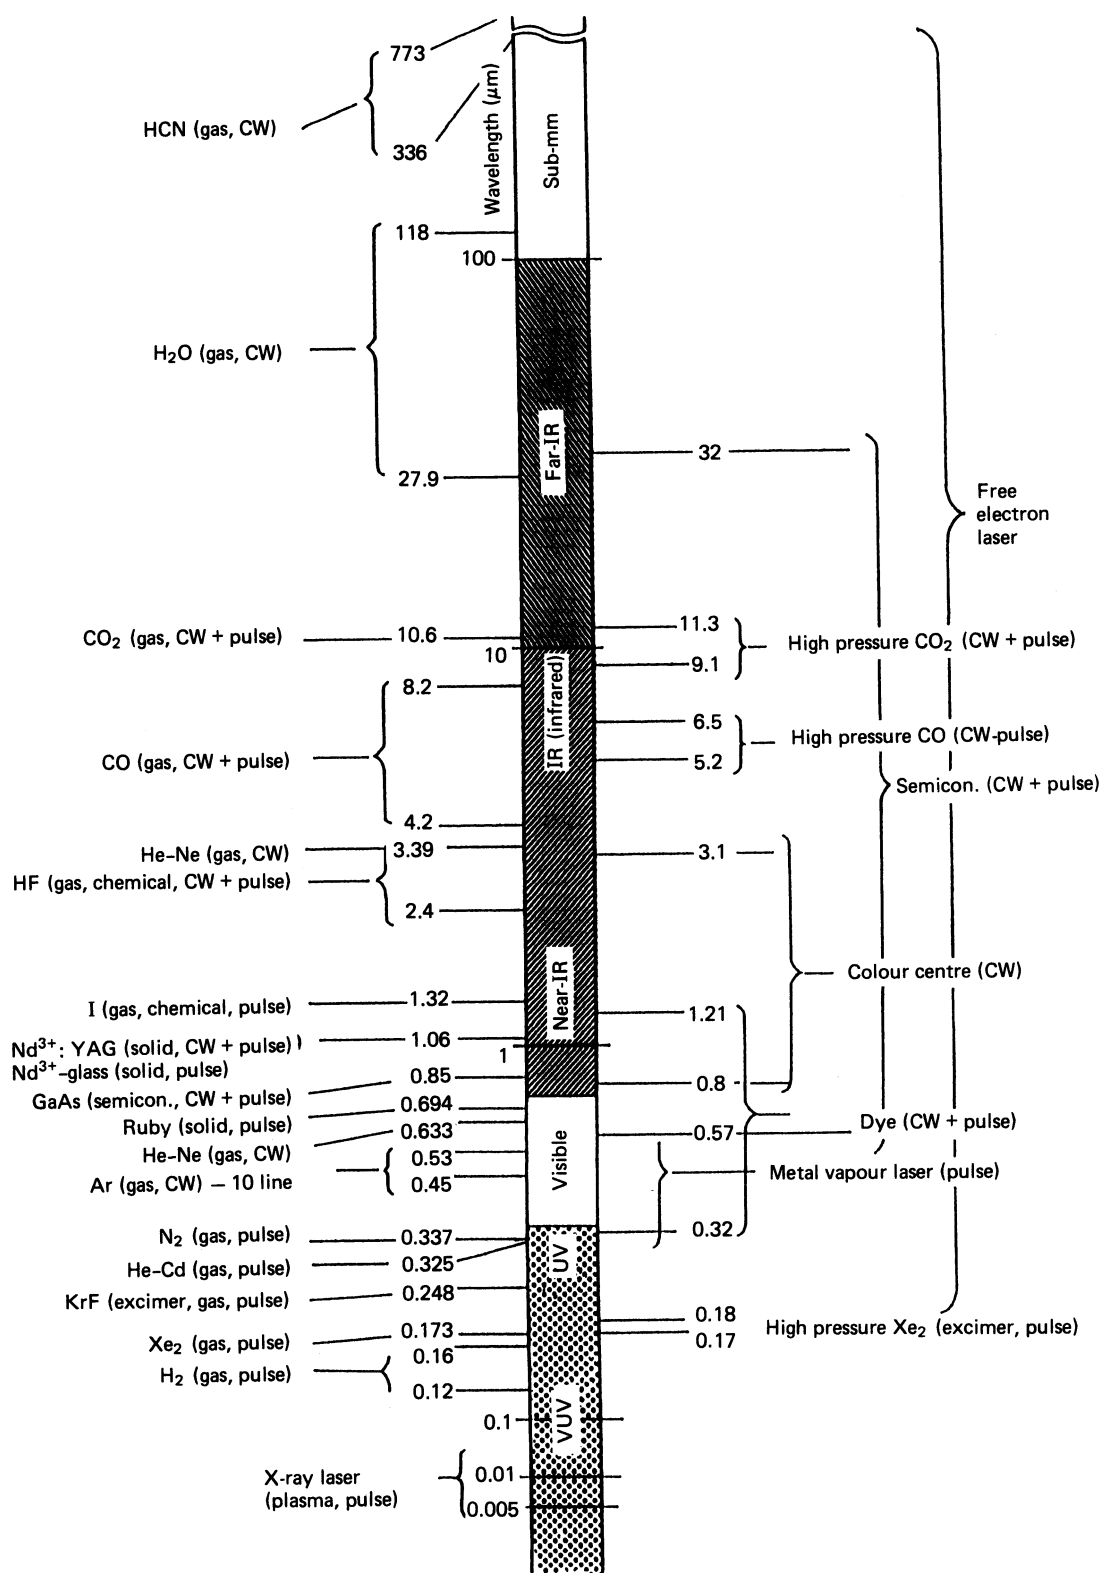

Figure 9.40 Typical lasers and wavelengths. CW, continuous wave; IR, infra-red

**Table 9.12** Features and applications of excimer lasers

Excimer	Wavelength (nm)	Output	Efficiency (%)	Application
ArF	193	5–25 ns pulse 1–1000 Hz, ~500 mJ	≤1	Spectroscopy, photochemistry
KrF	248	2–50 ns pulse 1–500 Hz, ~1 J	≤2	Medical, lithography, dye laser pumping
XeCl	308	1–80 ns pulse 1–500 Hz, ~1.5 J	≤2.5	
XeF	351	1–30 ns pulse 1–500 Hz, ~500 mJ	≤2

## 9.11.2 Gas lasers

### 9.11.2.1 Excimer lasers

Typical excimer lasers that are commercially available are shown in Table 9.12 along with their wavelengths and performance characteristics. An excimer is an excited molecule ( $AB^*$ ) which is stable only in its excited state. When the electronic state of A or B is excited or ionised in a mixture of both, they combine to form the excimer ( $AB^*$ ). A population inversion between ( $AB^*$ ) and ( $AB$ ) can be formed because the ground state ( $AB$ ) is not stable and dissociates to A and B as shown in Figure 9.41 with the potential curve of ( $AB^*$ ) and ( $AB$ ), as in the example of KrF.

Due to the short life-time of the upper state, excimer lasers operate in a pulsed mode with short-pulse duration. The wide bandwidth gain also enables pulse widths of pico- and femto-seconds to be generated, which is a useful feature for the investigation of high time-resolution phenomena. Repetitive operation of up to 1000 Hz provides a high average power of the order of 100 W.

The high photon energy of the short-wavelength light from an excimer laser, along with its high power capability, provides new application possibilities for photochemical material processing, medicine and as a light source for lithography of large scale integrated circuits.

The KrF laser has the potential for use in nuclear fusion,<sup>4</sup> which requires an output energy of megajoules per pulse and megawatts average power with high efficiency of 5–10%. A 10 kJ KrF laser has been constructed in the USA and a 100 kJ KrF laser is being planned and designed in

Europe for application to fundamental science and industrial technology.

### 9.11.2.2 CO<sub>2</sub> lasers

A discharge of CO<sub>2</sub>, N<sub>2</sub> and He excites a specific vibrational level of the CO<sub>2</sub> molecule and produces population inversion for laser action. The wavelength of the CO<sub>2</sub> laser extends from 9 to 11 μm, corresponding to the different vibrational-rotational levels. The efficiency of the CO<sub>2</sub> laser is typically 5–15%. The CO<sub>2</sub> laser is the laser with the capability of delivering the highest output power in continuous wave (CW) operation at the present state of technology and a 100 kW laser is commercially available with a high gas flow circulating system in conjunction with a stabilised discharge.

The CO<sub>2</sub> laser is one of the most widely used industrial lasers. The fields of application are material processing, such as cutting, welding, hardening and surface treatment, medical processing, diagnostics and heating of plasmas, and as a pumping source for various infra-red lasers.

### 9.11.2.3 Other gas lasers

The He–Ne laser is one of the most popular lasers and has been used extensively for diagnostics, data processing and alignment. The ion laser operates at short wavelengths (350–800 nm), and relatively high power (CW 20 W). This laser is used for spectroscopy, dye laser pumping for tunable-laser applications, and laser colour displays. The N<sub>2</sub> laser can generate short pulses of 0.3–10 ns duration at 337.1 nm wavelength (ultraviolet radiation) and with high peak powers of a few tens of megawatts. This laser is used for non-linear spectroscopy and dye laser pumping.

Metal-vapour lasers, especially copper vapour lasers, are under development as pumping sources for dye lasers used for laser isotope separation. Output powers of 100 W to 1 kW at 510 and 578 nm (green light) have been achieved. The He–Cd laser is a three-colour laser emitting at 441.6, 537.8 and 636.0 nm, with a relatively high CW power of 100 mW.

## 9.11.3 Solid-state lasers

### 9.11.3.1 Neodymium (Nd): YAG lasers

A single crystal of Nd doped yttrium–aluminium–garnet (YAG) produces laser radiation at a wavelength of 1.064 μm. A xenon flashlamp is used for pumping. The efficiency is relatively high at a few per cent. High average

power of CW or repetitive pulse operation of 100 W to 12 kW has been obtained.

Frequency conversion of the fundamental output at  $1.064\mu\text{m}$  has been obtained to give third (355 nm blue light) and fourth (266 nm UV light) harmonics using non-linear optical crystals with high efficiency. This feature of multicolour output leads to applications ranging from thermal to photochemical processing. The technology of crystal growth for manufacturing large laser elements is progressing rapidly and a single crystal of about 10 cm diameter without a central core is already being successfully manufactured. Laser diode (LD) pumping techniques are also under development and an LD pumped YAG laser with high efficiency of 30–40% has been demonstrated.

#### 9.11.3.2 Neodymium:glass lasers

Neodymium doped glass emits radiation at  $1.053$  or  $1.062\mu\text{m}$  when *phosphate* glass or *silicate* glass is used, respectively, as a host material. The thermal conductivity of glass is low, and the cooling rate to remove the residual heat should not be too high. Therefore, the repetitive operation of a glass laser is limited. On the other hand, large laser elements with high optical uniformity can easily be manufactured.

Glass lasers are therefore used for laser fusion experiments where high peak power (terawatt) with short pulse (nanoseconds) is required even without repetitive operation and high efficiency. The largest glass laser amplifier is 45 cm in diameter with segmented elements or 35 cm in diameter with a monolithic element. The largest laser system is the NOVA glass laser at Lawrence Livermore National Laboratory, USA, which can deliver 120 kJ/ns at  $1.053\mu\text{m}$  fundamental wavelength and 70 kJ in third harmonics of blue light. The GEKKO XII glass laser at the Institute

of Laser Engineering, Osaka University, which is used for international collaborative research, has output powers of 20 kJ/ns at  $1.053\mu\text{m}$ , 15 kJ as green and 12 kJ as blue light.

Glass lasers of higher power are planned and are being designed to generate 100 kJ to megajoules output energy as blue light for thermonuclear fusion ignition experiments and also for basic high-energy-physics research.

#### 9.11.3.3 Laser diode and laser-diode-pumped solid-state lasers<sup>5</sup>

Semiconductor diode lasers have progressed in terms of performance and application achievements. One of the most important fields of application is in optical communication with fibre transmission. A wide tunable range with narrow spectral width is required for applications in coherent optical communications with frequency division multiplexing. Laser disks and laser scanners also provide a demand for LDs. High power and long life are the basic requirements for commercial use.

Typical LD performance specifications that have been individually achieved include:

- (1) long life (>10 years),
- (2) high power (>1 W (CW, one junction), >115 W (CW, 1 cm array), >200 W (pulse, 1 cm array)),
- (3) efficiency (>50%),
- (4) spectral purity (<1 MHz (20 mW)), and
- (5) tunability ( $\Delta\lambda \leq 6$  nm).

One of the most important energy applications of LDs is as a pumping source for solid-state lasers. Figure 9.42 shows the energy levels and absorption spectrum of an Nd laser compared with the emission spectra of a laser diode and an Xe flash lamp. The output emission of the LD can be tuned to the most efficient absorption line for population inversion. Thus the LD laser pump has the potential for high

**Figure 9.42** Spectrum of Neodymium: glass absorption, flash lamp emission and LD oscillation line. The transition and energy state of the neodymium laser is shown

**Figure 9.43** LD-pumped solid-state lasers and various layouts. (a) End pump; (b–d) Side pump

efficiency, low residual heat and solarisation for high repetition operation and long life. Solid-state lasers can be assembled as compact and easily manipulated devices by using LD pumping. Figure 9.43 shows a schematic of an LD pumped solid-state laser. An end-on pumping scheme is suitable for micro-tip lasers with single-mode operation. A side-on pumping scheme is more flexible for assembly with high power lasers. The record for output power is 3.8 W CW with 10.9 W CW pumping or 4.9 W CW with 14 W CW pumping, with end-on pumping and 5 kW with side-on pumping.

Research trends for high-efficiency frequency-conversion technology (to green ( $2\omega$ ), blue ( $3\omega$ ) and UV ( $4\omega$ ) light) and for the development of new solid-state laser materials which have tunability or long fluorescence life-times are opening new fields of laser technology. Together with LD pumping techniques and in conjunction with gas, liquid or solid-state lasers, such trends are leading to new applications of laser technology in science, industry and medicine.

#### 9.11.3.4 Tunable solid-state laser and new materials

The development of new solid-state laser materials is now proceeding rapidly, with the aim of achieving tunability and higher performance characteristics. Many materials capable

of emitting at wavelengths between 680 and 2500 nm are under investigation. These are neodymium or chromium doped gadolinium–scandium–garnet (GSGG), neodymium, erbium or holmium doped yttrium–lithium–frolide (YLF), neodymium doped  $\text{YVO}_4$ , etc. One of the well developed solid-state tunable lasers is the Ti : Sapphire laser which has a wide tunable range of 660–1180 nm with a high power output.

### 9.11.4 Application of high-power lasers

#### 9.11.4.1 Laser processing and machining

**Laser interaction with matter** The interaction of laser beams with matter may be divided into three categories with regard to both physical processes and applications: thermal processes, photochemical processes, and plasma processes.

When a material is irradiated by laser light it absorbs the photon energy at the surface. The efficiency depends on the reflectivity of the surface and hence on such material properties as electrical conductivity or the existence of an appropriate absorption band. The heat on the surface then transfers to the substrate. This process can be calculated from thermal models when the thermal conductivity and heat capacity are known. At higher intensities, melting and evaporation occur. Laser-induced thermal effects provide a wide variety of laser machining technologies.

Another characteristic laser-induced process is the laser photochemical effect or laser-induced chemical reaction. The photochemical effect may be divided into three fundamental physical processes, excitation of molecular vibrational/rotational and electronic states, dissociation of molecules, and photoionisation. These processes may induce subsequent chemical reactions if appropriate reaction materials are introduced. Because laser light has a high degree of monochromaticity, a specific energy state can be selectively excited. This effect provides the means of controlling the chemical reaction by using a tunable laser. The correspondence of photon energy and wavelength produced by a number of typical excimer lasers with the chemical bonding energy of some organic radicals is shown in Figure 9.44. By using a short-wavelength laser, direct dissociation can be initiated.

At ultra-high laser emission intensities, plasma effects become dominant. In this region of interaction, temperatures of millions of degrees can be realised. Strong UV and X-ray radiation and the formation of multiply ionised atoms are observed.

**Laser machining**<sup>6</sup> Laser machining is dominantly based on the thermal processes induced by the interaction of the laser beam with matter. The characteristic features of laser machining are non-contact, rapid scan, fine spot and high energy density. Laser machining is one of the most widely distributed technologies currently used in industry. Its uses include drilling, cutting, joining or welding, material removal for trimming, marking and scribing, surface modification by transformation hardening, shock hardening, cladding and alloying. By controlling the heating and cooling rate, the crystalline structure of a surface can be manipulated to be amorphous, polycrystalline or non-equilibrium alloy.

Neodymium: YAG lasers or  $\text{CO}_2$  gas lasers are widely used for these applications with CW operation or repetitive pulse operation to give a high average power.

Figure 9.44 Chemical bonding energy and related wavelengths of excimer lasers

Figure 9.45 Laser CVD

**Laser photochemical processing** Excimer lasers are now being used because of their short wavelengths for the initiation of photochemical processes, relying on their wavelengths being coincident with the bonding of the chemical compounds involved (Figure 9.44).

**Laser chemical vapour deposition (CVD):** a schematic diagram of a laser CVD system is shown in Figure 9.45. The source gas (for example  $\text{Si}_2\text{H}_6$ ) is dissociated by a parallel laser beam (ArF excimer laser) and silicon is deposited on the surface of the substrate. In the case of Figure 9.45, the perpendicular beam is used to write some patterns on the substrate by the selective evaporation of the deposited thin layer.

Thin metal and dielectric layers as well as oxide may be formed by laser CVD through a combination of various source gases and laser wavelengths.

Thus laser CVD provides a means for a wide variety of processing techniques with low intrinsic damage to the substrate, and with the capability of maskless patterning.

**Laser etching:** laser-induced photochemical etching can be categorised into two different schemes, reactive photoetching and direct dissociative etching. Semiconductors or metals can be etched by irradiation with a laser in an atmosphere of reactive gas.

Plastics can be etched by direct dissociative etching without thermal effect by using short-wavelength lasers, the photon energy of which is higher than the bonding energy of the molecules.

Laser etching can be a low intrinsic damage process and maskless patterning is possible. Figure 9.46 shows an example of patterning by direct dissociative etching of plastics.

**Lithography:** the process of microlithography provides a means of microprocessing integrated circuits. Shorter wavelengths are desirable and excimer lasers are being developed as the light sources. X-ray lithography is also under development. Plasmas produced by lasers are expected to be feasible as intense X-ray sources because of a high conversion efficiency from laser to X-ray (more than

Figure 9.46 Excimer laser etching on a hemisphere of thin polyimide film

**Figure 9.47** Progress towards laser fusion. (a) Neutron yield; (b) Compressed density

50%), a small point source of the order of the focal spot of the laser light, a bright source of  $10^{12}$ – $10^{13}$  W/cm<sup>2</sup> steradian, soft X-rays which are suitable for lithography, and a short X-ray pulse of the order of the laser pulse width.

These features of laser produced plasma X-ray sources can also be useful for X-ray microscopy and X-ray microanalysis.

#### 9.11.4.2 Laser fusion<sup>4,7</sup>

Laser fusion is one of the most interesting applications of power lasers, where the many properties of a laser are fully utilised. The extreme concentration of energy in time and space which produces a high-density compression of fusion fuel has only become possible via laser implosion.

Focused laser beams are irradiated uniformly onto the surface of a fuel pellet and produce high-temperature plasma on the surface. The outward expansion of the plasma generates inward dynamic pressures which compress the hydrogen isotope fusion fuel. Adiabatic compression increases the density and also the temperature of the fuel and initiates the nuclear fusion. The progress which has been made towards realising laser fusion is illustrated in Figure 9.47 via the enormous increases in compressed core density and neutron yield which have been achieved. The temperature and density which have been realised are  $10^8$  K and 1000 times the solid hydrogen density, respectively.

Glass lasers are widely used for present laser fusion experiments.

**Table 9.13** Glass laser systems world-wide

Laser systems which are now becoming operational are listed in Table 9.13 along with several parameters of each system.

The next stage in the research and development of laser fusion is a demonstration of ignition and energy gain. The required laser energy is estimated to be 100 kJ to megajoules of green or blue laser light with a pulse width of the order of nanoseconds.

For energy production in a commercial laser fusion reactor, repetitive operation of 1–10 Hz with a megajoule pulse energy and with 5–10% laser efficiency is required. This corresponds to the need for a megawatt short-wavelength laser with high efficiency and high focusability, which would also have a wide range of industrial applications other than laser fusion.

#### 9.11.4.3 Other applications of high-power lasers

The fields of diagnosis and measurement are where lasers have been primarily used since the early days of their evolution. Measurements of physical quantities such as position, velocity, acceleration, direction, surface configuration, and three-dimensional configuration, utilise the coherence and directionality of laser light. Scattering measurements of Thomson (electron), Rayleigh (atom or molecule), Mie (microparticle), Raman and Brillouin provide a wide variety of methods for diagnosing physical and chemical parameters of gases, liquids, solids and plasma. Monochromaticity of laser light is widely used in these applications.

Medical applications use the thermal effect of focused laser beams. Photochemical effects are being developed for medical treatment with the progress that is being made in realising short-wavelength high-power lasers.

#### 9.11.5 Laser pumping methods and electric power supplies

The methods of pumping a laser with their associated power supplies depend on the type of laser. They may be classified as follows.

*D.c. discharge through low pressure laser gas for HeNe, HeCd, low-pressure CO<sub>2</sub>, and ion lasers.* The characteristics of the power source depend on the type and design of laser through parameters such as gas pressure, length and bore radius of the discharge tube, mixing ratio of the laser gases and the buffer or energy transfer gases. The output required from the power source may vary from milliamperes to kiloamperes, and a few volts to kilovolts.

*Pulse discharge with pre-ionisations for excimer lasers, TEA CO<sub>2</sub> lasers (transversely excited atmospheric pressure).* To obtain a uniform discharge through the high-pressure laser gas, pre-ionisation by ultraviolet irradiation, or by surface corona discharge on the cathode is used. For the fast discharge needed for the pre-ionisation, a fast circuit with small capacitor and low stray inductance is needed in close proximity to the laser chamber. The main circuit for pumping discharge is composed of a fast capacitor bank (for the CO<sub>2</sub> laser), pulse forming network (PFN) with lumped capacitors and inductors or pulse forming line (PFL) with distributed transmission line. To obtain a faster rise of source power, a magnetic switch with a saturable core is used. A newly developed circuit for powering high-power excimer lasers is shown in Figure 9.48; this has spiker and sustainer circuits. A high repetition frequency of 1 kHz and an average output power of 2 kW can be obtained.

*Electron-beam-controlled discharge for high-pressure, high-power CO<sub>2</sub> lasers.* One of the most advanced electrical discharge concepts is electron-beam-controlled discharge. A uniform discharge through a high pressure gas up to a few tens of atmospheres and with an optimised  $E/p$  ratio for laser pumping can be achieved, where  $E$  is the electric-field strength and  $p$  is pressure. A uniform electron beam is introduced into the discharge region through a thin foil that separates the high-pressure region from a vacuum region where the electron beam gun is situated. Rectangular high voltage pulses of a few microseconds duration and a few hundred kilovolts amplitude are generated by a PFN with the capacitor elements of a Marx type generator.

*Optical pumping of solid-state lasers with d.c. or pulse operation.* For d.c. laser operations, a krypton arc lamp is widely used. The specifications for the power source depend

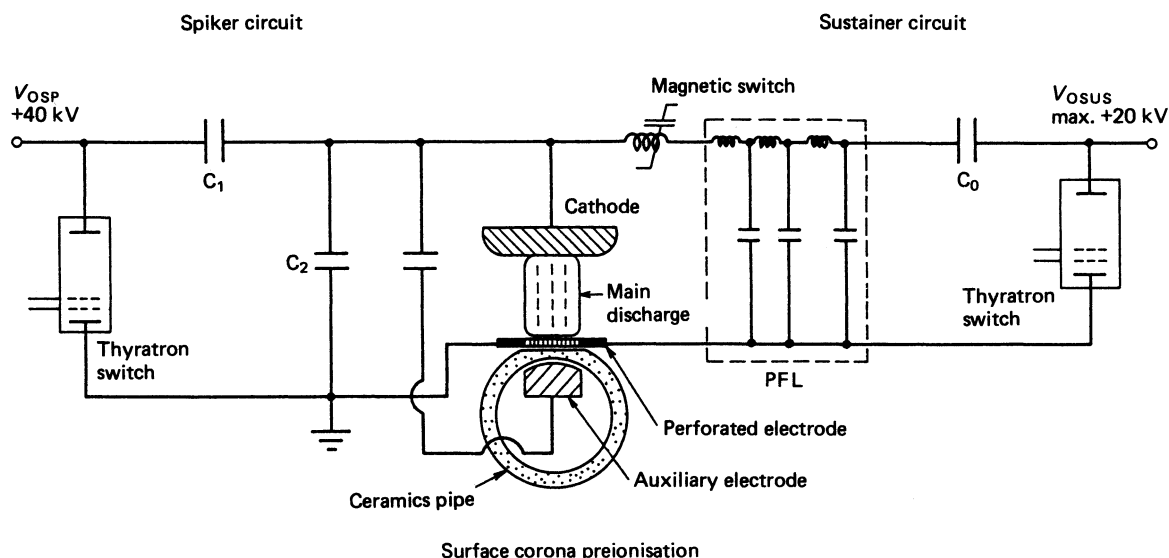

Figure 9.48 Combination of a surface corona pre-ionised discharge electrode with a spiker-sustainer pulse circuit (repetitive operation)

on the current density, bore radius, arc length, and gas pressure of the lamp. Typical discharge parameters are 100–200 V, 10–40 A, for a krypton arc lamp of 6 mm inner diameter, 150 mm arc length, with 4 atm gas pressure. A constant-current d.c. power supply with feedback stabilisation and a few kilovolts trigger circuit is used.

For pulse operations, a xenon flash lamp is widely used. The power source is usually PFN with the lamp elements, the length of current pulse is designed to match the fluorescent life-time of the laser material which is between 100  $\mu$ s and 1 ms.

Recently, LD pumping has become a feasible technology for high-efficiency, d.c. or high repetitive-pulse operation of solid-state lasers. The most important feature of LD pumping is the matching of the LD emission spectrum to the absorption of the laser materials. The specification of the power source for an LD is 2–3 V and a few amperes for one element. LDs with an output of 1–150 W (quasi-CW) are commercially available and 420 kW with 10 Hz, 100–400  $\mu$ s pulsewidth with arrayed LD has been reported. LD-pumped solid-state lasers, together with frequency conversion, will become one of the key technologies of high-power laser systems of the future.

## 10.1 Arc welding

The arc is an ideal means of generating intense heat of sufficient power to melt most materials, especially metals. The arc is formed between an electrode and the workpiece. The electrode can be of a refractory metal rod, such as tungsten, or a metal rod or wire, as shown in *Figure 10.1*. In the tungsten arc process, the arc is formed between the pointed tip of the electrode and the abutting faces of the two components being welded. The faces are melted and the bridge or weld is formed between the components. In the case of a metal electrode, the electrode fulfils the same function as the tungsten electrode in forming a point heat source, but in this case, the electrode is consumed in the course of welding and the molten metal from the electrode helps to bridge the gap between the components being welded.

The welding current can be either d.c. or a.c., but in either case the voltage, in particular, must be sufficient so that the arc discharge or plasma can be sustained. With the tungsten electrode, the arc formed is in a gas flow of argon or helium gas, whilst in the metal arc processes, the plasma is formed either from CO<sub>2</sub> or an argon based gas with a small amount of oxygen or CO<sub>2</sub>. The plasma reaches a temperature of the order of 15 000 K, at least in the core, but it is noteworthy that most of the heat is associated with the arc root mechanisms. The voltage distribution across the arc shows three distinct regions, the anode drop, plasma column drop and the cathode drop, *Figure 10.2*. The anode and cathode voltage drops are determined by the electrode material and

**Figure 10.2** Voltage distribution across a tungsten arc

**Figure 10.3** Typical voltage-current arc characteristics

(a)

(b)

**Figure 10.1** Principles of operation for the tungsten electrode and metal electrode welding processes. (a) Tungsten electrode; (b) metal rod (or wire) electrode

the ionised gas compositions, but for welding applications the plasma drop is a function of the arc length.

The arc voltage-current characteristics are shown in *Figure 10.3*. There are three regions, depending on the current level. At low currents, the voltage-current relationship has a negative slope (as the current increases, the voltage decreases), the flat portion at intermediate current levels is essentially a constant voltage irrespective of current, and at high currents the slope of the voltage-current relationship is positive.

### 10.1.1 Power sources for arc welding

The basic function of the arc welding power supply is to provide sufficient power to melt the joint between the parts and, if required, the additional weld metal provided by a filler wire. As most arc welding processes require a high current, (50–500 A) but at relatively low arc voltages (10–50 V), the high-voltage mains supply (240 or 440 V) must be reduced. Thus, in its basic form the arc welding power source comprises a transformer to reduce the mains voltage and increase the current. For d.c. a rectifier is placed on the secondary side of the transformer (*Figure 10.4*).

The conventional d.c. power source operates on either a single-phase or a three-phase a.c. supply. The disadvantage of the former is that, even with full wave rectification, the output waveform contains a high degree of ripple, as shown schematically in *Figure 10.5*; a high level of ripple can result in poor arc stability at low current levels. A much smoother d.c. output is provided by a three-phase input and a bridge rectifier which produces full rectification, as shown schematically in *Figure 10.6*. Nevertheless, even with the three-phase output, the final current waveform will contain a

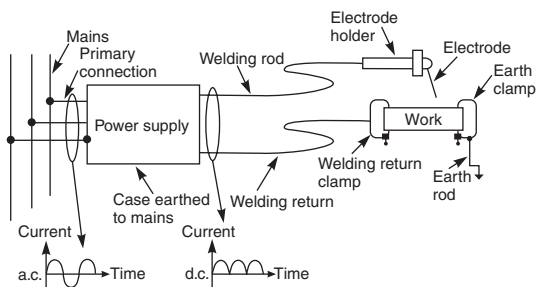

Figure 10.4 Reducing high voltage using a transformer

significant amount of 300 cycle ripple (as shown in *Figure 10.6*), which can noticeably affect the shape of the arc and its stability. The more advanced, so-called 'electronic', control systems have been designed to provide an accurate d.c. output, with high response and sophisticated control of the output.

#### 10.1.1.1 D.c. power-source control

Traditional power-source control uses a variable reactor, moving coil or moving iron transformer, or a magnetic amplifier to control the welding current. Such equipment has the highly desirable features of simple operation, reliability and robustness, making it ideally suited for

application in aggressive industrial environments. The disadvantages are relatively high material cost, large size, and limited accuracy with slow response. The latter feature, in particular, can limit the performance of the power source, especially when sophisticated control of the output is required.

In recent years, electronic power sources employing high power semiconductors, have become available which do not suffer from these disadvantages. The various types of electronic power source are:

- (1) thyristor phase control;
- (2) transistor, series regulator;
- (3) transistor, secondary switched (chopper); and
- (4) a.c. line, or primary, rectifier plus inverter (SCR or transistor).

The advantages and disadvantages of these types of power source compared with conventional variable reactor or magnetic amplifier power sources are listed in *Table 10.1*. The main features of the different power sources are described below.

**Thyristor-phase control** Of the power source designs listed in *Table 10.1*, thyristor control represents an excellent compromise in terms of performance and cost. In this power-source design, the output is controlled by the phase angle of the a.c. voltage, at which the thyristors (SCRs) are switched on. Whilst high current sources have a three-phase input, low current sources normally have a single-phase input with current control on the primary side of the

Figure 10.5 D.c. power source with single-phase supply

Figure 10.6 D.c. power source with three-phase a.c. supply

**Table 10.1** Major operational features of electronic power sources compared with conventional variable reactor or magnetic amplifier power sources

<i>Control type</i>	<i>Method of control</i>	<i>Advantages</i>	<i>Disadvantages</i>
Thyristor, phase	Thyristors replace diodes on secondary output of the transformer. Alternatively, triacs or inverse parallel thyristors are used in the primary of the transformer	Better accuracy of current and time settings. Can be used to produce square-wave a.c. waveform. Can be used for pulsed operation	High ripple unless large amount of inductance is placed in series with output. Pulsed response normally limited to 100 Hz
Transistor, series regulator	Power transistors in parallel; analogue control from low current input signal	Very stable and accurate control of current level—better than 1% of set level. Pulsing over wide range of frequencies (up to 10 kHz), and pulse shape can be varied	Poor electrical efficiency. D.c. supply only
Transistor, switched	Transistor, high frequency switching (20 kHz) of d.c. supply	Accuracy and control similar to series controller. Less wasteful of energy compared with series regulator. Greater arc stiffness can be exploited for low current operation	Although the output is similar to that of a series regulator, pulse frequency and wave shaping is less flexible
A.c. line rectifier, plus inverter	Mains supply rectified to high voltage d.c. and then converted by transistors or thyristors to a.c. operating at 2–50 kHz. Final output produced by small mains transformer and rectified to d.c.	Because the transformer operates at high frequency, the size and weight of the mains transformer can be greatly reduced. Because of its small size, the cost of raw materials is significantly reduced. Accuracy of control is better than with a magnetic amplifier	Rapid switching can cause an unpleasant whining noise from the arc

transformer. The output waveform suffers from inherent ripple, the frequency being a simple multiple of the mains supply, i.e. 100, 150 or 300 Hz. Whilst the ripple is not normally a problem at medium or high welding currents, excessive ripple can cause problems in arc starting and in operating at currents below 20 A.

**Transistor-series regulator** The transistor based control systems offer highly desirable features for precision welding, namely accuracy and reproducibility of the welding parameters. The analogue type control (*Figure 10.7(a)*) where the current flowing through all the transistors is regulated, provides a ripple-free and easily controlled output. The output, under feedback control, can be pulsed at a frequency within the kilohertz range and the pulse waveform and the overall operating sequence can be precisely shaped. However, the regulator stage tends to be wasteful of electrical energy as the excess power in the transistors must be dissipated by water cooling; as the difference in the voltage between the arc and the open circuit appears across the transistors, this excess power (voltage difference times the current) is dissipated by the transistors which are usually cooled by mounting on water-cooled copper heat sinks.

**Transistor-switched** Switching transistor control, in which each transistor operates in either an 'on' and 'off' state, (*Figure 10.7(b)*) is an attractive alternative to analogue

control. The output is determined by the ratio of the 'on' time to the 'off' time. As power is dissipated at the moment of switching, this design is more efficient which obviates the

**Figure 10.7** Transistor controlled power sources. (a) Series regulator transistor control; (b) Switching on/off transistor controlled power source

**Figure 10.8** High frequency inverter power source

need for water cooling. The output is 'chopped' at a frequency usually in excess of 10 kHz, which has the beneficial effect of constricting the arc shape, thereby making it more directional. Thus, switching transistors have enabled the advantageous features of transistor control (high accuracy and reproducibility) to be exploited without the limitations of the analogue control system, particularly its high energy consumption. Various models of this type of power source have also been designed for specific welding operations, e.g. for welding thin sheets at low current levels, or for high-speed welding at higher current levels.

**A.c. line rectifier plus inverter** The a.c. line rectifier, plus inverter, type of control (*Figure 10.8*) represents a basically different approach to power source design. Compared with the normal mains frequency transformer/rectifier, the mains supply is first rectified and stored by a capacitor. The medium-voltage d.c. is then converted to a.c. at a frequency in excess of 500 Hz by means of switching transistors or thyristors. The high-frequency a.c. is finally transformed down to a voltage suitable for welding and then rectified to d.c. to provide the normal range of welding current levels. As the transformer operating within the range 20–100 kHz can be substantially reduced in size, compared with conventional transformers for use at mains frequency, higher electrical efficiency and power factor and small size have been achieved. The main limitation at this stage of development concerns the performance of the switching devices which must withstand a high hold-off potential in excess of approximately 1.5 kV. With regard to the operation of the power source itself, the relatively high level of arc noise can be an annoying factor; the noise is related to the switching frequency and power sources operating at frequencies above 20 kHz do not suffer from this problem.

#### 10.1.1.2 A.c. power source control

The simplest a.c. power source is the single-phase type, with moving core control. A.c./d.c. power sources have moving core or thyristor control with the thyristors (phase angle control) acting on either the primary or the secondary side. The problem of operating an a.c. welding arc is that a high open-circuit voltage is required to ensure that the arc re-ignites on polarity reversal. For example, when welding with a metal electrode, a covering which contains easily ionised elements is required to sustain the arc, and sine wave power sources are normally operated with an open-circuit voltage of 80 V. When using a tungsten electrode which does not have a flux coating, high voltage or high-

**Figure 10.9** AC waveform showing voltage required to re-ignite the arc

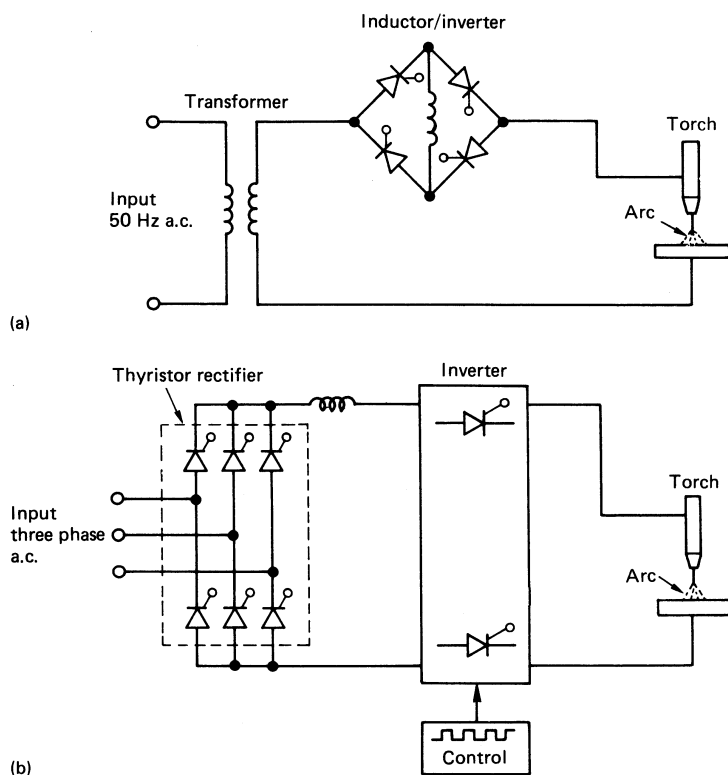

**Figure 10.10** Characteristic re-ignition waveforms for: (a) sine wave supply at an open-circuit voltage of 100 V; (b) switched d.c. supply at an open-circuit voltage of 75 V; (c) output waveform of a square wave a.c. power source

frequency oscillation is also applied continuously to ensure arc re-ignition (*Figure 10.9*).

In an alternative form of power source the output current assumes a more square waveform as compared with the conventional sine wave (*Figure 10.10*). Two types of power source are available: the squared sine wave a.c., and the switched d.c. power source. The squared a.c. wave is generated by using inverted a.c. (*Figure 10.11(a)*), whilst the more truly square waveform is produced by directly inverting a d.c. supply (*Figure 10.11(b)*). The rates of circuit current rise for the two types of power source on polarity reversal are typically 110 A in 0.1 ms and 160 A in 0.02 ms for the square wave a.c. and the switched d.c. power source, respectively. In comparison, the rate of change of current for conventional sine wave a.c. can be as much as two orders of magnitude less than the switched d.c. power source; a time of approximately 3 ms is required to achieve a circuit current of 110 A from zero with 50 V across the arc gap.

The advantages of rapid current build up on polarity reversal are:

- (1) a reduction in the open-circuit voltage;
- (2) easier arc re-ignition; and
- (3) reduction in electrode heating.

**Figure 10.11** Square wave d.c. power source designs: (a) 'squared' a.c.; (b) switched d.c.

These advantageous features of square wave power sources are discussed when considering specific arc welding processes (see Sections 10.1.3 to 10.1.8).

#### 10.1.1.3 Intelligent control

Whilst the earliest welding power systems implemented control using electronic analogue feedback, today a number of power sources on the market employ digital control concepts. Digital control systems have the advantage of being cheaper to develop, less susceptible to the degradation of the electronic components, and easier to update and modify.

Employing software to control the power source output enables intelligence to be included in the control system. For example, power sources have the capacity to store welding parameters and welding programmes tailored to the application i.e. type of welding process, material etc. As an indication of the increase in the intelligence of power sources, the memory requirements have increased typically from 50 kb for the early inverter power sources to 500 kb for the latest designs.

Power sources are also available which implement the control strategy using fuzzy logic. This approach makes it easier to develop sophisticated and intuitive control strategies than would otherwise be possible using traditional coding techniques. Fuzzy logic is being applied in the dynamic control of the welding arc.

#### 10.1.1.4 Rating plate/power source specification

In selecting a suitable power source design for a welding process, it is important to check that the specification of

(1)3~				EN 60 974-1	
		40A/22V – 250A/30V			
		==	X	35%	60%
U <sub>0</sub> V		I <sub>2</sub>	250 A	200 A	150 A
60		U <sub>2</sub>	30 V	28 V	26 V

Degree of protection      Symbol for protection, Class 2 equipment      Suitable for welding operations in hazardous situations

**Figure 10.12** Rating plate for arc welding power sources

the power source will be suitable for the intended job. Information about a new power source can be obtained direct from the manufacturer or from the product literature. For an existing power source, the handbook can be consulted but often the rating plate information is all that is available. Any power source controlling the welding parameters made to a National, European or International standard should have a rating plate similar to the one shown in *Figure 10.12*. This plate provides information about the

manufacturer, supply requirements, performance and suitability for use. For equipment built in the last few years the rating plate should conform to IEC 60974-1 (EN 60974-1).

The following symbols are used on the manufacturer's rating plate to indicate the type of protection:

- Insulation protection, class 2 equipment.
- S Power source suitable for supplying power to welding operations carried out in an environment with increased hazard of electric shock.
- IP XX Degree of protection of the enclosure.

The symbol S refers to the suitability of the power source for operating in environments with increased hazard of electric shock. The rated no-load voltage of such power sources shall not exceed:

- D.c. 113 V peak
- A.c. 68 V peak and 48 V r.m.s.

The symbol S is also often displayed on the front of the power source. The code for the degree of protection which refers to risk of electric shock in normal service from direct contact is as follows:

- IP2X The 2 refers to protection to solid objects larger than 12 mm. e.g. fingers.
- IPX1 The 1 refers to protection from vertically falling drops of water.
- IPX3 The 3 refers to protection from drops of rain water up to 60° from the vertical.

The minimum degree of protection for welding power sources is IP 21. However, power sources specifically designed for outdoor use shall have a minimum degree of protection of IP 23.

#### 10.1.1.5 Welding installations

Typical arc welding installations for both single and multi-welder operations are described in National guidelines e.g. the UK HSE Guideline No 118, 'Electrical Safety in Arc Welding'. In connecting the welding circuit, the following best practice should be adopted:

- the connection between the welding power source and the workpiece should be as direct as practicable;
- use insulated cables and connection devices of adequate current carrying capacity;
- extraneous conductive parts should not be used as part of the welding return circuit unless part of the workpiece itself;
- the current return clamp should be as near to the welding arc as possible.

When attaching the welding current and current return cables, it is essential that an efficient electrical contact is achieved between the connection device and the workpiece to prevent overheating and arcing. For example, the current and return clamps must be securely attached to 'bright' metal i.e. any rust or primer coatings should be locally removed.

**Power source and earthing** The normal practice in the UK has been to provide a separate earth connection to the workpiece. The reason is that, in the unlikely event of an insulation breakdown between the primary and the secondary circuit, the fuses will blow. However, the separate earth connection increases the risk of stray currents which may cause damage to other equipment and conductors.

As modern power sources have been designed to have a much higher level of insulation (termed double or

reinforced insulation), a separate earth connection is not recommended.

There is a potential problem in that both power source designs can often be found in the same welding shop. The newer (double or reinforced insulation) power source can be identified by reference to the power source's rating plate (*Figure 10.12*) which will indicate that it has been manufactured to current standards e.g. EN 60974-1 or IEC 60974-1.

In older power source designs, the welding circuit was sometimes connected internally to the power source enclosure. However, the danger is that even with the welding return lead disconnected, and a separate earth connection, welding is possible with the current flowing through the earth. Because of the risk of damaging protective earth and other connectors, this type of power source is considered to be obsolete and should not be used.

**Supply requirements** Power sources will require either a single- or three-phase supply at 230 V a.c. or 400 V a.c. In many parts of Europe the 230 V supply is 16 A, but in the UK the standard ring main is 13 A. Therefore, the relatively low power output of the 230 V system is further reduced if a 13 A plug is fitted and a dedicated circuit may be required.

Three-phase supplies may be limited to 30 A, but higher power welding equipment may require a 45 A or even 60 A supply. The effective current is displayed on the rating plate. This value should be used to determine the cable size and fusing requirements.

Apart from the obvious hazards associated with overloading a supply, e.g. overheating and blowing fuses, problems with other equipment may be caused. If the supply has a high impedance (commonly known as soft) as may be the case in rural areas supplied by overhead cables, a high current draw may cause the voltage of the supply to fall below levels which may cause problems with other equipment.

**Engines and motor drives** For equipment not supplied from the mains, such as generators, information is provided about the characteristics of the motor, load and idle speed and power consumption. While this type of equipment may be ideal for welding outside in remote locations, it tends to generate a high level of acoustic noise. The noise levels are limited by an EU directive but can be as high as 97 dBA.

**Environment** All power sources should be marked with an IP rating which provides information about the degree to which the equipment is protected against water. Normally equipment will be IP 21 or IP 23. The first number means that it should not be possible to touch live parts and the second number describes protection against water ingress. A power source marked IP 21 is protected from vertical drops of water, as for example may occur if the roof leaks. If the equipment is marked IP 23, this means that the equipment is protected from water at up to 60° from the vertical and is thus suitable for outdoor use. Additional letters to the IP number indicate tests with or without the fan running and increased mechanical protection from electrical hazards.

Areas of increased risk are in wet or humid conditions, confined spaces or when the welder is exposed to large areas of bare metal. For use in this type of environment, it is important to use a power source with an S mark which means that the no-load voltage is below 48 V r.m.s. a.c. or 113 V peak d.c. If the power source has a higher no-load voltage, a voltage reduction device should be used which will limit the voltage at the holder to approximately 25 V.

### 10.1.1.6 Relevant standards

The relevant standards for arc welding power sources, equipment and accessories are:

EN 60974-1:1998, IEC 60974-1:1998, 'Arc welding equipment—Part 1: Welding power sources'

EN 60974-7:2000, 'Arc welding equipment, Part 7, Torches'

EN 60974-11:1995, 'Arc welding power equipment, Part 11, Electrode holders'

EN 60974-12:1995, 'Arc welding equipment, Part 12, Coupling devices for welding cables'

EN 169:1992, 'Specification for filters for personal eye protection equipment used in welding and similar operations'

EN 60529:1992, 'Specification for degree of protection provided by enclosures' (IP codes)

EN 470-1:1995, 'Protective clothing for use in welding and allied processes—general requirements'

EN 50199:1996, 'Electromagnetic compatibility (EMC)—Product standard for arc welding equipment'

EN 50060:1989 'Power sources for manual metal arc welding with limited duty'

## 10.1.2 Manual metal arc welding

### 10.1.2.1 Principles of operation

The manual metal arc (MMA) process is the most versatile welding method. It can be used to weld most materials in a wide range of thicknesses and in all welding positions. The basic principles of the process are shown in *Figure 10.13* and the essential features are a central metal rod surrounded by a flux covering. The function of the flux is as follows:

- (1) The vaporised flux contains easily ionisable elements which help to stabilise the arc.
- (2) The molten flux surrounds the molten droplets to prevent oxidation.
- (3) The presence of slag on the weld pool and the gas shroud of mainly carbon dioxide, prevent oxidation of the weld pool.
- (4) The composition of the flux also influences the chemical composition of the weld metal and hence its mechanical properties.
- (5) The properties of the molten flux and the flux residue or slag, particularly its fluidity and rate of freezing,

**Figure 10.13** Principles of operation of the manual metal arc process

determine the so-called 'handleability' of the electrodes and their ability to weld in positions other than flat; a viscous fast-freezing slag is preferred for welding in vertical and overhead positions.

- (6) The slag also has an influence on the final shape of the weld bead—for example, a fluid slag/weld pool will 'wet' more smoothly into the parent metal producing a flat weld bead, whilst a less fluid slag will produce a more convex weld bead profile.

### 10.1.2.2 Electrode

The MMA electrode which has a diameter of typically 3.25, 4.0 or 5.0 mm, is classified into one of three main types according to the flux covering (cellulosic, rutile or basic). Iron powder may also be added to the covering to increase the deposition rate and to improve the arc stability and smoothness of operation.

Cellulosic electrodes contain a high proportion of cellulose in the covering and are characterised by a deeply penetrating arc with a thin slag covering on the weld pool and weld bead. The low slag volume makes these electrodes highly suitable for vertical down and pipe welding and the resulting mechanical properties of the weld metal are reasonably good. The main disadvantage is the high level of hydrogen generated which increases the risk of hydrogen induced cracking in the heat affected zone. Cracking in this zone is preventable by preheating the material prior to welding which allows the hydrogen to diffuse away from the hard crack susceptible heat affected zone. The preheat temperature is determined by the thickness of material, the carbon equivalent (as determined by the chemical composition), the amount of hydrogen generated in the weld metal and the heat input.

Rutile electrode coverings contain a high proportion of titanium oxide (rutile). The presence of titanium oxide promotes easy arc ignition and smooth arc operation and low spatter. Iron powder can be added to improve metal deposition, and recovery rates above 150% can be achieved without deterioration of the arcing characteristics. The lower weld metal mechanical properties and high hydrogen levels (ca. 20 ml/100 g) make these electrodes less suitable for welding the higher strength steels or thicker materials.

Basic electrodes contain a high proportion of calcium carbonate and calcium fluoride in the form of limestone and fluorspar in their coverings. The electrodes are used for high quality (high strength/good toughness) and low hydrogen weld metal. Low hydrogen electrodes can produce deposits with less than 5 ml/100 g hydrogen. The slag from the covering melts at a lower temperature than that from rutile electrodes and has a higher surface tension. The welding characteristics are termed 'fast freezing', which promotes welding in the vertical position and permits higher welding currents and faster welding speeds. The main disadvantages are the convex weld bead surface profile, and the slag can be more difficult to remove from the weld surface.

### 10.1.2.3 Power source

As the metal rod electrode is consumed under the action of the arc with the droplets forming the weld bead, the function of the power source can be viewed as simply providing a current for melting. However, the power supply must be capable of providing sufficient voltage to sustain the arc, a rapid rate of rise to a high current level to initiate the arc and to clear the periodic short circuiting of the electrode to

the workpiece, and constant current during the welding operation itself. With regard to accommodating short circuits, it must be noted that small diameter molten droplets of metal are not projected across the arc from the end of the rod, i.e. in free flight; large droplets form on the tip of the electrode which then transfer as large globules or during short-circuit bridging of the arc gap. The power supply must provide sufficient current to clear the short circuit, but at a controlled rate of rise to prevent explosive rupturing of the metal bridge.

The operation of the power source can be described in terms of the arc characteristics and the static and dynamic characteristics of the power source. The arc characteristic is nominally flat or slightly rising over the range of current levels (as shown in *Figure 10.3*). The power source static characteristic (*Figure 10.14*) is drooping so that there are well-defined current levels according to the arc length, and the current is essentially constant for a given current setting. Also shown in *Figure 10.14* is the open-circuit voltage which is available both to strike the arc and to ensure arc resumption in the operation. The short-circuit current is the maximum current available for clearing short circuits. Because of the steeply drooping characteristic, the current will only vary by approximately  $\pm 10\%$  for changes in the arc length.

The welding current can be adjusted by varying the secondary connections of the transformer which produces a series of voltage-current characteristics. In the more usual design of power sources, the inductance can be adjusted which has the advantage of maintaining a high open-circuit voltage (*Figure 10.14*).

The dynamic characteristics of the power source relate to the way in which the power source reacts to variation in the load, e.g. during arc ignition, a short circuit, a momentary arc outage, or fluctuations in the arc length.

In the UK, the specification for the design and construction of welding power sources is EN60974 *Arc welding equipment Part 1 Welding power sources*; hobby transformers are covered by EN 50060: 1989. The load voltages for air-cooled power sources can be calculated using the equation

$$U_2 = (20 + 0.04 I_2) \text{ V (up to 44 V at 600 A and above)}$$

**Figure 10.14** Variation in static output characteristics of the power source to adjust the welding current.  $V_0$ , open-circuit voltage

where  $U_2$  is the conventional load voltage, and  $I_2$  is the conventional welding current.

The standard also specifies the following maximum open-circuit voltage for oil- and air-cooled power supplies:

a.c. equipment	80 V (r.m.s.)
d.c. > 10% ripple	80 V (r.m.s.)
d.c. < 10% ripple	100 V (r.m.s.)

EN 60974-1:1998 does not specify a ripple level, but the maximum no-load voltage is 113 V peak for d.c. and 68 V peak and 48 V r.m.s. for a.c.

The maximum permissible no-load voltage (open-circuit voltage) for normal a.c. welding has been agreed by the European Committee for Electrotechnical Standardisation (CENELEC) to be 80 V. However, in confined spaces or wet conditions, the open-circuit voltage can be further restricted to 42 V, and 12 V in certain European countries. As 12 V, in particular, is insufficient to operate the process, a voltage-reduction device is incorporated in the equipment which allows the full open-circuit voltage to be obtained when the electrode is short circuited to the workpiece.

The minimum open-circuit voltage and electrode polarity requirements for the various types of electrode are given in BS EN 499:1995—*Welding Consumables—Covered Electrodes for Manual Metal Arc Welding of Non Alloy and Fine Grain Steels—Classification*. The requirements can be related to the various electrode types. For example, most cellulosic electrodes require an open-circuit voltage of > 50 V, but some electrodes can be used with either d.c. electrode-positive (DCEP) or d.c. electrode-negative (DCEN) and require a low open-circuit voltage of only 50 V for a.c. operation. Basic electrodes are the more demanding for a.c. operation and require a higher open-circuit voltage (> 60 V). D.c. operation is the more normal electrode polarity.

#### 10.1.2.4 Single operator transformer equipment

The most common form of single-operator equipment comprises a transformer wound on the primary side for normal low-voltage (1 V) mains and on the secondary side for 60–100 V, together with a tapped inductor (*Figure 10.15*) or moving-core inductor. It is preferable to connect the primary across the two lines of a three-phase supply rather than between line and neutral. Sets are produced with T or open-delta connection to three-phase supplies, but as the single-phase load cannot actually be balanced over three phases no great advantage is obtained. The voltage-reduction device is placed in the secondary circuit of the transformer, i.e. between the output side of the welding equipment and the electrode holder.

#### 10.1.2.5 Two-operator equipment

Transformer welding sets are also available for two welders who can work simultaneously. These may consist of two single-phase units included in a single tank (*Figure 10.16*) or comprise a single transformer to which two variable inductors are connected in parallel on the secondary side. Sets of both types have the advantage that the two secondary circuits can be connected together to a single arc to give a high current for large electrodes or heavy work.

#### 10.1.2.6 Power-factor correction

Because the load taken by a welding transformer is highly inductive, the power-factor will necessarily be

Figure 10.15 Single-phase transformer and tapped inductor

Figure 10.16 Double-operator welding equipment

low. For single-operator equipment it is of the order of 0.3–0.5 lagging, depending on the design of the set and the type of electrode used, arc length, etc. It is well known that the greater the inductance of the welding circuit, the better the conditions. A welding set which is not provided with a capacitor or other means of power-factor correction cannot, therefore, operate at a high power-factor.

The simple, single-phase transformer welding source lends itself readily to power-factor correction by the connection of a capacitor on the primary side. Power sources are available in which the capacitor is incorporated in or attached to the welding transformer.

Where many single-operator sets are connected, care must be taken not to overcorrect the power-factor. It must be borne in mind that a welding load is intermittent, and probably for 50% of the time for which the set is connected no welding will be in progress. If, therefore, each welding equipment is provided with a separate capacitor, there is the danger of a leading load being taken if the diversity factor of the welding load is small. This difficulty may be overcome by:

- (1) automatic switching on of the capacitors when the load is applied;
- (2) a central bank of capacitors to correct the load of the whole work based on an average observed load; and
- (3) careful instructions to operatives to switch off capacitors as soon as they stop welding.

#### 10.1.2.7 Multi-operator transformer equipment

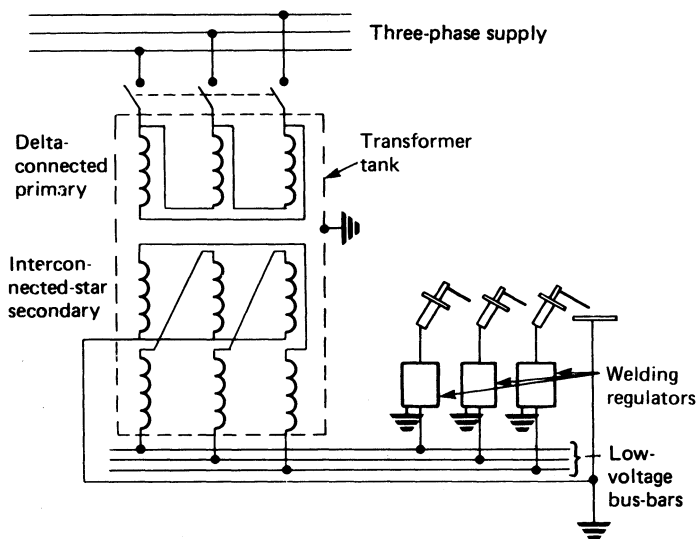

Multi-operator transformer equipment consists of a single transformer to the secondary windings of which a number of arcs can be connected. Each welding circuit must be provided with a current regulator which can be a variable resistor or inductor. The latter gives higher efficiency and improved arc stability.

The most common form of installation is a three-phase transformer having a delta-connected primary winding and an interconnected-star secondary (Figure 10.17). It will be noted that the inductive current regulators are connected to the line terminals and the material to be welded is connected to the star or neutral which should be connected to earth.

The number of reactors and welders' circuits on the three-phase system must be a multiple of 3, so that they can be distributed evenly on the three secondary windings.

This type of plant is economical for installations where work is concentrated in one shop, and also for outside construction work where it is desirable to safeguard welders from possible shock from the primary voltage of the supply. This precaution is particularly necessary in the case of ship-building and bridge and storage-tank construction.

EN 60974-1:1998 IEC 60974-1:1998 indicates a method of connecting the welding equipment and specifies special plug and socket connections and distribution boxes. The leading dimensions of these are laid down, so components from different manufacturers are interchangeable.

**Figure 10.17** Three-phase multi-operator welding equipment

The sizes of transformers are limited to four (57, 95, 128 and 160 kV-A continuous rating) which are capable of providing one, two, three or four welding operators per phase, each at a maximum continuous hand-welding current of 350 A, or a lesser number at a higher current. The three standard sizes of current regulators are designed to give a maximum welding current of 350, 450 or 600 A, at 90 V.

#### 10.1.2.8 Application

There are no special power source requirements for any of the particular group of electrodes (cellulosic, rutile and basic) although some power source manufacturers claim superior running characteristics with cellulosic electrodes. If recommended by the manufacturer, particular brands of electrodes can be operated with a.c. or d.c. power sources. Note, not all d.c. electrodes can be operated on a.c. but a.c. electrodes can usually be used on d.c. For a.c. operation, the no-load voltage is important and some electrodes, particularly the basic types, may require 70 to 80 V (a.c.).

A.c. electrodes are frequently operated with the simple, single-phase transformer whilst for d.c. electrodes, thyristor and transistor controlled power sources are used. The small size and weight of the inverter type power source offers the advantage of being easily transported and, therefore, ideal for moving around the workshop or site work.

The welding current level is determined by the size of the electrode and typical operating ranges for a range of electrode sizes are 50 to 400 A. As a rule of thumb, when choosing a suitable power source of adequate capacity, an electrode will require approximately 40 A per millimetre (diameter). As an example, for a commonly used electrode size of 4 mm, with an operating range of 140 to 180 A, the power source should have a current capacity of at least 200 A at an appropriate duty cycle i.e. 20%, 60% or 100%, depending on the type of work.

With small hobby type MMA transformers a duty cycle figure is not given. Instead, the rating is based on the number of electrodes that can be burnt in one hour, both when welding from cold and when the equipment has warmed up.

### 10.1.3 Metal inert gas welding

#### 10.1.3.1 Principles of operation

The generic name 'metal inert gas (MIG) welding' has been given to those welding processes which use a continuously fed small-diameter, solid-wire electrode and a gas shroud. The principal operating features are shown schematically in Figure 10.18. The wire diameter is normally 0.8, 1.0, 1.2 or 1.6 mm and the shielding gas is usually CO<sub>2</sub> or argon with 2–5% O<sub>2</sub>, or 5–25% CO<sub>2</sub>. Argon–helium mixtures (with O<sub>2</sub> or CO<sub>2</sub> additions) can be used for special applications, e.g. for welding stainless steel.

MIG welding is slowly replacing MMA for manual welding, especially in the welding of thin section ferrous and non-ferrous materials, and when continuous operation or high deposition rates are required. Because of the continuous feeding of the wire electrode, MIG welding has found special application in mechanised and robotic welding. The process can also be used at high current levels, almost

**Figure 10.18** Principles of operation for the MIG process

twice that of MMA which can be exploited for welding thicker materials at higher speeds, but only in a mechanised operation.

Because the process is often used to increase the deposition rate/welding speed, care must be taken to avoid introducing weld defects such as lack of fusion. For this reason the process requires careful tuning of the power source, and welder training, when high quality is required.

### 10.1.3.2 D.c. metal transfer modes

There are three main metal transfer modes:

- (1) short circuiting or dip;
- (2) spray; and
- (3) pulsed.

Short circuiting is a low-current mode of metal transfer, whilst the spray mode only occurs at high current levels. The pulsed mode is a technique used to obtain spray-type metal transfer at low current levels.

**Short circuiting metal transfer** The short-circuiting mode is used at low current levels, typically less than 250 A with a 1.2 mm diameter wire at which levels it is impossible to operate with an open arc to give free flight (spray) metal transfer. The transition from the short-circuiting mode to the spray-mode is shown schematically in Figure 10.19. The mode is established by setting a low open-circuit voltage so that the molten metal forming at the tip of the electrode wire transfers by short circuiting with the weld pool as shown in Figure 10.20.

If a free-flight technique, i.e. a spray-type mode of metal transfer, were to be attempted below the threshold current level, the low arc forces would be insufficient to prevent large globules forming at the tip of the wire which would then transfer erratically across the arc under normal gravitational forces. Thus, in operating the short circuiting transfer mode, the initial selection of the welding parameters (open-circuit voltage, inductance and wire feed speed) and the dynamic characteristics of the power source are crucial in stabilising the arc and metal transfer.

**Spray metal transfer** The spray metal transfer mode operates above the threshold current level (see Figure 10.19) and

**Figure 10.19** Normal operating ranges in MIG welding. Note that the voltage must be reduced at low current levels to induce short circuiting metal transfer

in this mode the droplets transfer to the workpiece in free flight. The voltage must be set at a higher current than for the short-circuiting mode in order to ensure that the tip of the wire does not bridge the arc gap which is typically set at 6 mm. The droplet diameter at current levels slightly above the threshold level approximates to the wire diameter.

The threshold current level is determined by the wire diameter and the shielding gas composition. Typical values for 1.6 mm diameter, low carbon steel wire in a range of argon–helium gas mixtures are shown in Figure 10.21. It can be seen that the threshold value increases significantly in high helium gas mixtures, indicating that the spray transfer is more difficult to obtain.

The droplets are detached by a combination of an electromagnetic effect, a plasma jet and the formation of gas bubbles in the molten droplet. The droplets have velocity when they are detached from the tip of wire but then accelerate across the arc gap.

**Figure 10.20** Short circuiting metal transfer in MIG welding. Note that a fluctuation in the welding current waveform occurs whenever the electrode short circuits to the workpiece

**Figure 10.21** Threshold values for spray metal transfer

**Figure 10.22** Droplet frequency for various material-gas compositions of 1.6 mm diameter wire

The frequency at which the droplets transfer increases as the current level increases; the relationship between droplet frequency and the current for various material combinations is shown in *Figure 10.22*. The droplet size is about the same as the wire diameter at the threshold level, but decreases significantly as the welding current increases. At current levels well above the threshold level the droplets transfer in a stream of fine droplets and the wire tip assumes a pencil-point shape.

At very high current levels, e.g. above 450 A for 1.0 mm diameter, low carbon steel wire, the end of the wire which is softened by resistive heating can rotate. Rotation of the wire is promoted by extending the electrode stick-out, i.e. the distance the wires extend from the contact tip to the arc. The principal benefits of extended stick-out are increased deposition rate and an improved weld bead penetration profile (bowl shaped).

**Conventional pulsed metal transfer** The pulsed transfer mode is a free-flight technique, i.e. non-short-circuiting, which can be operated at welding currents below the threshold level. For this technique, high current pulses at a frequency of typically 50 Hz and 100 Hz are applied. The magnitude of the pulses must be sufficient to detach the droplets and project them across the arc. Droplet transfer to the weld pool is often completed during the background period; the process of metal transfer is shown schematically in *Figure 10.23* where it can be seen that, although significant melting occurs during the background period, the high current pulse is required for droplet detachment.

The pulsed MIG technique is an attractive alternative to the short-circuiting mode at low current levels because the open arc/free flight metal transfer greatly reduces spatter and provides greater tolerance to variations in the gun-to-workpiece distance. Until recently, the technique was not widely practised because of the difficulty in setting up and maintaining suitable welding parameters at a fixed pulse frequency. For example, as the mean current level demanded by the wire feed speed is set by adjusting the pulse and background current levels, the welding parameters are likewise a compromise for arc and metal transfer stability and weld bead penetration. The effect of the compromise can be seen in the metal transfer where the droplet size and frequency of transfer can vary depending on the number of pulses used to detach each droplet. Thus, power sources which can generate pulses over a range of frequencies

**Figure 10.23** Pulsed metal transfer in MIG welding

are significantly more flexible, as the pulse frequency can be better matched to the wire feed speed.

**Synergic pulsed MIG** In the synergic process, the pulse parameters are varied according to the operating conditions. The basic concept is that a 'unit' pulse can be derived which, when applied, will detach one droplet of metal. A typical unit pulse is shown in *Figure 10.24*. There is range of unit pulses which will detach droplets of specific volume; to a first approximation the droplet volume increases proportionally with pulse duration.

Process stability can be readily achieved by relating the pulse-repeat frequency to the wire feed speed, i.e. the number of droplets (or increments of wire feed) to be detached from the wire. Under open-loop control; the pulse current and pulse time are set to detach one droplet of the desired volume and the background time and level are then adjusted to generate the required number of pulses to maintain the current burn-off rate. In synergic control, the unit-pulse principle has been used to produce a fully automated control system. The unit pulse (pulse current level and time) is uniquely determined by the material composition and the wire diameter. However, once the unit pulses have been determined for the desired range of materials, the power source is preprogrammed and the operator is merely required to select the appropriate programme for the wire being used. On setting the desired wire feed speed, the

**Figure 10.24** Typical oscillogram of arc current and voltage for 2 m/min wire feed speed, 50 Hz pulse frequency and 4 ms pulse duration

power source delivers the correct number of pulses to maintain arc stability.

### 10.1.3.3 D.c. power source

**Short circuiting and spray metal transfer** The basic power source for MIG welding has a nominally flat or constant voltage output characteristic as shown in *Figure 10.25*. The welding current is principally determined by the wire feed speed and the arc length by the power source voltage level (open-circuit voltage). Automatic adjustment of the wire burn-off rate is used to compensate for minor variations in the torch-to-workpiece distance, wire feed speed or current pick-up in the contact tip. For example, if the torch is moved away from the workpiece the arc length is momentarily increased, but this results in an increase in the voltage and a reduction in the level. Consequently, as the wire speed is constant, the reduction in the burn-off rate forces the arc length to return to the set arc length. If the torch is moved closer to the workpiece, the converse occurs, i.e. the burn-off rate is momentarily increased to maintain a constant arc length. Alternatively, a low inductance produces a rapid rise in current which assists arc starting.

In setting the power source for the two main operating modes (spray and short-circuiting metal transfer), the open-circuit voltage must be set to produce the required arc length for a given wire feed speed. For the short-circuiting mode, the inductance must also be selected by the operator to give a smooth rupturing of the metal bridge formed between the wire tip and the weld pool during the short circuit. Failure to set these parameters gives an erratic arc, as indicated by momentary arc outages and wire stubbing which results in excessive ejection of molten droplets from the weld pool (termed 'spatter') and a poor weld-bead profile. For the spray metal transfer mode, circuit inductance is not essential, but it helps to smooth the process, especially when operating with a short arc length.

The modern electronic, high response power sources have been designed to overcome some of the inherent limitations of operating the MIG process with more conventional power sources, namely the sensitivity to variations in gun-to-workpiece distance, wire-feed fluctuations, and long-term variations in the main supply voltage or through

'warm-up' drift in the control system. These limitations can make it difficult to sustain a high level of weld quality under low spatter conditions, particularly in mechanised or robotic applications. Transistor controlled power sources, in particular, can have sophisticated control systems such as:

- (1) programmable parameter selection—the optimum welding parameters can be generated from the input of information on the wire being used (composition, diameter), shielding gas composition and the wire feed speed; or
- (2) arc voltage as the setting up parameter—the operator is only required to set the desired voltage level and the wire feed speed is automatically adjusted by the system control.
- (3) automatic setting of circuit inductance.

The trend in electronic power sources is towards 'one-knob' control with the wire feed speed level, which is under feedback control, being held within much closer limits.

**Pulsed MIG** In conventional pulsed MIG power sources, current pulses are generated through half-wave rectification of the mains supply to give sinusoidal pulses at a frequency of 50 Hz. The background current is usually supplied by a separate and independent supply. Full-wave and three-phase half-wave rectification are used for 100 and 50 Hz, respectively, whilst submultiples of these frequencies give sinusoidal pulses at repeat frequencies of 75,  $37\frac{1}{2}$ ,  $33\frac{1}{3}$  and 225 Hz.

In synergic control, high response, electronic (transistor or inverter) power sources are required in order to generate the 'unit' pulses; typical pulse durations are 2–5 ms and the pulse frequency lies within 25–500 Hz for current levels up to 300 A. The first type of synergic control modified the output of the power source (pulse frequency) by monitoring the wire feed speed. More recently, commercial power sources began to employ a range of synergic control systems to set the pulse frequency and the wire feed speed. The arc length is controlled by monitoring the arc voltage, and the wire feed speed or the pulse frequency may be adjusted to compensate for changes in the gun-to-workpiece distance.

Unlike conventional (constant current) MIG power sources, the first synergic power sources employed a constant-current characteristic with adaptive control of the arc length; the output of a tachogenerator mounted on the wire feed was used to vary the pulse frequency to maintain arc stability. However, the more modern power sources use a combination of constant-current and constant-voltage characteristics. A common technique is to employ constant-current characteristics during the background period but constant-voltage characteristics during the pulse period for self-adjustment of the arc length. A limitation of this technique, however, is the very high peak current that can be produced. An alternative design is to use a constant-current supply with instantaneous voltage feedback acting on each pulse.

### 10.1.3.4 Control of short circuiting

In the conventional short circuiting process, metal transfers from the tip of the wire by periodically dipping into the weld pool (*Figure 10.20*). The process is controlled by setting the arc voltage to control the arc length and the circuit inductance to control the rate of rise of the current during the short circuit and the peak short circuit current.

The short circuiting process is characterised by spatter and low heat input to the material. The spatter originates from

**Figure 10.25** Nominally constant voltage output characteristic of the power source for MIG welding and self-adjustment of the arc length.  $V_a$ , set arc length;  $V_s$ , momentary shortening of the arc length;  $V_i$ , momentary lengthening of the arc length

the explosion of the wire tip as it ruptures under the high short circuit current in a similar manner to the breaking of a fuse. The intermittent periods of arcing and arc outages during the short circuits increase the risk of cold laps.

As power sources have become more intelligent (see Section 10.1.1.3), control strategies can be used to improve process performance. For example, the Surface Tension Transfer (STT) process aims to control spatter and increase the heat input by improving the control of the current waveform and the sequence of events is as follows:

- (1) At the onset of the short circuit, the current is reduced immediately and the molten metal on the tip of the wire is allowed to transfer under surface tension forces.
- (2) A high 'pinch' current level is applied to speed up transfer of the molten metal.
- (3) When the wire tip approaches 'necking', the current is quickly reduced to produce a smooth rupture of the wire.
- (4) As the arc will form at a low current level, the risk of eject molten metal from the weld pool is greatly reduced.
- (5) During the arcing period a pulse of current is applied to broaden the arc and reduce the risk of weld laps.

The advantages claimed for the STT process over conventional short circuiting metal transfer MIG are a reduction in parent metal dilution and lower labour costs through the higher travel speeds, reduction in repairs and less clean-up work.

#### 10.1.3.5 A.c pulsed MIG

The a.c. arc has been recently stabilised for MIG welding by using a special power source with two inverters. The primary inverter controls the output current whilst the secondary inverter produces rapid switching between electrode positive and electrode negative polarities. A high voltage pulse is applied at current reversal to ensure that the arc is re-ignited. A pulse of current is also applied during the electrode positive half-cycle to ensure that the molten metal droplets are smoothly detached from the end of the wire. The pulse parameters (pulse current level and duration) are set to give one droplet per pulse.

Compared with conventional d.c. MIG, in the a.c. MIG process the wire burn-off rate is increased for a given current level which produces a 'colder' arc and a shallower weld pool penetration. These process features provide greater tolerance to joint gap as demonstrated for lap joints in thin sheet.

#### 10.1.3.6 Twin wire MIG

As a means of increasing the deposition rate, two in-line wires, i.e. one behind each other, are fed simultaneously into the weld pool, *Figure 10.26*. The wires are powered by two separate power sources and as the contact tips are electrically isolated, they can be operated independently i.e. with different wire diameters, current levels or operating modes (continuous or pulsing). In practice, current pulsing is normally used but synchronisation of the power source outputs is necessary to minimise arc interaction. The current pulses are out of phase to avoid arc instability which would be caused by the interaction of the strong magnetic fields generated by the high current pulses. Metal transfers from one wire during the pulse period whilst the other wire has a low background current to avoid droplets being ejected from the arc. To control the process, the power source supplying current to the lead wire is designated as the lead (master). The current from trailing power source

**Figure 10.26** Electrical connections for twin wire with separate contact tips

(slave) is then synchronised to the current supplied to the lead wire.

The process requires a special torch but is sufficiently compact for welding the root in a V joint. In a fully automatic operation, very high welding speeds and high deposition rates can be achieved. Welding speeds are up to 3–4 times faster than those achieved using a single wire. For example, for 6 mm leg length fillet welds, the welding speed using the tandem wire process was 1.1 m/min compared with 300 mm/min for the single wire MIG process. Deposition rates can be as high as 20 Kg/hr which is about three times greater than is normally possible with a single wire.

Typical welding parameters for welding thin sheets components are:

Wire feed speed:	1st wire	12 m/min
	2nd wire	10 m/min
Pulse parameters:	pulse current	380 A
	pulse voltage	38 V
	background current	70 A
	frequency	280 Hz

The process uses the pulsed mode on each wire with a deposition rate of 10 kg/hr and a travel speed of 5 m/min.

### 10.1.4 Flux cored arc welding

#### 10.1.4.1 Principles of operation

Flux cored arc (FCA) welding is an alternative to MIG and MMA welding. The wire consists of a hollow tube which is filled with flux and metal powder. The flux filling is similar in nature to the MMA covering, e.g. basic or rutile. The wire can be used without a separate gas shield (self-shielded welding), and the gas which is required to protect the weld pool is generated from the burning of the flux. In gas-shielded (FCA) welding, a gas shield of CO<sub>2</sub> or an argon–CO<sub>2</sub> mixture is used in the same manner as in solid-wire MIG welding.

#### 10.1.4.2 Wire electrodes

As the first generation of wires were of large diameter (3.2 mm and above), the FCA process was initially used for welding at high deposition rates: the welding current levels were greater than 400 A, which gave deposition rates in excess of 24 kg/h. The availability of smaller diameter wires gives a wide range of deposition rates and the capacity to

**Figure 10.27** Deposition rates for various steel wires and welding processes

weld in the vertical and overhead positions; a comparison of deposition rates for the MIG solid wire, and is given in *Figure 10.27*. However, the past disadvantages of the quality of the wire (e.g. consistency of the core filling) and the cost compared with solid wire, have restricted widespread application of FCA welding. Advances in flux formulations and manufacturing technology to produce an attractive range of smaller diameter wires (down to 0.9 mm) with all-position welding capability and good mechanical properties will make the FCA process more competitive than the alternative MIG and MMA processes.

Cored wires are normally classified according to the American Welding Society Standard AWS-A5.20 which defines the type of wire in terms of the core composition, the performance and the mechanical properties of the weld metal. The more commonly used wires are listed below.

- Type T1** These wires are usually rutile based with a CO<sub>2</sub> or argon-CO<sub>2</sub> shielding gas. As the wires have a spray transfer mode with a fast freezing slag, they can be used in all welding positions.
- Type T5** These wires have a basic flux core and use a CO<sub>2</sub> or argon-CO<sub>2</sub> gas shield. The transfer mode is globular which produces a convex bead shape, generates more spatter and is not suited to positional welding operations.
- Type T7** These wires are self-shielded and have a globular type metal transfer. The slag is designed for high current/high deposition rates. However, the resulting welds have good mechanical (impact) properties.
- Type T8** These are self-shielded wires which can be used in all welding positions and with good low-temperature impact properties. Small diameter wires, typically 1.2 mm, have all-position welding capability.

Recent developments in cored wires include barium free E71T-8 wires and E70T-1 all-position rutile wires.

#### 10.1.4.3 Power source

The power source designed for normal MIG welding is suitable for operating with cored wires. However, as the wire diameter can be significantly larger, and because higher deposition rates are possible in the flat position, the capacity of the power source is greater than is normally specified for MIG welding. For example, a 2.4 mm diameter wire can be used at current levels up to 500 A and a 3.2 mm diameter wire can require a power source with over 600 A capacity.

The wires are normally operated with d.c., but both electrode-positive and electrode-negative polarities are used. The usual practice is to use electrode-positive for a rutile wire and electrode-negative for basic and metal cored wires. As both the short circuiting and spray transfer modes are used, the power sources require voltage range and inductance settings to control the process. The pulsed mode of transfer is not normally used, but claims have been made that the technique can improve metal transfer, especially for larger diameter wires at low current levels.

### 10.1.5 Submerged arc welding

#### 10.1.5.1 Principles of operation

The submerged arc process is a high current, bare wire electrode process in which the arc operates below a bed of powdered flux. The principles of the process are shown in *Figure 10.28*. The flux has a similar function as in MMA and FCA welding in generating gases to protect the arc and the weld pool from the atmosphere, and providing alloying elements to achieve the desired mechanical properties in the weld metal. However, unlike the MMA and FCA processes, excess flux is laid down which must be recycled via a hopper. The slag, as is formed in MMA, must be removed after welding and discarded.

The electrode is normally wire (1.6–6.0 mm diameter), but for cladding large surface areas a strip electrode of up to 130 mm in width, 0.5 mm thickness can be used. The normal welding current range is 200–2000 A and the corresponding arc voltage level is 25–45 V.

The weld metal recovery rate is almost 100%, as very little metal is lost through spatter. The flux consumed in forming the slag, is approximately equal to the weight of wire deposited. As heat losses from the arc are exceptionally low, due to the insulating effect of the flux bed, the thermal

**Figure 10.28** The principles of the submerged arc process

efficiency of the process can be as high as 60%, compared with about 25% for MMA welding.

#### 10.1.5.2 Power source

The power sources can be a.c. or d.c. but, because the process is used for large diameter wire or strip electrodes giving high deposition rates, the capacity can be high as 2000 A.

**Single wire** For a.c. operation, the power source has a constant-current characteristic (drooping  $V/I$  output) or the open-circuit voltage should be at least 80 V to ensure reliable arc reignition on reversed polarity. The d.c. power sources have either constant-current (drooping output) or constant-voltage (flat) characteristics. With the constant-current power source, the arc length must be set by balancing the wire feed for the given current setting, i.e. to match the burn-off rate. The arc length can be adjusted automatically by using the arc voltage to vary the wire feed speed. In the constant-voltage power source, the normal self-adjustment of the arc length is obtained using the arc voltage as the control parameter for a given wire feed speed/welding current setting.

The constant-voltage power source is normally used for thin sheet welding, but the constant-current power source is preferred for welding thicker plates. The constant-current arc is more stable for deep penetration applications where the self-adjustment effect of the constant-voltage power source can lead to arc instability.

#### 10.1.5.3 Electrode polarity

The electrode polarity can be either d.c. (electrode-positive or negative) or a.c. D.c. electrode-positive gives the deepest penetration, d.c. electrode-negative has the greater deposition rate, and a.c. has an intermediate characteristic. The effect of electrode polarity on deposition rate is shown in Figure 10.29. The d.c. electrode-positive polarity will produce approximately 20–25% increase in penetration compared with d.c. electrode-negative. For this reason, d.c. electrode-positive polarity is normally used for the root run in welds to ensure that adequate penetration is achieved. However, for surfacing applications where low penetration and parent metal dilution is required, d.c. electrode-negative is preferred.

The wire burn-off rate can be increased significantly by increasing the electrode extension (the distance between the

**Figure 10.29** Effect of electrode polarity on deposition rate (standard electrode extension 32 mm; 4 mm diameter wire; 32 V). EP, electrode-positive; EN, electrode-negative

**Figure 10.30** Effect of stick-out on deposition rate (d.c. electrode-positive; 4.75 mm diameter wire). ESO, extended stick-out

contact tip and the arc). The effect is to preheat the wire according to the relationship

$$\text{Heat generated} = \frac{I^2 LR}{d}$$

where  $I$  is the current,  $L$  is the electrode stick-out,  $R$  is the resistivity of the wire, and  $d$  is the diameter of the wire.

Preheating of the wire can be used to increase significantly the deposition rate (see Figure 10.30). As the wire will soften through resistance heating, the stick-out must be limited or supported to avoid arc wander under the high electromagnetic forces. It is usual practice to support the wire with an insulated guide tube to a distance of 25 mm above the workpiece surface. Even with a guide tube, it is normally recommended that the maximum stick-out be limited to, typically, 76 mm for 3.2 mm diameter wire, but this can be increased to, typically, 130 mm for a 4 mm diameter wire.

#### 10.1.5.4 Hot wire welding

The resistance heating of a wire can be used to increase the weld metal deposition rate by feeding a separate ( $I^2 R$  heated) wire into the weld pool. The wire is heated using a low voltage of typically 8–15 V from a separate a.c. power source. The wire, which is typically 1.6 mm in diameter, enters the weld pool at a temperature just below its melting point and no arcing occurs. Deposition rates are in excess of those achieved with single-wire d.c. electrode-negative polarity, even with an extended electrode stick-out.

#### 10.1.5.5 Series arc welding—single power source

As series arc welding is used for high deposition rate welding applications, specialised techniques have been designed specifically to increase the deposition rate and the welding speed. As the maximum welding current on a single wire is limited by a deterioration in weld quality through excessive arc forces, the techniques are based on the use of multi-arcs.

The simplest arrangement is two wires connected to the same power source to give d.c. electrode-positive and d.c. electrode-negative arcs or, alternatively, two a.c. arcs (Figure 10.31). When used in tandem (d.c. electrode-positive leading), a substantial increase in welding speed, typically 1.5 times the single-wire process, can be achieved with no deterioration in the weld-bead shape.

Figure 10.31 Series arc welding

The two arcs operate into a single weld pool and, because of this close proximity, there is significant arc interaction. With d.c., the arcs will diverge, i.e. be repelled by each other, whilst two a.c. arcs will be largely unaffected.

#### 10.1.5.6 Series arc—multipower

Multipower systems use separate wire feed systems and power sources. The increased flexibility of electrode polarity and number of arcs permits a substantial increase in the deposition rate and welding speed and an improvement in the weld-bead shape. Of the possible combinations, multiple d.c. arcs are normally avoided to reduce the risk of arc blow which is caused by the large magnetic fields associated with the high current levels. High current, multipower systems are, therefore, normally a combination of d.c. and a.c. arcs.

The most commonly used arrangement is a twin-wire system with a d.c. electrode-positive leading arc and an a.c. trailing arc (Figure 10.32). When operated at high current and low voltage, the d.c. electrode-positive arc will give deep penetration, whilst the lower power (lower current/higher voltage) a.c. arc will provide joint filling with minimum weld pool disturbance and a smooth final weld bead surface profile. The normal spacing between the arcs is 30–50 mm. The power sources are normally a d.c. thyristor controlled rectifier and a single-phase transformer for the a.c. arc.

For three-wire systems, the leading arc is d.c. electrode-positive, but the middle and trailing arcs are normally a.c. as shown schematically in Figure 10.33. The phasing of the two a.c. arc voltages is important to minimise arc interaction. In order to produce a phase difference, separate a.c. power sources are preferable, but a Scott-type transformer will give a 90° difference in phase shift between the two outputs. As the deposition rates can be substantially increased with multi-wire welding processes, the techniques are used in industries such as shipbuilding, where large flat plates must be welded. Typical welding speeds for various plate thicknesses are given in Figure 10.34, where it can be seen that the joint completion rate for a 20 mm thick plate

Figure 10.32 Two-wire welding

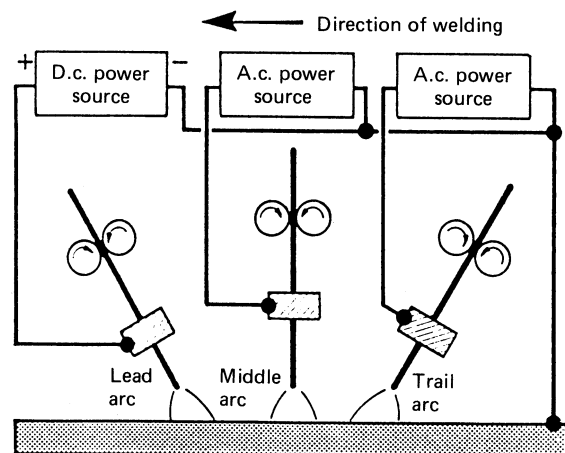

Figure 10.33 Three-wire multiple-electrode welding

Figure 10.34 The effect of the number of electrodes on joint completion rate (speed/side)

is doubled for a twin-wire system and trebled for the three-wire system.

### 10.1.6 Tungsten inert gas welding

#### 10.1.6.1 Principles of operation

In the tungsten inert gas (TIG) welding process, the arc is formed between a pointed tungsten electrode and the workpiece in an atmosphere of argon or helium (see *Figure 10.35*). The small intense arc provided by the pointed electrode is ideally suited to precision and controlled melting of the workpiece. Since the electrode is not consumed during welding as with the MMA and MIG processes, autogenous welding can be practised without the continual compromise between the heat input from the arc and the deposition of filler metal. When filler metal is required, this must be fed separately into the weld pool using a wire or rod feed system.

The process can be operated with d.c. or a.c. In d.c. welding the electrode polarity is always negative so that its electron thermionic emission properties reduce the risk of overheating which would occur with electrode-positive polarity. The arc heat is distributed approximately one-third into the electrode and two-thirds into the workpiece. However, the alternative of d.c. electrode-positive would have advantages in that the cathodic action on the workpiece surface would clean the surface of the oxide coatings. For this reason, a.c. is the preferred polarity for welding materials such as aluminium which have a tenacious oxide film.

#### 10.1.6.2 Electrode

The electrode for d.c. welding is pure tungsten with 1, 2 or 4% thoria, the thoria being added to improve electron emission which facilitates arc ignition. Alternative additives to lower the electron work function are lanthanum oxide or cerium oxide, which it is claimed have improved starting characteristics, lower electrode consumption and, compared with thoria, are non-radioactive. When using thoriated electrodes it is recommended that precautions are taken to avoid contact with the grinding dust and smoke.

The electrode tip angle for the d.c. arc must be tapered to a fine point to concentrate and stabilise the arc. The general

rule is that the lower the welding current, the smaller the electrode diameter and the tip angle. Recommended electrode diameters and tip angles for d.c. and a.c. arcs are given in *Table 10.2*.

In a.c. welding, the electrode must operate at a much higher temperature due to the heat generated during the positive half-cycle. As the rate of tungsten loss is somewhat less than with thoriated electrodes, pure tungsten or tungsten with zirconia electrode is preferred. Furthermore, because of the greater heating of the electrode, it is difficult to maintain a pointed tip, and the end of the electrode assumes a spherical or 'balled' profile.

#### 10.1.6.3 Shielding gas

The shielding gas must be inert or slightly reducing and the composition is normally selected according to the material being used.

- (1) *Argon*—This is the most common gas employed because of its low cost compared with the other inert gases, and it can be used for most materials.
- (2) *Argon-H<sub>2</sub>*—Hydrogen can be added (up to 5%) to produce a slightly reducing atmosphere. The gas is hotter and, being slightly more constricted, produces deeper penetration and higher welding speeds.
- (3) *Helium and helium/argon*—A typical gas mixture is 75/25, helium/argon mixture which produces a higher heat input and higher welding speeds; the greater heat input is produced by the higher ionisation potential which is 25 eV for helium compared with 16 eV for argon. Besides the higher cost (approximately three times the cost of argon), the arc may be more difficult to ignite, especially in pure helium.
- (4) *Nitrogen*—As nitrogen is diatomic, on reassociation at the workpiece surface it is capable of transferring more energy than the monatomic argon or helium. The gas is used to weld high-conductivity metals, e.g. copper, but because of nitrogen pick-up in the weld pool, it cannot be used with steels due to the reduction in the toughness.

#### 10.1.6.4 Power source

The power source necessary to maintain the TIG arc has a drooping voltage-current characteristic which provides an essentially constant-current output even when the arc length is varied over several millimetres. Hence, the natural variations in arc length which occur in manual welding have

**Figure 10.35** Principles and features of the plasma arc process

**Table 10.2** Recommended electrode diameter and vertex angle for TIG welding at various current levels

Welding current (A)	D.c. electrode-negative		A.c.

‡ Use current slope-in to minimise thermal shock which may cause splitting of the electrode.

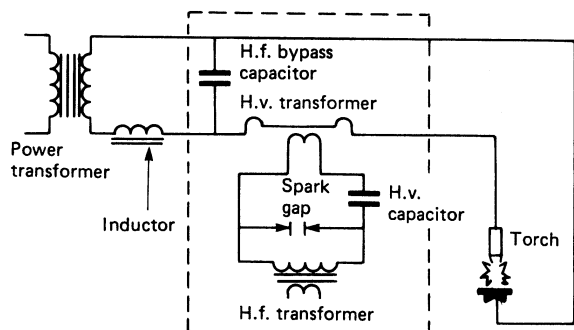

little effect on the welding current. The capacity to limit the current to the set value is equally crucial when the electrode is inadvertently short circuited onto the workpiece. Otherwise, excessively high currents would be drawn, damaging the electrode and even fusing the electrode to the workpiece.

In practice, the power source is required to reduce the high-voltage mains supply (240 or 440 V and a.c.) to a relatively low voltage (60–80 V, a.c. or d.c.) supply. In its basic form, the power source comprises a transformer to reduce the mains voltage and to increase the current and the rectifier, placed on the secondary side of the transformer, to provide the d.c. supply. Traditional power-source designs employ a variable reactor, moving coil or moving iron transformers, or a magnetic amplifier to control the welding current. Such equipment has the highly desirable features of simple operation and robustness, making it ideally suited to application in aggressive industrial environments. The disadvantages are relatively high material costs, large size, limited accuracy and slow response. Electronic power sources (described earlier) have become available which do not suffer from these disadvantages:

- (1) thyristor (SCR) phase control;
- (2) transistor, series regulator;
- (3) transistor, switched; and
- (4) a.c. line rectifier plus inverter.

The major operating features of these systems are described in Section 10.1.1 and the advantages/disadvantages compared with conventional power sources are given in Table 10.1. Of the above power sources, the transistor based control systems offer greater accuracy and reproducibility of welding parameters, but tend to be wasteful of electrical energy. The a.c. line rectifier, plus inverter type offers a combination of high electrical efficiency and small size.

Because of the constant-current output characteristics, the arc can be ignited by either touching the electrode to the workpiece or in a contact system by a series of high-frequency high-voltage sparks. The effect of the high-frequency is to ionise the gas between the electrode and the workpiece. As the voltage and frequency are approximately 10–20 kV at 100 MHz, care must be taken to prevent insulation breakdown of the welding control system. Line and air-borne high frequencies can cause problems in instrumentation and electrical equipment in the vicinity of the arc and the power lines of the welding system. High-frequency feedback to the power source can be eliminated by placing an air-cored inductor between the high-frequency generator and the transformer rectifier; the isolator may be

**Figure 10.36** High-frequency arc-starting unit for TIG welding.  
H.f., high frequency; h.v., high voltage

built into the high-frequency transformer, as shown in Figure 10.36. Care must be taken to ensure that all equipment is properly earthed and that all welding leads are kept as short as possible.

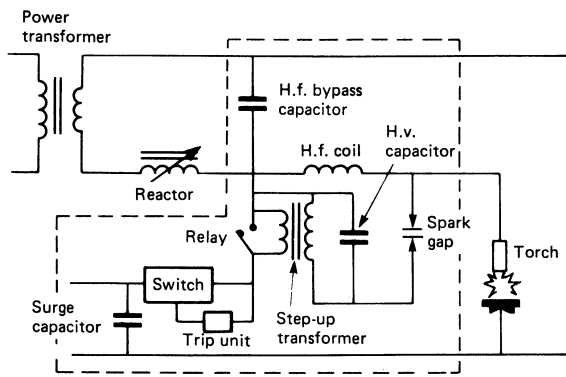

**Sine wave a.c.** The cyclical nature of the current introduces certain difficulties. When the tungsten electrode changes from positive to negative polarity, a smooth transition takes place because the tungsten electrode (being a thermionic emitter) has an electron cloud available for re-ignition as an arc cathode. When the change in electrode polarity is from negative to positive, a cathode root or a group of multiple cathode roots have to form on the plate. This function requires a high restriking voltage to re-ignite the arc, which is over 150 V when welding aluminium.

For the usual inductive supply, the arc voltage and current waveforms (Figure 10.37) both lag considerably on the open-circuit voltage. As a result, a high restriking voltage is available (Figure 10.37(a)). If the arc fails to re-ignite because of insufficient restriking voltage, a rectifying arc can occur, with the current flowing predominantly in the negative half-periods. Under low-voltage conditions, it is possible to secure positive half-period current by use of auxiliary equipment to give, for example, spark re-ignition. The sparks must be properly timed, as otherwise some degree of rectification will occur.

A more precise method of obtaining the electrode-positive half cycle is the use of the surge injection technique. With a surge injector added to a welding transformer, the open-circuit voltage can be reduced to 50 V. The basic circuit of the

**Figure 10.37** Waveforms of voltage and current for TIG a.c. welding

**Figure 10.38** Surge injector unit and welding circuit. H.f., high frequency; h.v., high voltage

surge injector together with the high-frequency arc starter is shown in relationship to the welding circuit in *Figure 10.38*.

The operation of the circuit is as follows. When full open-circuit voltage is applied to the system, the relay contact is opened, and the trip unit operates the switch to discharge the surge capacitor into the primary of the step-up transformer. The voltage induced in the secondary builds up until the breakdown voltage of the spark gap into the torch is reached. When the arc has been established, the voltage applied to the relay falls to the arc voltage level and the relay contact closes, the surge capacitor then being discharged directly into the arc. The instant of discharge is governed by the trip unit and is so timed as to occur at arc extinction when the polarity is changing to the electrode-positive half-cycle. The surge capacitor, which is charged to a voltage of sufficient amplitude, is then used to provide an artificial restrike voltage.

**Square wave a.c.** An alternative design of power source which is becoming more popular is the square wave power source. The principal feature of such designs is that the output current assumes a more square waveform, compared with the conventional sine wave (*Figure 10.10*). Two types of power source are available, differing in the manner in which the square waveform is produced. Whilst a 'squared' sine wave-form is generated by using inverted a.c., a more truly square waveform is produced by a switched d.c. supply (see *Figure 10.11*). In either case the importance for TIG welding is that the current is held at a relatively high level prior to zero and then transfers rapidly to the opposite polarity. In comparison, the current developed by sine wave power sources decreases more slowly to current zero, and likewise the current built up after re-ignition is at a much lower rate.

As shown in *Figure 10.39(a)*, if a square wave a.c. derived from a switched d.c. supply is used at 75 V open circuit and 160 A r.m.s. welding current, a voltage of 50 V and a circuit current of some 160 A are both obtained within 0.02 ms from zero. With a squared sine wave, a voltage across the gap of above 50 V is achieved in 0.02 ms and a circuit current of 110 A is attained in 0.1 ms from zero (*Figure 10.39(b)*). In comparison, the equivalent rise time for a conventional sine wave supply is 0.15 ms to achieve 5 V across the arc gap, and a relatively long time of approximately 3 ms to achieve 110 A from zero.

The benefit of square wave a.c. is that, aided by the inherent high surge voltage associated with the rapid current

**Figure 10.39** Typical positive re-ignition waveforms of voltage and current when welding at 160 A r.m.s. (a) Square wave supply at 75 V open-circuit voltage. (b) Square sine wave at 79 V open-circuit voltage. (c) Sine wave supply at 75 V open-circuit voltage

reversal, a.c. TIG can in some instances be practised at 75 V r.m.s. without the need for high-frequency spark injection to be superimposed for arc re-ignition.

An additional feature of square wave a.c. power sources is the capacity to imbalance the current waveform, i.e. to vary the proportion of electrode-positive to electrode-negative polarity. In practice, the percentage of electrode-positive polarity can be varied from 30 to 70% at a fixed repeat frequency of 50 Hz. By operating with a greater proportion of electrode-negative, heating of the electrode can be substantially reduced compared to that experienced with a balanced waveform. Although cleaning of the oxide on the surface of the material is normally sufficient with 30% electrode-positive, the degree of arc cleaning may be increased by operating with a higher proportion of electrode-positive polarity (up to a limit of approximately 70%).

#### 10.1.6.5 TIG hot wire

The TIG hot wire variant was developed as a means of achieving very high deposition rates without reducing the high weld quality normally associated with TIG welding. The essential feature is that filler wire is fed directly into the back of the weld pool and resistance heated using a separate power source (see *Figure 10.40(a)*). This second power source is usually a.c., to minimise any interference with the welding arc through the magnetic field generated by the current flowing in the wire. In a low current manual system, a single power source can be used to provide both the arc and resistance heating currents, but in this case the hot wire current is d.c. (*Figure 10.40(b)*).

(a)

(b)

**Figure 10.40** Electrical system and torch arrangement for the TIG-hot wire process. (a) Separate hot wire a.c. power source; (b) Single d.c. power source for arc and wire currents:  $I$ , arc current;  $I_w$ , wire heating current;  $I + I_w$ , welding current

In operation, the arc melts the base metal to form the weld pool. The filler wire, heated to its melting point by its own power source, enters the weld pool behind the arc to form the weld bead (Figure 10.41). Smooth feeding of the wire, control of the angle of entry into the weld pool, and a stable power source are all essential for stable operation, otherwise random arcing from the filler wire will occur with the resulting pool disturbances, causing porosity.

The main advantage of the process is that deposition rates can be achieved which approach those obtainable with MIG welding, i.e. 5–20 kg/h. Hence, TIG hot wire is used for welding, thicker section material, where the significantly higher deposition rates compared with those of the TIG cold wire process, can be fully exploited without any reduction in weld quality. In a specific example—welding steel tube of approximately 20 mm wall thickness—the deposition rate could be increased by a factor of 4. As the number of passes was reduced from approximately nine to five, the overall joint completion rate was reduced by a factor of almost 3.

TIG hot wire is also used for high deposition rate cladding, and here deposition rates of 10 kg/h are readily obtained. Even higher deposition rates of the order of 14 kg/h can be achieved, but only through the use of oscillation of the torch.

#### 10.1.6.6 Pulsed current

Pulsing the welding current at a frequency of 0.1–10 Hz is used to improve control over the arc stability and weld pool behaviour. The essential feature is that a high current pulse is applied, causing rapid penetration of the workpiece.

**Figure 10.41** Photograph showing the TIG arc and the (hot) wire entering the weld pool behind the arc

If this high current is maintained, excessive penetration and ultimately burn-through occur. Therefore, the pulse is terminated after a pre-set time and the weld pool is allowed to solidify under a low background or pilot arc. Thus, the weld progresses in a series of discrete steps with the pulse frequency balanced to the welding speed to give approximately 60% overlap of the weld spots. The surface appearance of a typical pulsed current TIG weld is shown in Figure 10.42.

The pulsed technique has been found to be particularly beneficial in controlling the penetration of the weld bead, even with extreme variation in heat sink. Such variations are experienced either through component design, e.g. thick to thin sections, or from normal production variations in component dimensions, fit-up, clamping and heat build up. In conventional continuous-current welding, where a balance must always be achieved between the heat input from the arc, the melting to form the weld pool, and the heat sink represented by the material of the component being welded, the degree of penetration is greatly influenced by these variations. However, in pulsed operation, the rapidly penetrating weld pool during the high current pulse and the solidification of the weld pool between pulses, markedly reduce the sensitivity to process variation through the effects of heat build up and/or disparity in heat sink.

Despite the obvious advantages of the pulsed process to production, the technique may appear to be a further complication of the process in that a greater number of welding parameters must be considered, i.e.

- (1) pulse time;
- (2) pulse level;
- (3) background time; and
- (4) background level.

The technique can be simplified in the first instance from the knowledge that, for a given material, there is a preferred pulse level which is based on its diffusivity and, to a lesser extent, on its thickness. The preferred currents are approximately 400 A for copper, 150 A for stainless steel, and 50 A for lead. Thus, for a given component, the operator need only set the pulse time to achieve penetration which, as shown in the nomograph in (Figure 10.43(a)), is determined solely by thickness. For example, for welding 2 mm stainless steel at 150 A, a 0.5 s pulse would be demanded, whilst for a 1 mm thick material, the pulse time would be reduced to 0.1 s at the same current level. The background parameters are considerably less critical in the pulsing operation. The background level is normally set at approximately 15 A

**Figure 10.42** Photograph of a pulsed TIG weld

which provides the greatest possible heat dissipation during this period, whilst being high enough to maintain a stable arc. The background period is normally equal to the pulse period, but may be some two to three times greater when welding thicker sections.

The nomograph is presented only as a guideline for the initial selection of welding parameters and must be treated with caution, particularly when welding at the extremes of the thickness range, i.e. sections of  $>0.3$  mm and  $<1.0$  mm. In both instances, the preferred pulse current level will be outside the above theoretical operating ranges. For example, in the welding of stainless steel, practical trials have established that for a thickness of 4 mm the preferred pulse parameters are 200 A and 0.75 s, whilst for 0.5 mm thick material the preferred pulse parameters are 50 A and 0.1 s (*Figure 10.43(b)*).

Welding thick sections at too low a pulsed current can result in the loss of most of the advantages of pulsing, controlled depth of penetration and tolerance to variation in heat sink, as the weld pool takes a long time to penetrate the material and thermal diffusion occurs ahead of the fusion front. In welding thinner sections with too high a pulsed current, the excessive arc forces may cause cutting and splashing of the weld pool, resulting in a poor bead profile and electrode contamination.

The capacity to use lower pulsed currents and longer pulse time (see *Figure 10.43(b)*) is also of particular importance when using power sources which have a limited response, a low rate of rise and fall of the current between the background and the pulsed current levels. For instance, power sources in which the current is controlled by a magnetic amplifier are generally limited to pulses of 0.2 s duration, whilst in thyristor controlled types the response is markedly improved and pulses as short as 0.03 s can be generated. However, for complete flexibility, transistor controlled or inverter power sources are used which can generate pulses within an almost unlimited frequency range up to 10 kHz. An added advantage of these power sources is the capacity to reproduce accurately complex pulse waveshapes which can be of benefit in controlling the weld pool and solidification structure.

## 10.1.7 Plasma welding

### 10.1.7.1 Principles of operation

In plasma welding, the arc is formed between a non-consumable tungsten electrode and the workpiece as in

TIG welding. However, the electrode is positioned within the body of the torch and the plasma forming gas is separated from the shielding gas (*Figure 10.44*). Thus, the emanating plasma is constricted by a fine bore copper nozzle which produces a columnar, deeply penetrating arc, compared to the more conical TIG arc.

The penetration capacity of the arc is determined by the degree of constriction of the plasma (diameter of the bore of the nozzle) and the plasma gas flow rate. The electrode angle has no effect on penetration and is usually maintained at  $30^\circ$ . However, as in TIG welding, the gas composition has a secondary influence on penetration. In this instance hydrogen, which increases the temperature of the arc (as shown by the increase in arc voltage), is particularly effective. Helium is also used to increase the temperature of the plasma but, because of its lower mass, penetration can decrease in certain operating modes.

The properties of the constricted plasma with variable arc force, which results from varying the plasma gas flow rate, have led to three distinct welding process variants:

- (1) microplasma welding, 0.1–1.5 A;
- (2) medium current plasma welding, 15–100 A; and
- (3) ‘keyhole’ plasma welding,  $>100$  A.

### 10.1.7.2 Microplasma

Microplasma welding has been so termed because a very stable arc can be maintained, even at welding current as low as 0.1 A. It is possible to vary the arc length over a comparatively wide range, up to 20 mm, without adversely affecting arc stability and because of the columnar nature of the plasma, without causing excessive spreading of the arc. With TIG welding, the arc is more sensitive to variation in torch distance, both with regard to stability and to spreading of the arc, due to its conical shape.

### 10.1.7.3 Medium current

At higher currents, that is up to 100 A, the plasma arc is similar to the TIG arc, although it is slightly ‘stiffer’ and more tolerant to variation in arc length. The plasma gas flow rate can also be increased to give a slightly deeper penetrating weld pool, but with high flow rates there is a risk of shielding gas and air entrapment in the weld pool

**Figure 10.43** Nomographs as an aid to the selection of pulse parameters in pulsed TIG welding. (a) Theoretical pulse parameters according to material type; pulse duration determined by thickness of material. (b) Selection of pulse parameters in 304 stainless steel based on practical welding trials. Note that the pulse current level is selected according to the material-thickness range

**Figure 10.44** The plasma process showing constriction of the arc by a copper nozzle

through excessive turbulence in the gas shield and agitation of the weld pool.

#### 10.1.7.4 Keyhole

The most significant difference between the no and plasma welding arcs lies in the keyhole technique. A combination of high welding current and plasma gas flow rates forces the plasma jet to penetrate completely the material, forming a hole as in laser or electron beam welding (*Figure 10.45*). During welding, this hole progressively cuts through the metal with the molten metal flowing behind to form the weld bead under surface-tension forces. The deeply penetrating plasma is capable of welding, in a single pass, relatively thick sections up to approximately 10 mm. However, despite the tolerance of the plasma process to variation in

**Figure 10.45** Formation of the keyhole and efflux plasma in plasma keyhole welding of 5.0 mm stainless steel. The efflux plasma is inclined backwards as the arc cuts through the plate

torch-to-workpiece distance, this technique is more suitable to mechanised welding, as the welding parameters, i.e. welding current, plasma gas flow rate and welding speed, must be carefully balanced to maintain the stability of the keyhole and the weld pool. Instabilities can easily result in the loss of the keyhole, giving only partial penetration of the weld bead and increasing the risk of porosity.

#### 10.1.7.5 A.c. arc

*Sine wave a.c.* The plasma arc is not readily stabilised with sine wave a.c. for two reasons: arc re-ignition is difficult when operating with a constricted plasma, and a long arc length and the progressive balling of the electrode tip (during the electrode positive half-cycle) severely disturbs arc root stability. Thus, plasma welding of aluminium is not widely practised, although successful welding has been reported using d.c. (negative polarity) and helium shielding gas.

*Square wave a.c.* The recent advent of the square wave power supplies described in Section 10.1.6.3 has made it possible to stabilise the a.c. plasma arc without the need for continuously applied high frequency for arc re-ignition. In addition, by operating with only 30% electrode-positive, the electrode is kept so cool that a pointed electrode tip, and hence arc stability, can be sustained. It is particularly important, however, that to limit electrode/nozzle erosion, the maximum current is reduced to less than that which can be operated with a d.c. plasma arc. For example, using 30% electrode-positive, the current rating of a 4.8 mm diameter tungsten electrode with a 40° tip angle would be reduced from 175 A (d.c.) to approximately 100 A (a.c.). Furthermore, any increase in the proportion of electrode

positive polarity, so as to improve arc cleaning, would significantly reduce the maximum operating current.

Despite the reduction in the maximum current at which the various electrode sizes can operate, stabilisation of the a.c. arc represents a significant advance in plasma welding. Until now, in the welding of aluminium, no advantage could be taken of the deep penetration capability of the plasma arc—because of the need to use a blunt electrode, the alternative a.c. TIG process produces shallow penetration.

#### 10.1.7.6 Electrode and nozzle

The electrode in the plasma system is normally tungsten–2% thoria. Typical electrode diameters, vertex angles and plasma nozzle bore diameters for the various current ranges are given in *Table 10.3*. At low and medium currents, the electrode is sharpened to a point whilst at high currents, it is blunted to approximately 1 mm diameter tip.

The plasma nozzle bore diameter, in particular, must be selected carefully and it is prudent to employ a nozzle the current rating of which is well in excess of the operating current level. The plasma gas flow rate can also have a pronounced effect on the nozzle life with too low a flow rate possibly leading to excessive erosion. Multi-port nozzles, which contain two additional small orifices on each side of the main orifice, can be used at high current to improve control of the arc shape. Use of an oval or elongated plasma arc has been found to be beneficial in high current welding, particularly when operating in the keyhole mode.

#### 10.1.7.7 Plasma and shielding gas

Argon is the preferred plasma gas as it gives the lowest rate of electrode and nozzle erosion. Helium can be used for

**Table 10.3** Maximum current for plasma welding for selected electrode diameter, vertex angle and nozzle bore diameter. (Levels are for guidance only, it is important to refer to manufacturer's recommended operating conditions for specific torch and plasma nozzle designs)

§ Multi-port nozzle.

medium and high current operations to increase the temperature of the plasma which, in the melt (non-keyhole) mode, will often promote higher welding speeds. However, the use of helium as the plasma gas can reduce the current-carrying capacity of the nozzle. Furthermore, because of its lower mass, weld-pool penetration will be reduced which, in certain materials, will make the formation of a keyhole difficult. For this reason, helium is seldom used for the plasma gas when operating with the keyhole mode. Hydrogen is often added to the shielding gas, argon plus 2.5% H<sub>2</sub> being the most common mixture, but up to a maximum of 15% H<sub>2</sub> can be used to produce a hotter arc and a more reducing atmosphere. Hydrogen also constricts the arc, which can increase the depth of the weld pool penetration and promote higher welding speeds.

Helium or a helium–argon mixture, typically 75% helium–25% argon, can also be used as the shielding gas. Whilst a hotter arc will be generated, it is less constricted, which can result in a wider weld bead compared with argon or argon–hydrogen shielding.

#### 10.1.7.8 Pulsed current

Similar benefits of improved arc stability and better control over the behaviour of the weld pool can be derived from pulsing the welding current. However, pulsing has special advantages for improving the keyhole mode of operation which, with continuous current, requires careful setting of the welding parameters.

The same principle applies in that a high current pulse causes rapid penetration of the material and establishes a stable keyhole and weld pool. If this high current were maintained, the keyhole would continue to grow, causing excessive penetration and, ultimately, cutting would occur. Therefore, the pulse is terminated after a pre-set time and the weld pool allowed to solidify under a low background or pilot arc. It is equally important that the plasma gas flow be maintained during this period so that the keyhole does not close and, on re-applying the pulse current, the plasma can quickly penetrate the plate, re-establishing a stable keyhole and weld pool. Thus, welding progresses in a series of discrete steps with the pulse frequency balanced to the traverse rate to produce overlapping weld spots (see *Figure 10.46*). In pulsing, the important variables are:

Welding current	Plasma gas
Pulse time	Pulse level
Pulse level	Background level
Background time	
Background level	

Selection of welding parameters can be simplified, first with the knowledge that the pulse time is determined more by the physical requirements of forming the keyhole and weld pool at a given traverse rate, than by the plate thickness or material composition. For most materials, within a plate thickness of 3–5 mm, a minimum pulse time of 0.1 s is required to re-establish the keyhole and weld pool. At longer pulse times, the excess energy is largely dissipated in the efflux plasma. The background time is usually set equal

**Figure 10.46** Appearance of the pulsed (keyhole) plasma arc weld

to the pulse time, which is sufficient for solidification between pulses. Thus, the pulse frequency is determined by the welding speed and the need for at least 60% overlap of the pulses to provide a continuous seam. For instance, when welding 4.4 mm stainless steel at a speed of 0.15 m/min, a suitable frequency is 2 Hz.

It follows that the pulsed current level and plasma gas flow rate are the major welding parameters which must be set to give an over penetrating plasma for a particular material composition and plate thickness combination. The background current is held low to give rapid cooling between pulses, while the plasma flow rate is held constant to maintain the keyhole. For instance, when welding 4.4 mm austenitic stainless steel, the pulsed current and plasma gas flow rate are typically 140 A and 21/min, respectively. However, when welding the same steel in 5.0 mm thickness, the pulsed current and plasma gas flow rate are increased to 190 A and 2.31/min and all other parameters are held constant.

### 10.1.8 Electroslag and electrogas welding

#### 10.1.8.1 Principles of operation

Electroslag welding, originally developed for the welding of thick mild and low-alloy steels, is restricted to welding in the vertical or near-vertical position. *Figure 10.47* shows the basic arrangement.

Once established, the electroslag process is basically arcless, the heat required to melt the wire and fuse the parent material being supplied by resistive heating of the molten slag bath. To ensure uniform fusion of the joint faces, it is necessary with thick material either to use more than one electrode or to oscillate the electrode(s) across the joint. As the weld progresses, the level of the weld pool rises and the welding head and water-cooled shoes are moved slowly up the joint. A typical speed for electroslag welding of 76 mm thick mild steel would be 1 m/h at 550 A and 44 V. Since the process is only stable once a slag of appropriate depth has been established, it is essential that a run-on plate is provided so that the defective start position of the weld can be removed on completion of the joint.

**Figure 10.47** Electroslag process

As the electroslag process is virtually a continuous casting process, the resulting welds have large grain size and a tendency towards columnar growth. Because of this, the weld metal and heat-affected zone generally have extremely poor (mechanical) properties. While this can be mitigated by a post-weld, normalising heat treatment, such treatment may cancel out the economic advantages that the process otherwise offers.

Although electroslag welding is mainly used for the joining of mild and low-alloy steels, satisfactory welds have been made in high-alloy steels, titanium and aluminium.

#### 10.1.8.2 Consumable-guide welding

Consumable-guide welding is a much simplified version of electroslag welding. This simplification stems mainly from the use of a wire guide which is progressively melted into the weld. The consumable guide (or guides) eliminates the need for a moving welding head and also results in faster welding speeds. The two moving water-cooled copper shoes used for electroslag welding are generally replaced by two pairs of shoes which are leap-frogged up each side of the joint as welding progresses.

### 10.1.8.3 Electrogas welding

Electrogas welding is very similar in principle to electrosag welding in that it is used for welding thick section material in a single pass and in the vertical position. The main difference being that the heat for welding is generated by an arc which is formed between a flux-cored electrode and the molten weld pool. The flux from the electrode forms a protective layer over the weld pool, but additional protection in the form of a gaseous shield (usually CO<sub>2</sub>) is used. The electrogas process is generally faster than electrosag welding when used on relatively thin sections. The resulting weld metallurgy is similar to a high-current submerged-arc weld.

## 10.1.9 Metal cutting and gouging

Metal can be removed from workpieces by use of coated electrode, plasma-arc and carbon arc processes.

### 10.1.9.1 Coated-electrode process

Flux-coated electrodes are available in two types. The first has a specially formulated coating that gives a deeply penetrating and forceful arc, tending to create a weld pool and to blow out the molten metal: a hole or recess is left, which can be carried along the material. When thick material is being cut, a sawing action is employed. The second type of electrode is a hollow electrode through which a high-pressure stream of oxygen is passed. The cutting action is akin to that with oxyacetylene.

Electrode techniques are, in the main, limited to ferrous materials.

### 10.1.9.2 Plasma-arc process

The plasma-arc process can give neat and accurate cutting. The principles are basically the same as in plasma-arc welding, but the force of the plasma column is increased by higher gas flow through the nozzle and a higher power output. Virtually any conducting material can be cut, at speeds faster than those of other methods, e.g. 8 m/min for 6 mm thick aluminium.

The most common gases are argon-H<sub>2</sub>, nitrogen, oxygen and air. The use of air has increased in recent years especially for cutting thin sheet steel, e.g. automotive and 'do-it-yourself' users. The torch which is suitable for air and oxygen employs a water-cooled, copper-hafnium tipped electrode.

The power source is similar to the ones used for plasma welding, but the output (cutting) voltage can be as high as 200 V. Safety precautions in the use of these power sources are essential (see appropriate standards e.g. IEC 60974-8)

### 10.1.9.3 Carbon arc process

In this process an arc between a carbon electrode and the workpiece is used to create a molten pool of metal which is blown away by a jet of compressed air. The method is useful for all grades of ferritic steels.

## 10.2 Resistance welding

Resistance welding processes involve the welding of two or more metal parts together in a localised area by the application of heat and pressure. The heat is generated by the resistance to the passage of a high current through the metal

parts held under a preset pressure. Copper or copper alloy electrodes are normally used to apply pressure and convey the electrical current through the workpieces. In the case of spot and seam welding, the electrodes or wheels are shaped to concentrate the force and current. In projection welding and butt welding the shape of the components dictates the weld area. No consumable materials such as welding wire, fluxes or gases are required.

The heat generated depends on the current ( $I$ ), the time of application ( $t$ ) and the resistance ( $R$ ) and is proportional to  $I^2Rt$ . The heat generated is governed largely by the bulk resistance of the materials being joined and the interface resistance at the contact between the materials. In some cases, a fused zone is produced, as in the spot or seam welding of sheet materials. However, in many cases of projection welding, and particularly resistance butt and flash welding, a forge weld is produced without melting. The plastic deformation of the heated parts in contact produces a bond in the solid state analogous to the blacksmith's weld.

Resistance welding can be used to join a wide range of materials and the ease of welding depends on the metallurgical compatibility of the materials and their electrical resistivity. Mild steel is readily weldable, having a resistivity some six times that of the copper alloy electrode. Surfaces should be free from rust, scale, dirt and other materials likely to hinder current flow but light oils or lubricants do not normally interfere with the welding. Aluminium alloys, with their higher conductivity, require up to three times the current required for steel to develop the heat for welding. In addition, the surface resistance of aluminium alloys is strongly influenced by the oxide film and this needs to be closely controlled for high quality welds. Anodised or heavily passivated surfaces can be insulating and therefore impossible to weld.

## 10.2.1 Welding equipment

Figure 10.48 shows the essential features of a spot welding machine. The three basic units are a structural frame, a force application system and the electrical system. The frame provides strength and rigidity to react the electrode force without undue flexure of the machine. The electrical circuit on the low voltage secondary side of the transformer may constitute part of the frame or, in the case of the welding gun, provide most of the structural strength. The force application system is normally pneumatic. Regulated air pressure is fed to a cylinder to provide the electrode force. Servomotors are increasingly being used to provide programmable control of electrode position, approach speed and force. Hydraulic systems are used occasionally for compact, high force applications, and springs are used for very small hand or foot operated machines. The electrical system comprises a welding transformer and a timer/controller unit.

### 10.2.1.1 Machine types

Pedestal or bench mounted machines are fixed types and the workpieces are fed into the machines manually or mechanically using a carousel or pick and place device. Gun welders are used for welding fixed, often larger structures and the gun is manipulated either manually, being suspended from a counterbalance system, or using a robot. The transformer may either be remote from the gun, connected by a heavy water cooled kickless cable, or integral with the gun itself. In the latter case, the transformer can be of a substantially smaller size because of the reduced secondary impedance, and current is supplied at mains voltage through smaller

**Figure 10.48** A pedestal spot welding machine

cables. This allows the gun to be more manoeuvrable despite its greater weight, often in the region of 60 to 100 kg. Modern residual current circuit breakers provide the necessary safety protection for manual operation of integral transformer guns.

Multiwelders can be used to weld components in a dedicated machine where each spot is welded with a separate pair of electrodes. One electrode is operated with its own cylinder and the opposing electrode is fixed. A frame provides the structural support and reacts the electrode force. A number of transformers may be used, each usually serving two or more electrode pairs from a two turn secondary with separate outputs. If more than one electrode pair is supplied from one transformer connection, the machine is sequenced so that only one weld is made at a time, the other electrodes remaining open. In order also to prevent too high a mains current demand from simultaneous firing of the transformers, the weld times are sequenced or cascaded. Where two electrode pairs are connected to one transformer, it is important that the circuits are similar so that the impedance, and thus the current drawn, is the same in each circuit.

#### 10.2.1.2 Resistance welding power supplies

The most common power supply comprises a single-phase a.c. transformer, see Figure 10.49. This converts the mains supply primary voltage to a low (2–20 V) secondary welding voltage. The turns ratio of the transformer is the number of turns of the primary conductor, divided by the number of turns of the heavy secondary conductor (usually 1 or 2). This is the ratio by which the voltage is reduced and the mains current magnified. The open circuit secondary voltage may be considered nominally constant, so the current drawn on the welding circuit depends on the circuit impedance according to Ohm's law. This circuit is virtually a dead

**Figure 10.49** Single-phase a.c. power supply. (a) Welding circuit; (b) Current waveform, broken line illustrates phase shift control of current level

short with a resistance in the region of  $10^{-3} \Omega$ . Thus, several thousand amperes of welding current can be developed at the low secondary voltage.

The power capacity of a machine is normally quoted in kVA at 50% duty cycle. This refers to the power that may be drawn by the transformer over a long period of time, with current flowing for 50% of that time, without causing the transformer to overheat.

The maximum allowed current on the primary side of the transformer at 50% duty cycle is then the kVA rating

divided by the mains voltage. In practice, much higher primary current levels can be drawn by resistance welding machines for short times, and this is acceptable, provided account is taken of the actual duty cycle (current on time/total time) expressed as a percentage.

The allowable power at duty cycle  $x\%$  may be calculated as follows:

$$\text{kVA}_{x\%} = \text{kVA}_{50\%} \sqrt{\frac{50}{x}}$$

The single-phase a.c. transformers are of the shell/core type of a compact design and the insulation is cured to provide a robust unit capable of the mechanical and electrical loading typical of resistance welding equipment. Water cooling may be provided on the low voltage secondary conductors, thus improving its thermal rating. A number of standards cover the specific requirements of transformers such as ISO5826 (BS7125) and BS EN ISO 7284. Many transformers have tap switches so that the secondary voltage can be changed to provide step changes in the welding current range. Fine control of current is by phase shift control using the timer/controller.

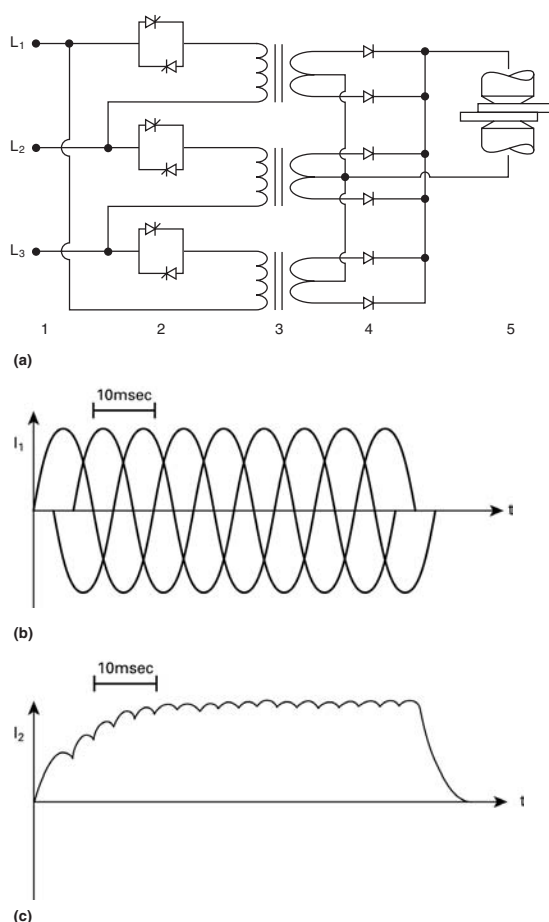

It is the available welding current rather than kVA rating that determines the suitability of a machine to weld a particular component. While the maximum short circuit current may be known for a particular machine, the welding current available will be much lower. This is because of the added resistance of the component being welded and the associated electrode or tooling. The secondary circuit impedance is also influenced by an inductive component, which is related to the area within the machine throat. Current is reduced if this area is increased, and even more so if there is steel within the throat. Thus, the arm spacing and routing of jumpers or flexible connections is important in order to minimise the losses.

A number of alternative power supply types are available, as follows:

**Secondary rectified d.c.** This type is used for high power applications as it uses a balanced three-phase supply and the rectified d.c. welding current is not subject to the inductive power losses suffered by a.c. current, see Figure 10.50. Single-phase d.c. machines are available but are much less common.

**Frequency converter d.c.** Primary rectification of a three-phase supply avoids the need to rectify high welding currents. A short duration d.c. pulse (less than 0.2 sec) is then delivered to the welding transformer. The d.c. polarity is changed for each pulse to avoid transformer saturation. This type of equipment has been widely used for high power applications, such as high quality welding of aluminium alloys.

**Inverter welders** Medium frequency inverter welders are used to enable more efficient, lighter weight welding transformers to be used, typically for robot guns. A three-phase supply is first rectified then chopped with a transistor unit to give medium frequency, typically up to 1000 Hz ac. This a.c. at about 600 V is then converted in the welding transformer to low voltage/high current at the same frequency. This is immediately rectified to give a d.c. welding current. These supplies are finding increasing use in robotic spot welding in the automotive industry and also for miniature applications, where fine control of the current pulse shape can be achieved.

**Figure 10.50** Three-phase secondary rectified d.c. power supply (a) Welding circuit. 1—mains supply, 2—thyristor current control, 3—welding transformer, 4—secondary rectification, 5—welding electrodes (b) Primary current waveform. (c) Welding current waveform.

**Capacitor discharge** A short duration d.c. pulse, typically less than 10 msec, is achieved by discharging a bank of capacitors through a welding transformer. A low power demand is required to charge the transformers. Such equipment is common for miniature applications, but large machines are available for large projection welding operations. These are often portal machines and have high force capacity with a fast follow-up, low inertia head. The heat input is relatively low compared to a.c. or d.c. power supplies.

**Transistorised power supplies** These are generally small to miniature supplies, up to about 5 kA. The current is pure d.c. and the pulse can be shaped accurately for fine control of the resistance heating of difficult material combinations or configurations, particularly in electrical and electronic applications.

In some cases, especially miniature applications in dissimilar materials, d.c. current is used and its polarity may be used to advantage in modifying the heat balance within a weld. The heating may be biased towards one electrode due to the Peltier effect.

### 10.2.1.3 Mains supply

When connecting resistance welding equipment to the mains supply, a number of factors need to be considered. As the primary current demand is high, the high voltage transformer (e.g. 11 kV) supplying the system should be of sufficient capacity that there is not an undue voltage drop on the mains voltage side. Cables connecting the machines do not necessarily need to be rated at the maximum continuous thermal rating for the size of machine being connected, as the duty cycle of the machine is usually low (except for seam welding). Account should be taken of the maximum anticipated duty cycle and any relevant local regulations. It is also important to consider the voltage drop associated with the supply cables, according to their size, length and the current demand. A reduction in supply voltage at the welding machine will reduce its capacity proportionally. The cable layout should also be so organised as to minimise reactive losses. Resistance welding equipment, particularly a.c. types have a reactive load and consequently a relatively low power factor. Occasionally, capacitive power factor correction equipment is used in the plant to reduce the voltage/current phase difference.

### 10.2.1.4 Resistance welding electrodes

Resistance welding electrodes play an important part in the achievement of good and consistent weld quality. The materials used are normally copper alloys, internally water-cooled, which provide a combination of high electrical and thermal conductivity, together with mechanical strength. This is required to withstand the electrode forces and a certain amount of hammering of the electrodes on initial contact. The dimensions of spot welding electrodes are covered by various ISO standards.

Electrode materials for resistance welding are covered by ISO 5182. The highest conductivity class 1 alloys, such as Cu/0.1%Zr, are used for spot welding coated steels and aluminium alloys. Harder, class 2 alloys with a conductivity of 75 to 80% IACS (International Annealed Copper Standard), such as Cu/1%Cr, are used for steels in general. Class 3 alloys, with 30 to 45% IACS, provide additional hardness for spot welding stainless steels and for projection welding dies, although tungsten/30%Cu inserts are also often used in projection welding. Refractory metals such as molybdenum or tungsten are also used for certain applications.

The diameter of the electrode contact face for spot welding should approximate to  $5\sqrt{t}$ , where  $t$  is the single sheet thickness in millimetres (up to 3 mm). This allows a weld of a similar diameter to be produced. In order to maintain weld quality, the electrode contact area and profile should be maintained by periodic electrode dressing or replacement by re-machined electrodes. An electrode dressing tool or form tool should be used where possible for greatest reliability. Automatic dressing equipment can be used in robotic applications. Typically, a few hundred spots for aluminium alloys, a few thousand for coated steels and several thousand for uncoated steels, are possible before electrode maintenance is required.

## 10.2.2 Welding process

### 10.2.2.1 Welding sequence control

In order to achieve the highest quality and repeatability in resistance welding, the control of welding current and its duration must be accurate. Modern electronic timers

provide two functions: (a) the synchronous timing of the weld sequence and current pulse, measured in cycles of mains frequency, and (b) control of the current level by phase shift control. Furthermore, on air-or hydraulic-operated equipment, the timer controls a solenoid valve and the welding sequence is interlocked once initiated. This takes the control of the machine out of the hands of the operator and prevents the electrode force being released until the end of the hold time. The basic welding sequence shown in *Figure 10.51* comprises the 'squeeze time', during which the electrode force rises to its preset level, the 'weld time' during which current flows and the weld is formed and the 'hold time' during which the weld is allowed to cool under pressure. The electrodes are then released. When spot welding 1 mm low carbon steel, the weld time would be about 0.2 sec, the welding current about 7 kA and the whole sequence less than 1 sec. More complex sequences can be used for special applications, and features include multiple current pulses, slope up of current and variation of force during the weld.

Solid state switches (thyristors) are used to control the flow of primary current to the transformer, the timer can be set to deliver the required duration of current, i.e. the number of cycles at 50 Hz mains frequency. The magnitude of the current can be adjusted finely by altering a heat or phase shift control. This changes the point at which the thyristors switch on during each half-cycle. The solid-state timers allow precise setting of time and current and often have constant-current control. This is based on feedback of the actual current measurement using a toroidal coil to adjust the phase shift (heat) control during the weld pulse. This compensates for mains voltage fluctuations and variation in secondary circuit impedance. Many also have programmable control to enable automatic equipment to select preset welding programmes, where one machine is required to weld a variety of thickness combinations, for example. Additional functions include diagnostics, fault detection and stepper functions, which allow welding current to be increased progressively to compensate for gradual electrode wear.

Prior to the introduction of modern controllers, weld timing developed from relatively crude control. Early machines that worked on a mechanical lever system incorporated the contactor for primary current within the lever system. Thus, the time of the weld was left to the judgement of the operator. This, however, led to unsuitable and unreliable welding conditions being used. By introducing simple timers and an electrically operated contactor, the duration of current flow was more reliable. Mechanical contactors were superseded by mercury vapour switches (ignitrons), which have now been replaced by thyristors.

**Figure 10.51** Timing sequence for spot, stitch and projection welding. A—hold time (forging time); B—pressure decay time (not critical); C—pressure off time

### 10.2.2.2 Welding parameters

The main welding parameters are electrode force, weld time and current. Recommended settings are available in the literature for many standard materials and applications, and guidelines are presented for spot welding uncoated and coated low carbon steels in BS 1140.

The electrode force required for spot welding low carbon steel is typically 1.5 to 2 kN per mm of its sheet thickness and is slightly higher for coated steels. The force required for stronger and high hot-strength materials such as stainless steel or nickel alloys may be 2 to 4 times this level.

Weld times for low carbon steels are normally about 7 to 10 cycles per mm of the single sheet thickness in the range 0.4 to 3 mm. The shorter times should be used in conjunction with the higher forces. Higher welding current is required at shorter weld times. However, it is not possible to compensate for insufficient current by excessively long weld times.

Welding current is adjusted to achieve a weld of the required size once other parameters are fixed. The current needed depends on the material type, the size of the electrode tip used and the other parameters set. Typically 7 to 10 kA is required for 1 mm and 15 to 20 kA for 3 mm uncoated steel. Higher current is required for coated steels because of the lower interface resistance.

It is important that welding current flows only through the electrode contacts and is not shorted through other parts of the tooling or components. Current can be lost through adjacent welds (current shunting). The degree of shunting depends on the material thickness and weld spacing. Welding current must be increased to compensate for close pitch welds (e.g. less than 3 times the tip diameter for thin sheet). Steel in the throat of the machine also causes a reduction in current on a.c. machines because of the increased inductive effect. Automatic compensation is possible in this case by using a constant current controller.

### 10.2.2.3 Weld quality and testing

The principal quality requirement of spot welds in sheet materials is weld size, and this is indicated by a destructive peel or chisel test to tear a plug or button from one of the sheets. The minimum acceptable weld diameter depends on the application standard but is typically  $3.5\sqrt{t}$  or  $4\sqrt{t}$  for sheet thicknesses up to 3 mm. A plug failure should normally occur and an interface failure may indicate the weld is weak due to lack of fusion or embrittlement.

Surface defects such as splash metal, cracks and excessive deformation are normally unacceptable, but metallographic examination of internal defects is usually only necessary for aircraft quality work.

For projection or butt welded joint configurations, testing in tension, shear, bend or torsion can be conducted to suit the component and service requirements.

Quality control in resistance welding is generally by process control and periodic destructive testing. Monitoring or routine checking of current, weld time and force can be done to ensure consistency of the main process parameters. A range of commercial in-process weld quality monitors and feedback controllers are also available that examine additional parameters such as weld resistance, weld energy or weld expansion. In order to exploit such monitors, the process must first be under control. A positive correlation between monitor output and quality must be demonstrated, and the monitor should be properly set up and maintained. Confidence in such monitors is easily lost if these criteria are not met.

Post-weld non-destructive testing of resistance welds is limited. Ultrasonic testing of spot welds requires a special-purpose high-frequency probe, incorporating a water column retained by a plastic membrane bubble, which is applied to the spot weld indentation. Skill and extensive training are required to interpret the multiple reflections on the flaw detector, but substantial reduction of destructive tests has been achieved by automotive manufacturers in particular.

### 10.2.2.4 Twin-spot welding

There are a number of cases where it is convenient to use twin-spot welding. These include welding components where access is limited to one side or where components are to be welded to large sheets. It is often possible to use a twin-spot method of operation where both electrodes are on one side of the material, the current being taken through a copper backing bar or plate below the bottom sheet (*Figure 10.52(a)*). If the lower sheet is significantly thicker than the upper sheet, the copper backing plate may be replaced by an insulated support to react to the load, or eliminated completely where a closed section is being welded.

An alternative technique, referred to as 'push-pull', involves initiating separate transformers simultaneously each side of the component, feeding two pairs of electrodes (*Figure 10.52(b)*). Series and push-pull welding allow small,

Figure 10.52 Twin-spot welding: (a) series weld; (b) push-pull weld

low inductive loss secondary circuits to be used, and minimise the amount of steel within the throat of the machine. This is an advantage on large components as smaller capacity equipment can be used.

### 10.2.3 Projection welding

In projection welding, the size and position of the weld or welds are determined by the design of the component to be welded. The force and current are concentrated in a small contact area between the components to be welded. This occurs naturally in cross wire welding, or is deliberately introduced by machining or forming. An embossed dimple is used for sheet joining and a V projection or angle can be machined on a solid component to achieve an initial line contact with the component to which it is to be welded. Nuts and studs are also widely projection welded. *Figure 10.53* shows some typical configurations.

Some of the advantages of projection welding are:

- Output is increased because a number of welds can be made simultaneously.
- Electrode life is extended because electrodes with large contacting surfaces may be used and these may have harder, sintered copper/tungsten inserts.
- The process is versatile, allowing a wide range of component designs to be resistance welded.
- Welds may be more closely spaced than practicable with spot welding without compensation for current shunting, and
- Minimum surface marking can be achieved on one side of the joints.

Consistency of projection height and shape, together with good electrode alignment and flatness are essential to ensure uniform share of the available force and current. Welding times are short, to ensure that sufficient heat is generated in the small contact area before the projection collapses completely. Rapid follow-up of the welding head ensures that the weld is consolidated as the projection collapses.

Projection welding machines operate on principles similar to those of spot welding plant, but are designed for much higher electrode force and current because it is usually required that several projections be welded simultaneously. Very large projection welding machines are available which can apply a total electrode force of several tonnes and deliver a welding current of over 500 kA. The larger machines are generally three-phase d.c., which gives a balanced mains demand and permits more even current distribution owing

to a minimal inductive effect. Large capacitor discharge machines with low inertia heads have also been used for projection welding applications. The weld time of only several msec duration results in a weld with low residual heat input. Although the welding current is much higher than for normal a.c. supplies, the mains current demand is low during the few seconds charging stage.

### 10.2.4 Seam welding

Seam welding (*Figure 10.54*) consists of making a series of overlapping spot welds by means of copper alloy wheel electrodes to produce a leak-tight joint. The electrode wheel applies a constant force to the workpieces and rotates continuously at a controlled speed. The welding current is either pulsed to give a series of discrete spots, or continuous for certain high-speed applications, where up to about 6 m/min can be achieved for 1 mm low carbon steel.

In the conventional technique, the track width of the welding wheel is approximately  $5\sqrt{t}$  mm and the minimum acceptable weld width is typically  $4\sqrt{t}$  mm. However, a leak-tight weld as strong as the parent material can be achieved with a weld width only a little wider than the sheet thickness. In narrow wheel seam welding, a radiused electrode face is used, giving a smaller contact area (*Figure 10.55(a)*). Weld widths of 2–3 mm are made in sheet thicknesses up to about 2 mm. Narrow wheel seam welding is particularly suitable for coated steels. The wheels are driven by a roller, which bears on the edge of the wheel and planishes the contact face, to maintain a uniform condition.

When welding speed is increased above about 20 m/min for very thin material, the spacing of welds made at each half cycle of the mains frequency becomes too great to produce a leak-tight weld. Higher frequency supplies, typically 600 Hz are used to weld tin cans in 0.2 mm thick steel at speeds to over 70 m/min. In this case, a mash weld is produced (*Figure 10.55(b)*) where the initial overlap is only 1.5 times the sheet thickness, and the seam is crushed during welding. The effect of electrode contamination is avoided by using a copper wire (formed to a flat oval) which is passed over each electrode in turn. Thus, the electrode face is continuously renewed. D.c. current is not used for such applications as it gives less effective heat generation in this case.

### 10.2.5 Resistance butt and flash welding

Resistance butt welding is the simplest form of resistance welding and is used predominantly to butt join wires and rods, including small diameter chain. The components to be joined are clamped in opposing dies, with a small stick-out, and butted under pressure. Current from a resistance

**Figure 10.53** Examples of projection welding configurations: (a) embossed projection; (b) stud to plate; (c) annular projection

Figure 10.54 Conventional wide wheel seam welding

Figure 10.55 Alternative seam welding techniques: (a) narrow wheel seam; (b) mash welding with consumable wire electrode (shown prior to welding)

welding transformer is passed between the dies, causing heating of the weld area. The material deforms under the applied load giving a forge weld. The welding current is normally terminated once a preset reduction in length has occurred, although pressure must be maintained until after

current has stopped flowing. Resistance butt welding is not normally suitable for larger components such as thin strip because of unevenness of heat generation. However, the use of d.c. power supplies together with programmed force and current cycles, has enabled components such as automotive road wheels to be welded on automatic equipment at up to 700 rims/hour.

Flash welding is used for a wide range of component shapes and sizes from bicycle wheel rims to rails. More efficient energy input, and a more localised and evenly heated zone, can be achieved compared with resistance butt welding. In this case, the components are clamped between dies and moved slowly towards each other with the current switched on. Current flows through successive point contacts, which heat rapidly, melt and blow out of the joint, giving the characteristic flashing action as the forward motion continues. After a preset material loss has occurred, sufficient to heat the material behind the interface to its plastic state, the components are forged together to expel melted material and contaminants, and complete a solid phase forge weld. The flash or upset metal may be removed while still hot using a shearing tool. When welding larger sections, the parts may be preheated to promote easier flashing. This is done by advancing and retracting the components to make repeated short-circuit contacts under pressure. The welding sequence and the welding machine are shown schematically in Figures 10.56 and 10.57.

Machines are predominantly single-phase a.c. in the power range 20–500 kVA. Such machines are designed with as small as possible secondary inductive loop as the flashing action is characterised by repeated breaks in the secondary circuit which cause transient arcs. The lower the inductance, the lower is the energy dissipated in the arc and the smoother are the melted surfaces prior to final forging. This helps to reduce the risk of weld interface flaws. Large d.c. flash welders have been produced to reduce the mains power demand, but there is a risk of sustained arcs produced during flashing, leading to undesirable deep melted areas at the interface. Modulated current may be used to counteract this tendency.

The flashing sequence must be accurately controlled and the forge applied with sufficient force and speed for best results. The forward movement of the components is normally accelerated as flashing progresses. The flashing speed

Figure 10.56 Generalised diagram of the flash welding sequence

Figure 10.57 A flash welding machine

should be as fast as is practicable for a given applied voltage, whilst avoiding premature butting or 'freezing' of the parts. This ensures that the flashing action is continuous and not so coarse that deep craters are blown in the contacting surfaces with a risk of interfacial flaws. These take the form of a film or planar distribution of oxide inclusions known as 'flat spots'. Feedback control of the travel speed maintains an optimum flashing action.

Welding conditions vary considerably for different materials and component size, but may be generalised as follows for a material of thickness  $t$ , flashing length  $0.7\text{--}1.5t$  and upset length  $0.2\text{--}0.5t$ . Forge forces are between  $60\text{ N/mm}^2$  for low carbon steels and  $150\text{ N/mm}^2$  for stainless steels, with even higher forces required for heat-resisting materials. Flashing speeds are typically  $0.5$  to  $3\text{ mm/s}$ , and upset speeds  $25$  to  $350\text{ mm/s}$ . Guidance on process control and weld testing is provided in BS 6944 for butt welds in steel and BS 4204 for tubular joints in pressure applications.

### 10.2.6 Safety aspects of resistance welding

There are a number of potential hazards in resistance welding. Although the machines are intrinsically safe, it is important to observe good welding practice, provide adequate training and adopt the appropriate safety measures. Machines should be manufactured and installed to the appropriate standards such as EN 50063.

Mechanical hazards involve the risk of trapping fingers or other parts of the body between electrodes or other moving parts. Safety devices include various types of guard, interlocked two-hand button operation and low force electrode approach. Where practicable, spot welding electrodes should have a working gap of no more than about  $6\text{ mm}$ .

Splash metal may be expelled under pressure from the weld. Eye protection and suitable protective clothing should therefore be worn. Burns and lacerations may result from careless handling of hot assemblies or materials with burrs or sharp edges. Suitable gloves and protective clothing should be worn.

Electrical hazards result from inadvertent contact with live terminals. Exposed conductors do not normally exceed  $20\text{ V}$ , but mains voltage is connected to the control cabinet and to the transformer taps and primary windings. The machine should be installed and enclosed to the appropriate standards, using the correctly rated cables and protection devices. Equipment should be switched off at the mains before removing covers or opening doors, such as for the purpose of changing taps where a tap switch is not fitted externally. Ideally, such doors should be provided with

safety interlocks. An additional hazard may be that the strong magnetic fields produced close to resistance welding equipment could affect the operation of heart pacemakers.

Fumes result from the vaporisation or burning of metal or organic coatings on material being welded, or from inter-weld adhesives, sealants, etc. This is not normally a major problem and adequate ventilation is usually sufficient. Local extraction may be required in some cases, depending on the type and concentration of the fumes.

## 10.3 Fuses

Fuses, which are now produced in vast numbers each year to protect electric circuits, were used as long ago as 1864 to protect submarine cables. In theory any conducting metal can be used as a fusible element. In practice, however, a variety of metals are used, ranging from cheaper materials such as copper to rarer and, therefore, more expensive materials such as silver.

The term 'fuse' is used in national and international standards to describe a complete assembly. In its simplest form, this consists of a piece of metal wire connected between two terminals on a suitable support; and at its most complex as a cartridge fuse-link mounted in a carrier and fuse base.

Modern cartridge fuse-links contain fusible elements mounted in rigid housings of insulating material. The housings are filled with suitable exothermal and arc-quenching powders, such as silica, and they are sealed by metal end-caps which carry the conducting tags or end connections. A typical fuse-link is shown in Figure 10.58. The metal parts, other than the fusible elements, are invariably of copper, brass, steel or composites and they must be capable of operating under the exacting thermal, mechanical and electrical conditions which may arise in service. The materials used for the fusible elements must enable predictable performances to be obtained under a wide range of conditions, from normal thermal cycling to the violent changes of state that occur when elements are subjected to arcing during the interruption of faults.

### 10.3.1 Fuse technology

Fuses operate for long periods during which they carry currents at levels up to those associated with healthy conditions on the circuits protected by them and they must be capable of interrupting overcurrents up to the maximum levels possible when faults occur.

**Figure 10.58** HRC fuse-link

To satisfy these requirements, a fuse must be able to carry normal load currents and even transient overloads (and the thermal cycling which accompanies them) for a service life of at least 20 years, without any change of state that might affect its electrical performance. This property of 'non-deterioration' requires that the fusible element be both thermally and chemically compatible with the ambient media. It must also respond thermally to overcurrents by melting and subsequently interrupting its circuit.

The melting of an element is followed by a period of arcing during which the electrical energy input can be very high, its magnitude and the duration of arcing being dependent on the protected circuit. Successful fault interruption implies that the arcing is wholly contained within the fuse-link and the level at which this can be achieved is termed the breaking or rupturing capacity of the fuse-link. It must be recognised that unsuccessful interruption can result in disastrous changes to a circuit and its surroundings.

The operating time of a fuse-link varies inversely with the level of an overcurrent and discrimination is obtained in networks by choosing fuses with the necessary time/current characteristics and current ratings.

An important property of a high-breaking-capacity fuse-link is its ability to limit the energy fed to a fault, by melting and achieving arc extinction long before the fault current can rise to the levels which the circuit could otherwise produce, i.e. the 'prospective' values. This property is achieved by selecting the necessary element material and geometry.

### 10.3.2 Element materials

Silver, copper, tin, lead, zinc or alloys of these materials are used to produce fuse elements. In the past, silver was used in the majority of fuse-links but copper has been employed increasingly in recent years because of its much lower cost. Copper is now used in most industrial type fuse-links but silver is still required to obtain the performance required of fuse-links needed to protect semiconductor devices. The other materials listed above are used in fuse-links intended for low-power circuits.

Apart from its cost, silver is ideal for elements because of its physical properties. It is reasonably immune to corrosion in normal atmospheric conditions and is chemically compatible with silica and other media by which it is surrounded in fuse-links. Even when oxidation of an element does occur at elevated temperatures, the conductance is hardly affected because the conductivity of silver oxide is close to that of

**Figure 10.59** Shaped fuse elements

the parent metal. Silver is ductile and easily fashioned into the shapes needed, some of which are shown in *Figure 10.59*. It is easily joined or connected to other materials and is hard enough to be mechanically self-supporting. It can also be combined with other dissimilar materials (e.g. to produce the M effect referred to later) to produce eutectic alloys without affecting its stability during thermal cycling. The physical break-up which follows the melting of an element is regular and predictable for material of the prescribed purity. The vaporised metal can be made to disperse within the arc-quenching media to combine and condense so that the resulting 'fulgurite' becomes an insulator.

A silver element may be heated almost to melting and then allowed to cool without its state changing significantly. Such situations arise in service when large overcurrents are interrupted elsewhere in a circuit and it is important that the fuse-links involved should not, as a result, be weakened or change their designed time/current characteristics.

Whilst the properties of copper are not quite so good as those of silver they are, nevertheless, of standards which allow satisfactory elements to be produced for industrial fuse-links.

### 10.3.3 Filling materials

Cartridge fuse-links are invariably filled with granular quartz of high chemical purity the grain sizes being in the region of 300  $\mu\text{m}$ . The filling material conducts heat energy away from fuse elements and, therefore, to obtain consistent performance it is necessary that a high and constant packing density be achieved. To further improve the consistency and raise the heat conduction it is now usual to employ inorganic binders in the filling material. This enables shorter operating times to be achieved and better performance is also obtained in d.c. applications.

### 10.3.4 Fuse-links with short operating times

All modern high-breaking-capacity fuse-links contain elements, usually with restrictions, of small cross-sectional areas connected between relatively massive end connections which act as heat sinks. To obtain rapid operation this principle is employed to a high degree. The extent to which the mass of the heat sink can be increased while reducing the length of the relatively thin element is determined by the requirement that the fuse should withstand the system voltage after the current has been interrupted (i.e. must not restrike). Considerable ingenuity has reconciled these two mutually incompatible requirements. More than one

restriction may be used in series along the length of an element to cater for increased voltage, but this aggravates the problem of dissipating heat from the elements. The solution lies in an increase in the transfer of radial heat through the surrounding media. Thus the fuse element must not be looked at in isolation, but as a composite whole with the rest of the assembly.

The fashioning of fuse elements to produce elaborate shapes is economically limited by the means available to achieve the shape required. A variety of means is employed and these often influence the choice of material as regards its physical constants, e.g. the purity of silver as a factor in hardness, etc.

### 10.3.5 The M effect

The M effect, deriving from an exposition by Metcalf, refers to exploiting the thermal reactions of dissimilar metals in the control of time/current characteristics. The thermally most stable fuse element is a simple homogeneous metal. Such an element provides the highest degree of non-deterioration and reliability with adequate breaking capacity at higher overcurrents, but it may be insensitive at lower overcurrents. A lower melting temperature metal with higher resistivity and, therefore, greater thermal mass, can be made to respond more sensitively to lower overcurrents but may be unreliable at higher currents.

The M effect is a means by which these extremes can be combined to produce a desired characteristic, but it needs to be used with care in design to avoid compromising non-

deterioration properties. An element incorporating the M effect is shown in *Figure 10.60(a)*.

### 10.3.6 Composite or dual-element fuses

Satisfactory operation throughout the overcurrent and short-circuit ranges is sometimes obtained in the same package by combining what are, in effect, two fuses connected in series in the same cartridge (*Figure 10.60(b)*). Typical of these is the so-called dual-element design common in the USA. The short-circuit zone is similar to the homogeneous element used in single-purpose HRC fuses. The overload zone may take the form of a massive slug of low-melting-point alloy, or some electromechanical device, e.g. two copper plates soldered together and stressed by a spring so that when the solder melts the plates spring apart to interrupt the current. The variables in such designs are considerable and many ingenious ideas have been exploited with some success.

## 10.4 Contacts

Contacts may be classified according to the load they control and are here discussed under four basic headings:

- (1) low voltage, light current;
- (2) low voltage, high current;
- (3) medium voltage (<660 V) and power levels; and
- (4) high voltage, high power.

An indication of the physical properties of contact materials and the performance and application of contact alloys is given in *Tables 10.4* and *10.5*.

### 10.4.1 Low-voltage, low-current contacts

These contacts are required to make and break a very low electrical duty so contact erosion is not a problem. Ideally the contacts should have a low contact resistance which does not introduce electrical noise by electrothermal or electromechanical means. Importance is therefore placed on surface contamination and deterioration in use and in storage. Silver–nickel alloys are commonly used in low-current control circuits, but for low noise a plated gold surface may be applied which survives a signal level service but rapidly exposes the silver–nickel for higher current applications. Rhodium or palladium may also be used in combination with gold for higher mechanical duty applications.

### 10.4.2 Low-voltage, high-current contacts

Separation of contacts carrying a current will create an arc. Since an arc requires a minimum voltage to maintain itself, the arc rapidly extinguishes for low voltage. However, inductance in the load will cause an arc of longer duration and results in contact burning. The high current requires a low contact resistance and large contacts with high contact force are used. Contact materials may be silver–nickel, though some automotive applications will use copper alloys for economy.

Contact resistance is a function of the contact materials, the force applied and, to some extent, the shape of the contacts. The resistance of a pair of contacts may be expressed as  $r = k/f^n$ , where  $f$  is the force applied, and  $k$  and  $n$  are constants depending on the contact materials and shape.

Typical values for  $f$  and  $n$  for copper are given in *Table 10.6*. At the instant of contact closure a single contact point

‡ The composition is given in weight %.

Table 10.5

<i>Material</i>	<i>Properties</i>	<i>Area of application</i>
<i>Base: tungsten or molybdenum</i> W/Ag 80/20 ... 20/80	Very low wear, decreasing with increasing W content. High contact resistance, increasing with increasing W content. Resistance increases during life. High contact forces necessary. Bad arc mobility properties. Not workable.	Low voltage and high voltage circuit-breakers, miniature circuit-breakers (in particular American systems). Railway switches
WO/Ag 80/20 ... 40/60	Slightly better than W/Ag for erosion. Suppression of forming of tungstate	As W/Ag, in particular for simple pairs of contacts (no special arcing contacts)
Mo/Ag 80/20 ... 50/50	Similar to W/Ag	Similar to W/Ag
W/Cu 85/15 ... 50/50	Similar properties to A/Ag, but more prone to forming of oxide	High voltage-load breaking switches and circuit-breakers (contacts in air, oil, SF <sub>6</sub> ); transformer tap-changers (contacts under oil). Electrodes for spark erosion, electrolytic removal and welding.
<i>Base: silver</i> Ag	Highest electrical and thermal conductivity. Oxidation resistant but formation of sulphide. Material transfers. Easily worked	Control switches, microswitches, regulators and selector switches: voltages $U > 60$ V; currents $I < 10$ A
Ag/Ni 99.85/0.15 (fine-grain silver) Ag/Cu 97/3 ... 90/10 (hard silver)	Similar to Ag, but lower erosion. Contact resistance increases with increasing base metal content. Welding tendency low for peak currents below 100 A	Control-, micro-, selector-, relax switches, regulators, miniature circuit-breakers with ratings up to 5 A
Ag/Ni 90/10 ... 80/20	Contact resistance similar to hard silver, but less increase in resistance during life. Lower erosion. No welding for current peaks up to 100 A. Low and flat material transfer when switching d.c. Erosion debris on insulating materials non-conducting. Good arc extinguishing properties	Control switches, regulators, selector switches for d.c. and a.c. up to 100 A. Switches for domestic appliances. Miniature circuit-breakers up to 25 A rating. Motor control switches, contactors up to 25 A rating. Automotive switches. M.c.b.s for d.c. and a.c. (unequal pairs with Ag/C). Controllers
Ag/Ni/ 70/30 ... 60/40	Contact properties similar to 10–20% Ni, but higher contact resistance and lower wear (increasing with increasing Ni content)	Circuit-breakers for d.c. and a.c. Automotive horn switches. Controllers
Ag/CdO 90/10 ... 85/15	Contact resistance somewhat higher than for Ag/Ni 90/10. No welding up to peak currents of 3000 A. Low arc erosion in the range 100 to 3000 A. Very good arc extinction properties. Unfavourable arc movement properties. Limited workability	Low-voltage contactors, motor and motor-protection switches with ratings from 10 A. Low-voltage circuit-breakers with ratings up to about 100 A. Miniature circuit-breakers and earth leakage circuit-breakers with peak currents up to 3000 A. Lighting switches
Ag/C 97/3 ... 95/5	Low contact resistance. Very high reliability against welding (increasing with increasing C content). Good friction properties. High wear. Bad arc-mobility properties. Bad workability	Miniature circuit-breakers and earth leakage circuit-breakers. Low voltage circuit-breakers (unequal pairs with Ag/Ni). Capacitor protective relays. Sliding contacts with self-lubrication
Ag/ZnO 92/8	Similar properties to Ag/CdO, but arc erosion in the current range 100–3000 A somewhat larger and in the range 3000–5000 A smaller	Low-voltage circuit-breakers with ratings up to 200 A. Earth leakage circuit-breakers
<i>Base: palladium</i> Pd	Highly resistant to corrosion, but prone to catalytic reaction with organic materials (brown powder). Highly resistant to arc erosion. Low electrical conductivity	Switching contacts at voltages $U = 20–60$ V

cont'd

**Table 10.5** (continued)

Material	Properties	Area of application
Ag/Pd 70/30 ... 50/50	Generally resistant to corrosion, but worse than Au alloys. For Ag compared to Ag/Pd 70/30 about 7 times faster and compared with Ag/Pd 50/50 about 100 times faster formation of surface films. Highly wear resistant	Switching contacts at voltages $U=20-60$ V, e.g. for telephone relays and selectors. Usual material in telecommunications. Sliding contact in precision potentiometers
Pd/Cu 85/15 and 60/40	Corrosion behaviour similar to Pd, but at 40% Cu thin oxide layers form high resistance to arc erosion. Low tendency to transfer	Switching contacts at voltages $U=4-60$ V. High switching currents
<i>Base: platinum</i>		
Pt/W 95/5 Pt/Ni 91.5/8.5	Resistance to corrosion better than for Pd alloys, but also formation of 'brown powder'. Low, even transfer. Very highly wear resistant	Switching contacts at high load currents and very long life
<i>Base: gold</i>		
Au, Au/Pt 90/10	Highest resistance to corrosion, contact resistance constant over long periods. Prone to cold welding. Material transfer	Opening contacts for very small currents and voltages (dry circuits), e.g. in measuring devices, need switches
Au with hardening additives, electrolytically produced (hard gold)	Similar to Au, but slightly higher contact resistance and less prone to cold welding	Plugs, slide rails, rotary and sliding switches. PCB edge connections
Au/Ag 92/8 ... 70/30 Au/Ag/Pt 69/25/6	Good resistance to corrosion. Higher hardness and resistance to wear and less prone to transfer than Au	Switching contacts with voltage $<24$ V and for small currents, e.g. circuits. Plugs for frequent operation
Au/Co 95/5	Resistance to corrosion similar to, hardness and wear resistance higher than Au/Ag alloys. Slight tendency to transfer. Less malleable	Switching contacts for long life, e.g. for flashers, measuring devices, clocks. Plugs with long life
Au/Ag/Cu 70/25/5, 70/20/10 Au/Ag/Ni 71/26/3	Good resistance to corrosion but slightly less than Au/Ag, decreasing with higher base metal content. Transfer worse than for Au/Ni and Au/Co	Switching contacts, e.g. telegraph relays at voltage $<24$ V. Plugs for normal life at contact forces at about 0.5 N

**Table 10.6** Constants for copper contact:  $r=k/f^n$  with  $r$  in ohms and  $f$  in newtons

Form	Surface condition	$n$	$k$
Point	Normal	0.5	0.0007
Line	Normal	0.7	0.0015
Plane	Normal	1.0	0.004
(160 mm <sup>2</sup> )	Lubricated	1.0	0.003
	Tinned	1.0	0.012
	Fine-ground, new	2.0	5

only may be considered; increasing force distorts the surface and more contact points are established in parallel with the first. With a 'soft' material and with a high force, contact is eventually established over an area which may represent a large proportion of the available contact area, resulting in a low contact resistance. This system would soon cause mechanical erosion of the contact surfaces and so such techniques are only applied to contacts which are only occasionally separated such as plugs and sockets or isolators. Sliding of the contacts may also be permitted to ensure clean surfaces are presented at each contact 'make'.

The contact shape has importance if the contacts are not expected to erode during their lifetime and thus change their original shape.

#### 10.4.3 Contact design

The passage of current at the contacting face will cause heating and this may cause a local softening of the material with a resulting increase in contacting area and reduced contact resistance. This would appear to be an advantage but represents a dangerous condition since welding may occur. In the minimal case the contacts may be separated mechanically and the weld broken but in the worst case the contacts become permanently joined! Welding may also occur due to contacts arcing and particularly so when contacts 'bounce' while carrying current.

To discourage welding, contact 'alloys' are available which contain low resistance silver and a hard material such as nickel or tungsten or an oxide of cadmium, tin or zinc. Graphite may also be included to reduce welding but at the expense of increased contact resistance. Some forms of contact are shown in *Figure 10.61*.

Figure 10.61 Basic forms of contact

#### 10.4.3.1 Medium voltage (up to 660 V)

Make and break contacts for this industrial range are required to provide a useful life of many thousands of operations. The duty may be a motor load where the starting current is typically six times the running current. For this duty (AC3), a long life can be expected since little erosion occurs at contact close. However, bounce can cause welding so contacts need to be rated according to the duty. Contacts which make and break equal currents (AC4) would erode more rapidly. At high currents shaped contacts may be used so that a defined area of the contact breaks last and carries the eroding arc. The remaining area, by staying clean, provides a low resistance for the continuous load current. The best combination of contact force, size, shape and material has to be made for a contactor to control a wide range of loads; capacitive loads (fluorescent lights) are particularly prone to weld problems. Silver-cadmium oxide is a common choice of contact material because of its good erosion and weld resistance properties. Silver-tin oxide is a recent alternative. The granular structure of these sintered materials has a great influence on their performance. The ratio of silver to cadmium/tin/nickel is high and thus acceptably low contact-resistance is obtained. However, the thermal rating of the contacts normally decides their dimensions.

#### 10.4.3.2 High voltage-high power ( $\geq 3kV$ )

This application is generally required for a low duty since the operating rate is slower. The higher voltages may require a multiple contact break and external influences are used to extend the arc into a shute where it is cooled and extinguished. Sulphur hexafluoride gas and oils may be used to assist in deionising the arc. (The special behaviour of an arc in a vacuum is used in the vacuum contactor which is capable of interrupting current at a non-current zero (current chopping).) Contact materials for which high-power duty have to withstand higher temperatures and tungsten alloys are common. In oil, copper is acceptable for the load-carrying part of the contact since oxidation does not occur and the arc tips only are fitted with tungsten alloy.

The effect of a current passing through closed contacts is represented by  $I^2rt$ . The contact resistance,  $r$ , is considered

low and stable, but  $t$  is large so the resulting heat needs to be dispersed. This is performed by conduction into the mass of the supporting contact backing and, in many constructions, into the cable connections. During the contact make and break,  $r$  is larger but  $t$  is small. The heat is dispersed only into the contact area, so the thermal capacity and thermal conduction of the immediate contact assembly is most significant. Good ventilation also assists in reducing contact temperature.

When separating contacts which are passing a current, the final contact is small so the resultant resistance produces considerable heat and high temperatures are reached.  $\theta = \frac{I^2}{\gamma \rho}$ , where  $V$  is the contact voltage,  $\gamma$  is the thermal conductivity and  $\rho$  is the electrical resistivity of the contact materials.  $V$  has a major influence and temperatures in excess of 10 000 K are readily attained. Such temperatures cause vaporisation, thermionic emission and, together with electromagnetic forces, these cause destruction of the contact surfaces evidenced as erosion.

When the contacts are subjected to an arc during circuit interruption, it is advantageous to minimise the duration of the arc. An a.c. circuit carries current which passes through zero twice per cycle and at this instant there is no energy to support the arc which then extinguishes. The rise in voltage across the contacts may restrike the arc if any ionisation remains. The contacts must therefore be separated to a sufficient distance and the gap cooled and ventilated. For a d.c. circuit, no such current zero occurs and the contact separation is required to break the arc. This may be assisted by multiple break contacts, extending the arc by magnetic fields, forcing the arc against cooling plates and generally by a very fast separation of the contacts. The use of blow-out coils to create a magnetic field is commonly used in large units but these are not effective at low currents and a permanent magnet may be added to assist the low current performance.

The life of contacts is a function of the current and the number of operations, there being both mechanical wear and electrical surface disruption. With d.c. there is a tendency for material to transfer from one contact to another in a unidirectional manner and advantage can be taken of this by the use of dissimilar contact materials or even dissimilar contact sizes. With a.c., the reversal of the arcing current will average the erosion so that the contacts erode equally. The unidirectional transfer by d.c. generates a 'pip and crater' condition which may reach the state where the 'pip' wedges into the crater effectively locking the contacts together. This effect is noticeable on small contacts which have too small a separation force to break the pip clear of the crater. Very low force contacts as in reed switches are particularly susceptible and gold contacts may even cold weld when left closed for a long period. Precautions are necessary to reduce these effects and for d.c. low current applications RC suppression and resistance to limit current pulses through the contacts is generally used.

## 10.5 Special alloys

Many alloys have been developed for special applications either at elevated temperatures for heating elements or as heat-resisting materials or at room temperature where a minimum change of resistance or dimensions is required.

### 10.5.1 Heating alloys

There is a considerable range of alloys used for heating elements for a wide range of applications including electric

fires, storage heaters and industrial and laboratory furnaces. These alloys usually contain nickel together with chromium, copper and iron in varying proportions and often with small amounts of other elements. Similar alloys are also used for the construction of fixed and variable resistors. For heating elements, a considerable resistivity is required to limit the bulk of wire required. In addition, the temperature coefficient of resistivity should be small so that the current remains reasonably constant at constant applied voltage. *Table 10.7* gives the properties and trade names of a range of resistance heating alloys.

The operating temperature of these alloys is dependent on the cross-section of the wire or strip and on the atmosphere in which the material is to be used. The manufacturer's literature should be consulted before any application is finalised.

For higher temperatures, ceramic rods are used. Silicon carbide may be used in applications ranging from below 600°C up to 1600°C in either air or controlled atmospheres, although the type of atmosphere will determine the recommended element temperature. For even higher temperatures there are various cermets. Molybdenum disilicide ( $\text{MoSi}_2$ ) with additions of a ceramic glass phase may be used up to 1900°C and a zirconia material (Zircotal) is used up to 2200°C. These maximum temperatures depend on the type of atmosphere in which they are to be used.

### 10.5.2 Resistance alloys

Alloys for standard and fixed resistors are required to have a low-temperature coefficient of resistivity in the region of room temperature.

*Manganin* (84% Cu, 4% Ni, 12% Mn) This has been the traditional material for high-grade standard resistors. Its resistivity is about  $0.40 \mu\Omega\text{-m}$  and its temperature coefficient is about  $1 \times 10^{-5}/^\circ\text{C}$ .

*Karma and Evanohm* Trade names for quaternary alloys (73% Ni, 21% Cr, 2% Al, 2% Fe or Cu) which are being used increasingly for standard resistors, especially those of high value. The resistivity is about  $1.30 \mu\Omega\text{-m}$  and the temperature coefficient is  $\pm 0.5 \times 10^{-5}/^\circ\text{C}$ . Each of the

above alloys has a low thermo-e.m.f. against copper. Normally joining the above alloys to copper should be by argon arc welding or if this is not possible hard soldering may be used.

*Constantan, Eureka Advance and Ferry* Proprietary names for copper-nickel alloys (55% Cu, 45% Ni) which are used for heavy-duty and fixed resistors, potentiometers and strain gauges. They have a resistivity of about  $0.50 \mu\Omega\text{-m}$  and the temperature coefficient varies between  $\pm 4 \times 10^{-5}/^\circ\text{C}$ . The high thermo-e.m.f. against copper ( $-40 \mu\text{V}/^\circ\text{C}$ ) is a disadvantage for d.c. resistors but the effect is usually negligible in a.c. resistors. These alloys may be soft soldered satisfactorily.

### 10.5.3 Controlled-expansion alloys

These give a range of thermal expansion required in precision parts, control devices and glass-to-metal seals. The lowest expansion alloy is a 36% nickel-iron alloy and is variously called Invar, Nilox or Nilo. The expansion coefficient of these alloys can be less than  $1 \text{ ppm}/^\circ\text{C}$  although this can only be attained over a limited temperature range. Other alloys in the nickel-iron series with additions of cobalt or chromium can be tailored to give the same expansion coefficient as various types of glass for use as metal-to-glass or ceramic seals for television tubes, integrated circuits and fluorescent lights. The expansion coefficient of these alloys will be in the range  $4\text{--}10 \text{ ppm}/^\circ\text{C}$ .

### 10.5.4 Heat-resisting alloys

A range of nickel-chromium based alloys has been specifically developed to meet strict limitations on the permissible creep of vital components in gas turbines in severe conditions of time, mechanical stress and working temperature. A 43/37/18/2% iron-nickel-chromium-silicon alloy is heat resisting in oxidising conditions up to 950°C or higher if the atmosphere is reducing. Developed originally for wire-woven conveyor belts for electric furnaces, it is now used also for a wide range of high-temperature applications.

## 10.6 Solders

Soldering is a process whereby metal components are joined together using a low-temperature filler metal, which is usually a tin-containing alloy. To assist in the wetting of the basis metal by molten solder, a flux, which is a weak acid, must be present to dissolve the thin oxide films already present on the surface of the components and to prevent further oxidation during heating of the joint.

### 10.6.1 Fluxes

Soldering fluxes are liquid or solid materials which, when heated, are capable of promoting or accelerating the wetting of metals by molten solder. Fluxes are usually divided into three groups by a classification based on the nature of their residues, namely corrosive, intermediate and non-corrosive fluxes. The National Standard for soft-soldering fluxes, BS 5625 (1980), incorporates a larger number of categories

which gives an indication of the chemical nature of each flux type and their application.

For electrical components and other applications where corrosive residues could be difficult to remove, a non-corrosive rosin flux is used. Solder wire with a continuous core, or cores, of rosin flux can be used for manual soldering operations. The National Standard outlining the requirements of such material is BS 441 (1980).

### 10.6.2 Solder types

A selection of solder alloys are available which melt at temperatures ranging between 60 and 310 °C. British Standard grades of solder, their maximum levels of impurities that are permissible and typical applications are listed in BS 219 (1977). For the soldering of electrical connections and high-quality sheet metal work, an alloy containing 60% Sn, 40% Pb (grade K) is often used. For the machine soldering of electronic assemblies a solder of equivalent alloy composition but with a lower level of impurities is recommended (grade KP). Tin solder alloys with lower tin contents are used for general engineering and the joining of copper conductors and lead sheathing, etc.

The shear strengths of soldered joints are generally within the range 20–60 N/mm<sup>2</sup> at room temperature. As the temperature is increased the strength of joints made with tin-lead solders can decrease significantly. For this reason several solder alloy compositions, such as 95% Sn, 5% Sb (grade 95A) and 96.5% Sn, 3.5% Ag (grade 96S) are recommended for use at service temperatures in excess of 100 °C. There are various methods of mechanically attaching two components prior to soldering in order to give added joint strength.

Depending on the soldering method employed solder can be used in the form of a bath of molten metal, sticks, solid wire, flux-cored wire, powder, solder creams, solder paint, or as preforms stamped out of thin foil. Solder creams, which are a mixture of oxide free solder powder, flux and rheology modifiers, can be pre-placed onto the area to be soldered by screen printing or syringe dispensing prior to heating. This technique is called 'reflow soldering' and is now widely used for the joining of surface mount electronic components to printed circuit boards.

## 10.7 Rare and precious metals

One of the most important and widespread electrical uses of the rare and precious metals is for contacts in applications, ranging from everyday electrical appliances to heavy-duty switchgear and contact-breakers, as well as in scientific and precision instruments, and communication equipment. Contacts can be broadly divided into light, medium and heavy duty and in *Table 10.8* the materials within these groups are approximately arranged in order of descending cost.

Light-duty contacts require that the surfaces do not corrode appreciably, so the more noble metals and alloys are often used, while currents are low, so that resistivity is less important.

Medium-duty contacts handle heavier currents, so that low resistivity is important and, since contact forces are normally high, slight corrosion/tarnishing is less important, but higher hardness becomes desirable.

For heavy-duty applications severe arcing and heavy mechanical wear must be expected, so that higher resistivity

can be accepted, in the interests of high hardness and arc resistance.

The choice of contact material is very much a compromise between the intrinsic initial cost, the ease and cost of replacement and the electrical and mechanical properties of the alloy.

Platinum and rhodium-platinum alloys are extensively used for high-temperature thermocouples, which are accurate and particularly stable, as well as for the elements of high-temperature furnaces. Iridium-platinum, and rhodium-platinum are also used as electrodes in cathode-ray tubes. Caesium salts are used in the manufacture of photo-electric cells.

Pure silver is commonly used for electrical fuses and also in certain types of batteries and in capacitors, while a wide range of precious metals and alloys are used for thermal fuses acting as overtemperature cut-outs in electric furnaces.

A number of precious metal alloys are used for precision variable resistances, where the contact resistance at the wiper brush must be minimised. Precious metals are extensively used in integrated circuit technology where resistance to tarnishing and oxidation are important as well as the high ductility essential to the drawing of fine wire and thermocompression bonding. The primary material used in these applications is gold, although platinum, palladium, osmium and iridium are also used. Gold is employed in fine-wire interconnections in packaging of devices and as a eutectic alloy with silicon, used to bond the chip to the header. In thin- and thick-film circuits gold alloys with chromium, copper, nickel, platinum and silver are extensively used in terminations.

New developments in circuit technology requiring ever higher density interconnections utilise tape automated bonding (TAB) and flip-chip techniques. In these techniques wire interconnections have been replaced by direct soldered connections between solder wettable pads on the chip and the substrate. The development of 'solder bumps' used in the bonding involves a gold plating stage to protect the metallised aluminium pads prior to deposition of the high-temperature solders necessary in these techniques.

## 10.8 Temperature-sensitive bimetals

Temperature-sensitive bimetals, commonly known as thermostatic bimetals, are produced by bonding together two metals having different coefficients of expansion and cold rolling the composite into strip. When subjected to a temperature change, the strip alters curvature in a precise and calculable manner. The bimetals can be used in forms such as the deflection of a straight strip, the rotation of spirals or helices and the snap action of dished discs. Applications include temperature indicators, thermostatic controls, energy regulators, temperature compensation and automotive fuel control devices.

The alloys used for the low-expansion components are normally Invars, 36% or 42% nickel-iron. The high-expansion components are mainly alloys based on manganese, iron or nickel. Alloys have been developed for special applications, such as shower temperature control units and steam traps, where the corrosion resistance is specially important. A range of bimetals with closely controlled resistivities are available for devices, such as overload circuit-breakers, where the bimetal is heated by the direct passage of current. These include a number of trimetals in which the centre component is a low resistivity metal such as copper or nickel.

**Table 10.9** Thermostatic bimetals

<i>Bimetal type*</i>	<i>Deflection Constant, <math>K</math> (<math>^{\circ}\text{C}^{-1}</math>)</i>	<i>Range of maximum sensitivity (<math>^{\circ}\text{C}</math>)</i>	<i>Modulus of elasticity (<math>\text{Kg/mm}^2</math>)</i>	<i>Electrical resistivity (<math>\mu\Omega\text{-m}</math>)</i>
200	$19.3 \times 40^{-6}$	-25-200	13 500	1.11

\*Telcon Limited.

†Corrosion-resistant type.

‡Frimetals.

A straight bimetal strip of length  $L$ , thickness  $t$ , and width  $w$ , fixed at one end and free to move at the other, will produce a free end deflection of  $d = 4/1 K (\Delta T)L^2/t$  for a temperature change  $\Delta T$ .

The force developed, if the free end is restrained from moving, is  $1.1 KE(\Delta T)wt^2/4L$ , where  $E$  is its modulus of elasticity. Similarly, for a bimetal spiral or helical coil of radius  $r$ , the angular deflection is  $130 KL/(\Delta T)t$  and the restrained force is  $0.19 KE(\Delta T)wt^2/r$ .

The properties of a representative range of bimetals are given in Table 10.9.

## 10.9 Nuclear-reactor materials

### 10.9.1 Introduction

A detailed description of the engineering design and mode of operation of the principal reactor types is given in Chapter 19 of this book. Reference to that chapter shows how varied is the detailed design of the various commercial types and how this variation requires large differences in the materials used, particularly within the reactor core. In this section, these diverse materials are identified and the reasons for their selection highlighted.

Before proceeding, however, it is worth noting that all the important commercial reactor types are 'thermal', i.e. neutrons have average energies of  $<0.1$  MeV. Such reactors use materials in six common applications:

- (1) as fuel;
- (2) as fuel cladding;
- (3) as pressurised coolant;
- (4) as a moderator which reduces neutron energies to thermal values;
- (5) as a pressure vessel which contains the high-pressure coolant; and
- (6) as radiation shields.

There is continuing interest in the *fast-reactor system* so-called because it produces nuclear fission using energetic, i.e. 'fast', neutrons with energies of  $>0.8$  MeV. Such reactors have some of the components of the present 'thermal' designs (e.g. fuel, cladding and coolant), but they do not require a moderator or a pressure vessel since the coolant does not operate at high pressure. Again, Chapter 19 provides further details. Although prototypical reactors have been in operation for many years (e.g. in the UK and France), a larger European fast reactor power station is currently being designed. Final choices of alloys to be used within this system have yet to be made in important areas,

e.g. the fuel cladding, and so the information given below will refer to the UK prototype fast reactor (PFR) at Dounreay in Scotland.

Table 10.10 summarises the various materials used within the cores of the major commercial reactor types but also including the PFR.

### 10.9.2 Fuels

The only naturally occurring fuel is the isotope  $^{235}\text{U}$ , present in natural uranium to about 0.7%. Uranium occurs as a complex silicate ore, chiefly pitchblende, which also contains lead, thorium, iron, calcium, radium, bismuth, antimony and zinc.

However, kasolite (essentially, a lead uranyl silicate) and carnotite ( $\text{K}_2\text{O} \cdot 2\text{UO}_3 \cdot \text{V}_2\text{O}_5 \cdot 3\text{H}_2\text{O}$ ) are also sources of uranium.

There are various methods of uranium extraction which depend in detail on the type of ore and the impurities it contains. In general, the ore is crushed (e.g. by ball milling), in order to increase chemical reaction rates, and then dissolved in either sulphuric or nitric acid. Thus, as an example, boiling of the ore in concentrated nitric acid would produce a nitrate solution of uranium as well as the principal metal impurities. Of the latter, radium may be precipitated by the addition of barium sulphate whereas iron, lead and manganese are removed by adding sodium carbonate. Uranyl nitrate may be decomposed thermally to produce  $\text{UO}_3$ . This higher oxide may then be reduced partially to  $\text{UO}_2$  by high-temperature exposure to hydrogen-bearing gases or may be reduced completely to uranium metal by fluorination to  $\text{UF}_4$  and subsequent reduction by magnesium.

Most modern designs of commercial nuclear reactors use uranium fuel (as  $\text{UO}_2$ ) enriched in the  $^{235}\text{U}$  isotope (see, for example, Table 10.10). Such enrichment is achieved by further fluorination of  $\text{UF}_4$  to  $\text{UF}_6$  and then making use of the different gaseous diffusion rates of  $^{235}\text{UF}_6$  and  $^{238}\text{UF}_6$  to achieve partial separation of the isotopes. An alternative technique of separation relies on the different masses of the isotopes and their response to centrifugal action. Such physical (rather than chemical) processes of separation are needed because the chemical properties of the isotopes are identical.

Early commercial reactors in Europe, USA, USSR and Japan relied on natural uranium metal as the fuel, but this technology has now been superseded by the world-wide use of  $\text{UO}_2$  pellets. This change allows higher fuel temperatures to be used and higher conversion rates of the  $^{235}\text{U}$  fuel. Both fuel types are enclosed in metal cans in order to

**Table 10.10** A summary of the principal materials within the core of the main commercial reactor types

Reactor type	Fuel	Fuel cladding	Coolant	Moderator
MAGNOX	U metal (natural)	Magnox Al-80 (Mg/0.8% Al)	CO <sub>2</sub>	Graphite
AGR	UO <sub>2</sub> (2% enriched)	20 Cr/25 Ni steel	CO <sub>2</sub>	Graphite

BWR = boiling water reactor

CANDU = Canada uranium deuterium

RBMK-1000 = Russian hybrid design

PFR = prototype fast reactor

contain the products of the nuclear reaction and to provide mechanical support and stability.

<sup>235</sup>U fissions on interaction with a neutron having energy in the thermal range, typically  $\ll 0.1$  MeV—hence, its use in so-called ‘thermal’ reactors. By contrast, ‘fast’ reactors derive their name from the use of energetic neutrons (e.g.  $>1$  MeV) to provide fission. <sup>235</sup>U cannot be used as a fuel in such cases and present fast-reactor designs employ <sup>239</sup>Pu as a fuel mixed as an oxide with UO<sub>2</sub>.

### 10.9.3 Fuel cladding

The fuel cladding must provide structural support to the fuel stack and contain the fission products. Cladding materials must have a relatively low neutron absorption, have suitable low- and high-temperature strength and ductility, have good chemical compatibility with both the fuel and reactor coolant and have a resistance to property degradation as a result of neutron irradiation. Even though these requirements are particularly onerous, a number of cladding alloys have found service in commercial reactors.

The first generation of gas-cooled reactors used a magnesium–aluminium (Mg, 0.8% Al) cladding alloy, known as Magnox. This name has been adopted as the generic title of this reactor system. The alloy has a low melting temperature (ca. 923 K) and this, coupled with the use of uranium metal as fuel, means that only low  $T_2$  temperatures can be used (ca. 685 K).

Accordingly, within the UK, the second generation of gas-cooled reactors (known as advanced gas-cooled reactors (AGRs)) made use of higher melting temperatures of both fuel and cladding: UO<sub>2</sub> for the former and 20% Cr, 25% Ni stainless steels for the latter. Although the latter material begins to melt at about 1630 K, normal operating temperatures will rarely exceed 1100 K, corresponding to a  $T_2$  temperature of about 930 K. This relatively modest operating temperature, in relation to the solidus temperature, is dictated by the need to limit oxidation of the cladding in the

CO<sub>2</sub> based coolant during normal operation and also to prevent melting under various postulated fault conditions. In addition, the conventional niobium stabilised steel cladding which is generally used, has relatively low creep strength at normal operating temperatures and this can result in mechanical interaction between the cladding and the UO<sub>2</sub> pellets during temperature and power changes. In the event that AGRs would ever be required to load follow, an alternative stainless-steel cladding, dispersion strengthened with titanium nitride particles, has been developed. The creep rate of this alloy at operating conditions is about a factor  $10^3$  less than that of the conventional alloy and, as a consequence, mechanical interaction with the pellet stack is much reduced.

However, the main development in thermal reactor systems world-wide has been to use pressurised water as coolant and a zirconium alloy as fuel cladding (Table 10.10). This alloy is nearly ideal under such conditions, having good neutron economy but also with high creep strength at operating temperatures (ca. 600 K) so that mechanical interaction with the fuel pellets is limited. Nevertheless, zirconium is chemically reactive both with the coolant and also with fission products contained within the fuel rod, particularly iodine. Operating constraints may be applied to limit such attack and the associated loss of load-bearing sections of the clad.

An important topical example is the potential problem of excessive waterside clad corrosion of zircaloy-4 in the pressurised water reactor (PWR) system at high power outputs or after extended dwell periods. Although zircaloy reacts readily with water at reactor temperatures to form ZrO<sub>2</sub>, the rate of reaction decreases with time as a protective film of the oxide forms over the clad surface. For film thicknesses greater than about 2.5  $\mu\text{m}$ , however, mechanical failure of the layer occurs and the corrosion rate increases. This sequence of events can repeat itself over the exposure period in reactor. This, in itself, is not a particular problem but the adherent surface oxide on the clad surface acts as a thermal insulation barrier which progressively raises the

temperature of the oxide-metal interface as the oxide layer thickens. Obviously, the increase in temperature, for a given oxide thickness, is greater the greater is the heat flux, i.e. the greater is the power rating of the fuel. Since the corrosion rate appears to be determined by the temperature of the oxide-metal interface, a positive feedback is created which produces a progressive increase in corrosion rate with time.

Whereas all PWR systems can readily achieve their original design fuel burn-ups of 30 GW-d/te-U, waterside corrosion of zircaloy is now widely perceived to be the most economic threat to achieving significantly higher burn-ups, e.g. to 50 GW-d/te-U at useful power ratings. An associated issue is that a fraction, perhaps 10%, of the hydrogen released from water during the oxidation of the zirconium alloy enters the cladding and can produce mechanical embrittlement by precipitation of zirconium hydride platelets. This effect also is exacerbated at high burn-ups and, together with the issue of water-side corrosion, presents corrosion scientists with the challenge of improving the system's economics whilst still retaining high reliability and safety.

### 10.9.4 Coolant

Both the Magnox reactor system and the AGR use a pressurised CO<sub>2</sub> based coolant. Additions of CO, CH<sub>4</sub> and H<sub>2</sub>O are made to this in a closely controlled manner to optimise gaseous reaction within the primary circuit. It is important to operate in a coolant which does not produce excessive oxidation of the graphite moderator since, in these reactor systems, the moderator also has a structural role and defines the location of fuel within the reactor core. This would be quite easily achieved by increasing the methane and/or carbon monoxide concentrations of the coolant but this also increases its carbon potential which could result in deposition of carbon on the fuel cladding and other core components. This is particularly important in the AGR since the steel cladding in this case contains both iron and nickel: elements which catalyse the deposition of carbon. Such deposits reduce the heat-transfer efficiency and will produce an increase in temperature of the cladding. Whereas, in practice, it is difficult to avoid some deposition, particularly in the AGRs, unacceptably bad behaviour can be prevented by good coolant control. Satisfactory current operation is achieved using a coolant with 1% CO.

Table 10.10 demonstrates that in the other principal thermal reactor designs the coolant is water, either light (H<sub>2</sub>O) or heavy water (D<sub>2</sub>O). Strict compositional control is also required in these cases. An excellent example of the balance that again needs to be struck between obtaining satisfactory fuel cladding behaviour without prejudicing other circuit or core components is offered by the PWR. In this case, the coolant is light water which contains up to 1200 volume parts per million (vpm) of boric acid which aids in reactivity control of the reactor. This addition lowers the pH of the water and produces an acidic solution which could dissolve iron rich components of the primary circuit. To minimise this, the coolant pH is raised (an ideal value would be to between 7.1 and 7.4) by the addition of an alkali. In nearly all Western plants, the alkali used is lithium hydroxide (LiOH), but its concentration tends to be limited to a maximum value of 2.2 ppm of lithium equivalent. This produces a coolant pH of 6.9, i.e. a little more acidic than the ideal. The reason for this is the wide-spread concern that higher lithium levels would increase the corrosion rate of the zircaloy cladding. This particular aspect is the subject of much world-wide investigation at the moment.

The generation of large quantities of heat in the relatively small core of a fast reactor necessitated the use of a liquid sodium coolant to achieve adequate heat transfer in the early conceptual designs of this system. This choice has been maintained in present prototypes. An advantage of such a coolant is that pressurisation is unnecessary but there are obvious disadvantages in the necessity to avoid water ingress from the secondary side of the heat-exchanger system and also in the need for separate heating circuits to avoid freezing during shutdown conditions. With recent advances in gas-circulator technology, it is now feasible to design a gas-cooled fast reactor using a pressurised CO<sub>2</sub> coolant.

### 10.9.5 Moderator

Thermal reactors require moderators to slow down fast neutrons to a sufficiently low energy to permit a fission reaction to occur with the <sup>235</sup>U isotope. In addition, the loss of neutrons within the moderator must be kept low in order that sufficient remain within the core for a chain reaction to proceed. Of the common moderator materials, viz. light water, heavy water and graphite, the last two provide good neutron economy and permit the use of unenriched fuel, e.g. in the Magnox and Canada Uranium Deuterium (CANDU) systems (Table 10.10); reactors moderated by light water, e.g. PWR and boiling water reactor (BWR), require some enrichment in the <sup>235</sup>U content of the fuel.

In the commercial gas-cooled reactors, graphite is used as a moderator. In practice, each pile consists of a vertical arrangement of fuel elements penetrating a large block of graphite fabricated from individual bricks. As has been pointed out earlier, the moderator in these cases has a structural role also and its oxidation in the CO<sub>2</sub> coolant is controlled by additions of CO, CH<sub>4</sub> and H<sub>2</sub>O. Although the Magnox reactors operate with unenriched fuel, the AGR fuel pellets need to contain about 2% <sup>235</sup>U to compensate for neutron losses within the steel components of the core (e.g. the fuel cladding is an advanced stainless steel).

The use of heavy water as a moderator has been pioneered by the Canadians in their CANDU system. In this design (see Chapter 19), the moderator 'block' is termed a *calandria* and is a large stainless-steel vessel holding the heavy water at atmospheric pressure. Some 400 horizontal pipes or 'channels' exist within this block and these contain individual fuel elements enclosed in a pressure tube. The pressurised coolant which passes through each pressure tube is also heavy water and contributes to the overall moderation. Again it is possible to use unenriched fuel (as UO<sub>2</sub> in this case).

Light-water reactors, as their name implies, use light water as both coolant and moderator. However, there is no physical segregation of function, the coolant/moderator being allowed to flow freely through the reactor core. This leads to a particularly simple design and relatively small structures. Nevertheless, enriched fuel needs to be used (typically, up to 4% <sup>235</sup>U) to compensate for poor moderator economy.

A hybrid design has been developed on a large scale in the USSR. This, identified as the RBMK-1000 type in Table 10.10, uses light water as coolant but with graphite moderation. This combination of coolant and moderator can result in large positive void coefficients of reactivity; that is, an increase in core reactivity will occur following a reduction in coolant flow or increase in coolant temperature. For this particular design, such an increase in reactivity also produces an increase in reactor power, particularly at low

power levels. The combination makes control difficult and was a contributing factor to the accident which befell this reactor type at Chernobyl.

### 10.9.6 Pressure vessel

All thermal reactors use a pressurised coolant so that the integrity of the primary system is a principal factor in reactor operation and safety. Most designs rely on a single, large pressure vessel but pressure-tube reactors enclose each fuel channel in a miniature cylindrical vessel or pressure tube.

The most widespread material for the construction of large pressure vessels is mild or low-alloy steel, manufactured to a wall thickness which varies with reactor type, e.g. 120 mm in the early Magnox stations to greater than 200 mm for PWR. A problem with such materials is the need always to demonstrate that brittle fracture of the vessel will not occur, particularly since neutron irradiation may itself tend to cause embrittlement. Only relatively simple cylindrical shapes are used for these vessels and contain a minimum of through-wall penetrations. As a consequence, the pressurised primary circuit extends beyond this pressure boundary and so similarly high standards of integrity need to be applied to the other components of this circuit, e.g. pipework, the recirculation pumps, steam drums, steam generators.

These difficulties were overcome in the later Magnox designs and in the AGR stations by the use of prestressed concrete vessels. These tend to be very large, e.g. 30 m high and 26 m in diameter, and contain the primary circuit components. The obvious disadvantages are the need for large on-site construction facilities, subsequent limited access and the requirement to use internal thermal insulation (based on stainless-steel-foil packages) to limit the temperature rise of the vessel.

A quite different approach is offered by the pressure tube reactors, e.g. CANDU and RBMK-1000. Here, the pressurised circuit is split into numerous small vessels or pressure tubes, each of which contains a single fuel channel. The tube wall is of a zirconium alloy (e.g. Zr, 2.5% Nb) which is separated by a gaseous (typically nitrogen) thermal insulation gap from the walls of the calandria in the CANDU system or is located within a graphite ring in the RBMK-1000 system. The obvious advantage is that the failure of a single pressure tube will not prejudice the integrity of the

reactor, provided that such failure cannot propagate from one channel to another, e.g. by the release of high-energy debris. It is for this reason that much attention is paid to the corrosion rate of the inner surface of the pressure tube and the associated pick up of deuterium or hydrogen, since subsequent solid-state reaction with zirconium can lead to the precipitation of brittle intermetallic compounds.

### 10.9.7 Shield

The reactor shield must attenuate neutrons and  $\gamma$  radiation. In most cases, the cheapest material is heavy concrete such as barytes concrete in which crude barium sulphate replaces the normal aggregate.

## 10.10 Amorphous materials

For many years soft magnetic alloys have been made by a casting, hot rolling and cold rolling regime. Development of such materials has concentrated on the reduction of impurities and the promotion of appropriate grain growth and metallurgical structure. More recently, a class of materials has emerged which uses quite different principles. Amorphous metals have no definite crystal structure and are cast from a melt in such a way that cooling to final thickness is very rapid (of the order of  $10^6$  °C/s). By an appropriate choice of composition which will include a ferromagnetic metal and 'glass forming' elements, plus the rapid cool, a structure is produced which is 'amorphous' in that no definite crystals are formed (as confirmed by X-ray crystal analysis). In such a structure, domain walls experience no lower energy in one position than another and so can move very freely to effect changes in magnetisation.

To achieve such very rapid cooling the material has necessarily to be very thin (of the order of 20–50  $\mu\text{m}$ ) and of quite high electrical resistance (of the order of 1.00–1.5  $\mu\Omega\text{-m}$ ) due to the presence of glass formers such as boron. The combination of freely movable domain walls, high resistivity and low thickness combine to give a material of very low power loss.

Potential application areas for this new class of material can be broadly divided into two categories: power transformers, and electronic/high-frequency devices.

**Table 10.11** Comparison of commercial grain-oriented silicon-iron and amorphous material

	3% Silicon-iron 0.3 mm thick	Iron based amorphous alloy Metglas 2605S-2 0.33 mm thick	Consolidated amorphous strip POWERCORE 0.13 mm thick
Curie temperature (°C)	745	415	415
Crystallisation temperature (°C)	—	550	540
Maximum working temperature (°C)	$\approx 650$	150	125
Tensile strength (MPa)	320–360	$\geq 1500$ –2000 (as cast)	—
Yield strength (MPa)	300–320	1500–2000 (as cast)	—
Resistivity ( $\mu\Omega\text{-m}$ )	0.45–0.48	1.37	1.37
Laminations factor (%)	95–98	80	90
Loss at 1.2 T, 50 Hz (W/kg)	0.64	0.11	0.12
Loss at 1.5 T, 50 Hz (W/kg)	0.83	0.27	0.28
Specific apparent power at 1.3 T (V-A/kg)	0.69	0.54	0.25
Specific apparent power at 1.5 T (V-A/kg)	0.94	2.33	1.3
Coercive force (A/m)	6.4	1.6–2.5	2.0
Saturation induction (T)	2.03	1.56	1.56

**Figure 10.62** Variation of loss with flux density in various materials. (a) 0.3 mm conventional grain oriented; (b) 0.3 mm high permeability; (c) 0.23 mm domain refined; (d) 6.5% semicrystalline silicon-iron; (e) POWERCORE; (f) Metglas 2605S-2

### 10.10.1 Power-transformer materials

The presence of a high alloy content means that the saturation induction of amorphous materials is a lot lower than for silicon steels and operating inductions are usually

confined to 1.5 T and below. At such inductions, power losses are of the order of one-third of those for grain-oriented electrical steels.

The mechanical properties of amorphous materials are less convenient. Amorphous materials are hard, brittle and difficult to cut accurately. Also, amorphous metals are very stress sensitive, so that cores must be built very carefully to avoid the degradation of magnetic properties which can follow from stress.

The production of power-transformer cores from amorphous metals is still at an early stage of development; however, transformers with wound cores designed to use thin amorphous ribbon directly are under widespread evaluation in the USA. In Europe where three-phase cut cores are more common, the employment of amorphous cores is more difficult.

Allied Signal Inc. in the USA has produced a multi-layered version of amorphous ribbon in which six or more layers of basic ribbon are bonded to give a composite strip which can be cut and stacked into three-phase cores. This material is sold by Allied Signal Inc. as 'Powercore'.

Magnetic and physical properties of a grade of amorphous foil material (Allied Signal Metglas 2605S-2) and of Powercore are given in Table 10.11.<sup>1</sup> Figure 10.62 compares the loss versus induction performance of amorphous and cold-rolled materials.<sup>1</sup>

The future of amorphous materials in the electrotechnical world will depend on the equilibrium which may be reached between attractively low power losses, physical difficulty of employment, stress sensitivity, reduced saturation induction and cost.

Any trend making for increased energy costs and a drive towards the conservation of energy is likely to favour amorphous materials for at least some applications.

### 10.10.2 High-frequency-device materials

The amorphous alloys developed to compete with silicon iron for the large power transformer market have compositions which are based on relatively cheap elements, i.e. iron, boron and silicon. These alloys have a high magnetostriction which inhibits their ability to develop high permeabilities and low coercive force. It was therefore necessary to develop a different type of alloy based on cobalt or nickel, with a low magnetostriction, to enable the amorphous materials to extend their application potential. The typical properties of these alloys are detailed in Table 10.12.

**Table 10.12** Properties of low magnetostriction amorphous alloys\*

Material	$Fe_{40}Ni_{40}(MoBSi)_{20}$	$(CoFe)_{70}(MoBSi)_{30}$
Magnetostriction ( $\times 10^{-6}$ m/m)	8	0.3
Coercive force (A/m)	3	0.5
Saturation flux density (T)	0.8	0.55
Permeability at 0.4 A/m	25 000	250 000
Maximum permeability	200 000	500 000
Loss at 0.2 T, 100 kHz (W/kg)	65	35
Resistivity ( $\mu\Omega\cdot m$ )	1.3	1.3
Curie temperature ( $^{\circ}C$ )	250	250
Crystallisation temperature ( $^{\circ}C$ )	450	450
Hardness (VPN)	800	1000
Maximum operating temperature ( $^{\circ}C$ )	120	80

\* Alloys of this type are supplied by Vacuumschmelze, Germany and Allied Signal Inc., USA.  
VPN = Vickers pyramid hardness.

Important characteristics to be noted are their low losses at high frequency, low coercive force, high permeability, and very high hardness. Hitherto, due to their expense and limited forms of supply, the commercial application of high-frequency-devices has been restricted to areas where these properties can be used to best advantage. These include inductive components for switched-mode power supplies, pulse transformers, transducers, electromechanical sensors and tape-recorder heads where their high mechanical hardness provides excellent wear resistance.

Great care has to be taken with amorphous alloys not to exceed the maximum operating temperature recommended by the manufacturers since the amorphous structure is unstable at elevated temperatures and can cause the alloy

to crystallise. The magnetic performance of the crystalline alloy is substantially inferior to that of the amorphous form. It has recently been discovered, however, that if the crystal size is restricted to nanometres, in an alloy of composition  $\text{Fe}_{73.5}\text{Cu}_1\text{Nb}_3\text{Si}_{16.5}\text{B}_6$ , low field permeabilities of  $10^4$  can be obtained. These nanocrystalline alloys could find wider application than the zero magnetostriction amorphous alloys due to their low basic raw-material cost.

## 11.1 Introduction

With increased interest in quality in manufacturing industry, the judicious selection of measuring instruments and the ability to demonstrate the acceptability of the measurements made are more important than ever. With this in mind, a range of instruments is described and instrument specification and accuracy are considered.

## 11.2 Terminology

The vocabulary of this subject is often a source of confusion and so the internationally agreed definitions<sup>1</sup> of some important terms are given.

*Measurement:* The set of operations having the object of determining the value of a quantity.

*Measurand:* A quantity subject to measurement.

*Metrology:* The field of knowledge concerned with measurement. This term covers all aspects both theoretical and practical with reference to measurement, whatever their level of accuracy, and in whatever field of science or technology they occur.

*Accuracy:* The closeness of agreement between the result of a measurement and the true value of the measurand.

*Systematic error:* A component of the error of measurement which, in the course of a number of measurements of the same measurand, remains constant or varies in a predictable way.

*Correction:* The value which, added algebraically to the uncorrected result of a measurement, compensates for an assumed systematic error.

*Random error:* A component of the error of measurement which, in the course of a number of measurements of the same measurand, varies in an unpredictable way.

*Uncertainty of measurement:* An estimate characterising the range of values within which the true value of a measurand lies.

*Discrimination:* The ability of a measuring instrument to respond to small changes in the value of the stimulus.

*Traceability:* The property of the result of a measurement whereby it can be related to appropriate standards, generally international or national standards, through an unbroken chain of comparisons.

*Calibration:* The set of operations which establish, under specified conditions, the relationship between values indicated by a measuring instrument or measuring system and the corresponding known value of a measurand.

*Adjustment:* The operation intended to bring a measuring instrument into a state of performance and freedom from bias suitable for its use.

*Influence quantity:* A quantity which is not the subject of the measurement but which influences the value of a measurand or the indication of the measuring instrument.

## 11.3 The role of measurement traceability in product quality

Many organisations are adopting quality systems such as ISO 9000 (BS 5750). Such a quality system aims to cover all aspects of an organisation's activities from design through production to sales. A key aspect of such a quality system is a formal method for assuring that the measurements used in production and testing are acceptably accurate. This is achieved by

requiring the organisation to demonstrate the traceability of measurements made. This involves relating the readings of instruments used to national standards, in the UK usually at the National Physical Laboratory, by means of a small number of steps. These steps would usually be the organisation's Calibration or Quality Department and a specialist calibration laboratory. In the UK, the suitability of such laboratories is carefully monitored by NAMAS. A calibrating laboratory can be given NAMAS accreditation in some fields of measurement and at some levels of accuracy if it can demonstrate acceptable performance. The traceability chain from production to National Measurement Laboratory can, therefore, be established and can be documented. This allows products to be purchased and used or built into further systems from organisations accredited to ISO 9000 with the confidence that the various products are compatible since all measurements used in manufacture and testing are traceable to the same national and international measurement standards.

## 11.4 National and international measurement standards

At the top of the traceability chain are the SI base units. Definitions of these base units are given in Chapter 1. The SI base units are metre, kilogram, second, ampere, kelvin, candela and mole. Traceability for these quantities involves comparison with the unit through the chain of comparisons. An example for voltage is shown in *Figure 11.1*.

The measurement standards for all other quantities are, in principle, derived from the base units. Traceability is, therefore, to the maintained measurement standard in a country. Since establishing the measurement standards of the base and derived quantities is a major undertaking at the level of uncertainty demanded by end users, this is achieved by international cooperation and the International Conference of Weights and Measures (CIPM) and the International Bureau of Weights and Measures (BIPM) have an important role to play. European cooperation between national measurement institutes is facilitated by Euromet.

### 11.4.1 Establishment of the major standards

#### 11.4.1.1 Kilogram

The kilogram is the mass of a particular object, the International Prototype Kilogram kept in France. All other masses are related to the kilogram by comparison.

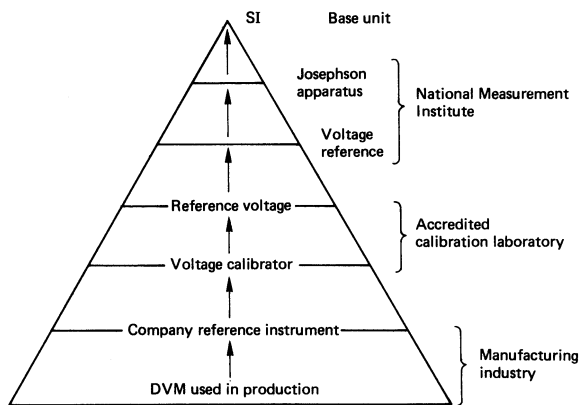

#### 11.4.1.2 Metre

The definition of the metre incorporates the agreed value for the speed of light ( $c = 299\,792\,458$  m/s). This speed does not have to be measured. The metre is not in practice established by the time-of-flight experiment implied in the definition, but by using given wavelengths of suitable laser radiation stated in the small print of the definition.

#### 11.4.1.3 Second

The second is established by setting up a caesium clock apparatus. This apparatus enables a man-made oscillator to be locked onto a frequency inherent in the nature of the caesium atom, thus eliminating the imperfections of the man-made oscillator, such as temperature sensitivity and ageing.

**Figure 11.1** The traceability chain. DVM, digital voltmeter

Using this apparatus, the second can be established extremely close in size to that implied in the definition. Time and frequency can be propagated by radio signals and so calibration of, for example, a frequency counter consists in displaying the frequency of a stable frequency transmission such as BBC Radio 4 on 198 kHz. Commercial off-air frequency standards are available to facilitate such calibration.

#### 11.4.1.4 Voltage

Work by Kibble<sup>2</sup> and others has led to the value of 483 597.9 GHz/V being ascribed to the height of the voltage step which is seen when a Josephson junction is irradiated with electromagnetic energy. A Josephson junction is a device formed by the separation of two superconductors by a very small gap. The voltage produced by such a junction is independent of temperature, age, materials used and apparently any other influencing quantity. It is therefore an excellent, if somewhat inconvenient, reference voltage. It is possible to cascade thousands of devices on one substrate to obtain volt level outputs at convenient frequencies. Industrial voltage measurements can be related to the Josephson voltage by the traceability hierarchy.

#### 11.4.1.5 Impedance

Since 1990 measurements of electrical resistance have been traceable to the quantised Hall effect at NPL.<sup>3</sup> Capacitance and inductance standards are realised from DC standards using a chain of AC and DC bridges. Impedance measurements in industry can be related through the traceability hierarchy to these maintained measurement standards. Research is in progress at NPL and elsewhere aimed at using the AC quantum hall effect for the direct realisation of impedance standards.

#### 11.4.1.6 Kelvin

The fundamental fixed point is the triple point of water, to which is assigned the thermodynamic temperature of 273.16 K exactly; on this scale the temperature of the ice point is 273.15 K (or 0°C). Platinum resistance and thermocouple thermometers are the primary instruments up to 1336 K (gold point), above which the standard optical pyrometer is used to about 4000 K.

## 11.5 Direct-acting analogue measuring instruments

The principal specification for the characteristics and testing of low-frequency instruments is IEC 51 (BS 89). The approach of this standard is to specify intrinsic errors under closely defined reference conditions. In addition, variations are stated which are errors occurring when an influencing quantity such as temperature is changed from the reference condition. The operating errors can, therefore, be much greater than the intrinsic error which is likely to be a best-case value.

Instruments are described by accuracy class. The class indices are 0.05, 0.1, 0.2, 0.3, 0.5, 1, 1.5, 2, 2.5, 3 and 5 for ammeters and voltmeters. Accuracy class is the limit of the percentage intrinsic error relative to a stated value, usually the full-scale deflection. For example, for a class index of 0.05, the limits of the intrinsic error are  $\pm 0.05\%$  of the full-scale value. It must be stressed that such performance is only achieved if the instrument is at the reference conditions and almost always extra errors in the form of variations must be taken into account.

### 11.5.1 Direct-acting indicators

These can be described in terms of the dominating torque-production effects:

- (1) *Electromagnetic torque*: moving-coil, moving-iron, induction and electrodynamic (dynamometer).
- (2) *Electric torque*: electrostatic voltmeter.
- (3) *Electrothermal torque*: maximum demand.

A comparison is made in *Table 11.1*, which lists types and applications.

#### 11.5.1.1 Torque effects

Instrument dynamics is discussed later. The relevant instantaneous torques are: *driving torque*, produced by means of energy drawn from the network being monitored; *acceleration torque*; *damping and friction torque*, by air dashpot or eddy current reaction; *restoring torque*, due usually to spring action, but occasionally to gravity or opposing magnetic field.

The higher the driving torque the better, in general, are the design and sensitivity; but high driving torque is usually associated with movements having large mass and inertia. The torque/mass ratio is one indication of relative performance, if associated with low power demand. For small instruments the torque is 0.001–0.005 mN-m for full-scale deflection; for 10–20 cm scales it is 0.05–0.1 mN-m, the higher figures being for induction and the lower for electrostatic instruments.

Friction torque, always a source of error, is due to imperfections in pivots and jewel bearings. Increasing use is now made of taut-band suspensions (*Figure 11.2*); this eliminates pivot friction and also replaces control springs. High-sensitivity moving-coil movements require only 0.005 mN-m for a 15 cm scale length: for moving-iron movements the torques are similar to those for the conventional pivoted instruments.

#### 11.5.1.2 Scale shapes

The moving-coil instrument has a linear scale owing to the constant energy of the permanent magnet providing one of the two 'force' elements. All other classes of indicators are

**Table 11.1** Comparison of instruments

<i>Measurement parameter</i>	<i>Type</i>	<i>Advantages</i>	<i>Disadvantages</i>
Direct voltage and current	Moving coil	Accurate; wide range	Power loss 50–100 mW Inaccurate; high power loss
	Induced moving-magnet	Cheap	
Alternating voltage and current	Moving iron	Cheap; reasonable r.m.s. accuracy	No low range; high power loss
	Electrodynamic	Adequate a.c./d.c. comparator; more accurate r.m.s.	Expensive; high power loss; square-law scale
	Induction	Long scale	Single frequency; high power loss; inaccurate
	Moving-coil rectifier	Low power loss (a few mW); wide range; usable up to audio frequency	Non-sinusoidal waveform error
	Moving-coil thermocouple	True r.m.s.; good a.c./d.c. comparator; usable up to radiofrequency	No overload safety factor; slow response; power loss (e.g. 1 W)
Direct and alternating voltage	Electrostatic	Negligible power; good a.c./d.c. comparator; accurate r.m.s.; wide frequency range	High capacitance; only for medium and high voltage; poor damping
A.c. power (active)	Electrodynamic	Accurate; linear scale	Expensive; high power loss
	Thermocouple electronic	High frequency; pulse power; true r.m.s.	Expensive
	Induction	Cheap; long scale	Single frequency; high power loss
A.c. power (reactive)	Electrodynamic	Accurate; linear scale	Power loss; needs phase-rotation network
A.c. maximum current	Thermal maximum demand	Long adjustable time constant; thermal integration; cheap	Relatively inaccurate

inherently of the double-energy type, giving a square-law scale of the linear property (voltage or current) being measured; for a wattmeter, the scale is linear for the average scalar product of voltage and current. The rectifier instrument, although an a.c. instrument, has a scale which is usually linear, as it depends on the moving-coil characteristic and the rectifier effect is usually negligible. (In low-range voltmeters, the rectifier has some effect and the scale shape is between linear and square law.) Thermal ammeters and electrodynamic voltmeters and ammeters usually have a true square-law scale, as any scale shaping requires extra torque and it is already low in these types. Moving-iron instruments are easily designed with high torque, and scale shaping is almost always carried out in order to approach a linear scale. In some cases the scale is actually contracted at the top in order to give an indication of overloads that would otherwise be off-scale. The best moving-iron scale shape is contracted only for about the initial 10% and is then nearly linear. Logarithmic scales have the advantage of equal percentage accuracy over all the scale, but they are difficult to read, owing to sudden changes in values of adjacent scale divisions. Logarithmic scales are unusual in switchboard instruments, but they are sometimes found in portable instruments, such as self-contained ohmmeters.

## 11.5.2 Direct voltage and current

### 11.5.2.1 Moving-coil indicator

This instrument comprises a coil, usually wound on a conducting former to provide eddy-current damping, with taut-band or pivot/control-spring suspension. In each case the coil rotates in the short air gap of a permanent magnet. The direction of the deflection depends on the polarity, so that unmodified indicators are usable only on d.c., and may have a centre zero if required. The error may be as low as  $\pm 0.1\%$  of full-scale deflection; the range, from a few microamperes or millivolts up to 600 A and 750 V, which makes possible multirange d.c. test sets. The scale is generally linear (equispaced) and easily read. Non-linear scales can be obtained by shaping the magnet poles or the core to give a non-uniform air gap.

### 11.5.2.2 Corrections

The total power taken by a normal-range voltmeter can be  $50 \mu\text{W/V}$  or more. For an ammeter the *total* series loss is 1–50 mW/A. Such powers may be a significant fraction of the total delivered to some electronic networks; in such

**Figure 11.2** Taut-ribbon suspension assembly (Crompton Parkinson Ltd)

cases electronic and digital voltmeters with trivial power loss should be used instead.

### 11.5.2.3 Induced moving-magnet indicator

The instrument is polarised by a fixed permanent magnet and so is only suitable for d.c. A small pivoted iron vane is arranged to lie across the magnet poles, the field of which applies the restoring torque. One or more turns of wire carry the current to be measured around the vane, producing a magnetic field at right angles to that of the magnet, and this drive torque deflects the movement to the equilibrium position. It is a cheap, low-accuracy instrument which can have a nearly linear centre-zero scale, well suited to monitoring battery charge conditions.

## 11.5.3 Alternating voltage and current

### 11.5.3.1 Moving-iron indicator

This is the most common instrument for a.c. at industrial frequency. Some (but not all) instruments may also be used on d.c. The current to be measured passes through a magnetising coil enclosing the movement. The latter is formed either from a nickel-iron alloy vane that is *attracted* into the field, or from two magnetic alloy members which, becoming similarly polarised, mutually *repel*. The latter is more usual but its deflection is limited to about  $90^\circ$ ; however, when combined with attraction vanes, a  $240^\circ$  deflection is obtainable

but can be used only on a.c. on account of the use of material of high hysteresis.

The inherent torque deflection is square law and so, in principle, the instrument measures true r.m.s. values. By careful shaping of vanes when made from modern magnetic alloys, a good linear scale has been achieved except for the bottom 10%, which readily distinguishes the instrument from the moving-coil linear scale. Damping torque is produced by eddy-current reaction in an aluminium disc moving through a permanent-magnet field.

### 11.5.3.2 Precautions and corrections

These instruments work at low flux densities (e.g. 7 mT), and care is necessary when they are used near strong ambient magnetic fields despite the magnetic shield often provided. As a result of the shape of the  $B/H$  curve, a.c./d.c. indicators used on a.c. read high at the lower end and low at the higher end of the scale. The effect of hysteresis with d.c. measurements is to make the 'descending' reading higher than the 'ascending'.

Moving-iron instruments are available with class index values of 0.3–5.0, and many have similar accuracies for a.c. or d.c. applications. They tend to be single-frequency power instruments with a higher frequency behaviour that enables good r.m.s. readings to be obtained from supplies with distorted current waveforms, although excessive distortion will cause errors. Nevertheless, instruments can be designed for use in the lower audio range, provided that the power loss (a few watts) can be accepted. Ranges are from a few milliamperes and several volts upward. The power loss is usually significant and may have to be allowed for.

### 11.5.3.3 Electrodynamical indicator

In this the permanent magnet of the moving-coil instrument is replaced by an electromagnet (field coil). For ammeters the moving coil is connected in series with two fixed field coils; for voltmeters the moving and the fixed coils each have series-connected resistors to give the same time-constant, and the combination is connected in parallel across the voltage to be measured. With ammeters the current is limited by the suspension to a fraction of 1 A, and for higher currents it is necessary to employ non-reactive shunts or current transformers.

### 11.5.3.4 Precautions and corrections

The flux density is of the same order as that in moving-iron instruments, and similar precautions are necessary. The torque has a square-law characteristic and the scale is cramped at the lower end. By using the mean of reversed readings these instruments can be d.c. calibrated and used as adequate d.c./a.c. transfer devices for calibrating other a.c. instruments such as moving-iron indicators. The power loss (a few watts) may have to be allowed for in calculations derived from the readings.

### 11.5.3.5 Induction indicator

This single-frequency instrument is robust, but limited to class index (CI) number from 1.0 to 5.0. The current or voltage produces a proportional alternating magnetic field normal to an aluminium disc arranged to rotate. A second, phase-displaced field is necessary to develop torque. Originally it was obtained by pole 'shading', but this method is obsolete; modern methods include separate

magnets one of which is shunted (Ockenden), a cylindrical aluminium movement (Lipman) or two electromagnets coupled by loops (Banner). The induction principle is most generally employed for the measurement of energy.

#### 11.5.3.6 Moving-coil rectifier indicator

The place of the former copper oxide and selenium rectifiers has been taken by silicon diodes. Used with taut-band suspension, full-wave instrument rectifier units provide improved versions of the useful rectifier indicator.

#### 11.5.3.7 Precautions and corrections

Owing to its inertia, the polarised moving-coil instrument gives a mean deflection proportional to the mean rectified current. The scale is marked in r.m.s. values on the assumption that the waveform of the current to be measured is sinusoidal with a form factor of 1.11. On non-sinusoidal waveforms the true r.m.s. value cannot be inferred from the reading: only the true *average* can be known (from the r.m.s. scale reading divided by 1.11). When true r.m.s. values are required, it is necessary to use a thermal, electrodynamic or square-law electronic instrument.

#### 11.5.3.8 Multirange indicator

The rectifier diodes have capacitance, limiting the upper frequency of multirange instruments to about 20 kHz. The lower limit is 20–30 Hz, depending on the inertia of the movement. Indicators are available with CI numbers from 1.0 to 5.0, the multirange versions catering for a wide range of direct and alternating voltages and currents: a.c. 2.5 V–2.5 kV and 200 mA–10 A; d.c. 100  $\mu$ V–2.5 kV and 50  $\mu$ A–10 A. Non-linear resistance scales are normally included; values are derived from *internal* battery-driven out-of-balance bridge networks.

#### 11.5.3.9 Moving-coil thermocouple indicator

The current to be measured (or a known proportion of it) is used as a heater current for the thermocouple, and the equivalent r.m.s. output voltage is steady because of thermal inertia—except for very low frequency (5 Hz and below). With heater current of about 5 mA in a 100  $\Omega$  resistor as typical, the possible voltage and current ranges are dictated by the usual series and shunt resistance, under the restriction that only the upper two-thirds of the square-law scale is within the effective range. The instrument has a frequency range from zero to 100 MHz. Normal radiofrequency (r.f.) low-range self-contained ammeters can be used up to 5 MHz with CI from 1.0 to 5.0. Instruments of this kind could be used in the secondary circuit of a r.f. current transformer for measurement of aerial current. The minimum measurable voltage is about 1 V.

The thermocouple, giving a true r.m.s. indication, is a primary a.c./d.c. transfer device. Recent evidence<sup>4</sup> indicates that the transfer uncertainty is only a few parts in 10<sup>6</sup>. Such devices provide an essential link in the traceability chain between microwave power, r.f. voltage and the primary standards of direct voltage and resistance.

#### 11.5.3.10 Precautions and corrections

The response is slow, e.g. 5–10 s from zero to full-scale deflection, and the overload capacity is negligible: the heater may

be destroyed by a switching surge. Thermocouple voltmeters are low-impedance devices (taking, e.g., 500 mW at 100 V) and may be unsuitable for electronic circuit measurements.

### 11.5.4 Medium and high direct and alternating voltage

#### 11.5.4.1 Electrostatic voltmeter

This is in effect a variable capacitor with fixed and moving vanes. The power taken (theoretically zero) is in fact sufficient to provide the small dielectric loss. The basically square-law characteristic can be modified by shaping the vanes to give a reasonably linear upper scale. The minimum useful range is 50–150 V in a small instrument, up to some hundreds of kilovolts for large fixed instruments employing capacitor multipliers. Medium-voltage direct-connected voltmeters for ranges up to 15 kV have CI ratings from 1.0 to 5.0. The electrostatic indicator is a true primary alternating/direct voltage (a.v./d.v.) transfer device, but has now been superseded by the thermocouple instrument. The effective isolation property of the electrostatic voltmeter is attractive on grounds of safety for high-voltage measurements.

### 11.5.5 Power

#### 11.5.5.1 Electrodynamical indicator

The instrument is essentially similar to the electrodynamic voltmeter and ammeter. It is usually 'air-cored', but 'iron-cored' wattmeters with high-permeability material to give a better torque/mass ratio are made with little sacrifice in accuracy. The current (fixed) coils are connected in series with the load, and the voltage (moving) coil with its series range resistor is connected either (a) across the load side of the current coil, or (b) across the supply side. In (a) the instrument reading must be *reduced* by the power loss in the volt coil circuit (typically 5 W), and in (b) by the current coil loss (typically 1 W).

The volt coil circuit *power* corrections are avoided by use of a *compensated wattmeter*, in which an additional winding in series with the volt circuit is wound, turn-for-turn, with the current coils, and the connection is (a) above. The m.m.f. due to the volt-coil circuit current in the compensating coil will cancel the m.m.f. due to the volt circuit current in the current coils.

The volt circuit terminal marked  $\pm$  is immediately adjacent to the voltage coil; it should be connected to the current terminal similarly marked, to ensure that the wattmeter reads positive power and that negligible p.d. exists between fixed and moving coils, so safeguarding insulation and eliminating error due to electric torque.

When a wattmeter is used on d.c., the power should be taken from the mean of reversed readings; wattmeters read also the active (average) a.c. power. For the measurement of power at very low power factor, special wattmeters are made with weak restoring torque to give f.s.d. at, e.g., a power factor of 0.4. Range extension for all wattmeters on a.c. can be obtained by internal or external current transformers, internal resistive volt-range selectors or external voltage transformers. Typical self-contained ranges are between 0.5 and 20 A, 75 and 300 V. The usable range of frequency is about 30–150 Hz, with a best CI of 0.05.

Three-phase power can be measured by single dual-element instruments.

### 11.5.5.2 Thermocouple indicator

The modern versions of this instrument are more correctly termed electronic wattmeters. The outputs from current- and voltage-sensing thermocouples, multiplied together and amplified, can be displayed as average power. Typical d.c. and a.c. ranges are 300 mV–300 V and 10 mA–10 A, from pulsed and other non-sinusoidal sources at frequencies up to a few hundred kilohertz. The interaction with the network is low; e.g. the voltage network has typically an impedance of 10 k $\Omega$ /V.

### 11.5.5.3 Induction indicator

The power-reading instrument includes both current and voltage coils. The energy meter is referred to later. The instruments are frequency sensitive and are used only for fixed-frequency switchboard applications. The CI number is 1.0–5.0, usually the latter.

### 11.5.5.4 Electrodynamical reactive-power indicator

The active-power instrument can read reactive power if the phase of the volt circuit supply is changed by 90°; to give  $Q = 4I \sin \phi$  instead of  $P = 4I \cos \phi$  (for sinusoidal conditions).

## 11.5.6 Maximum alternating current

### 11.5.6.1 Maximum-demand instrument

The use of an auxiliary pointer carried forward by the main pointer and remaining in position makes possible the indication of maximum current values, but the method is not satisfactory, because it demands large torques, a condition that reduces effective damping and gives rise to overswing. A truer maximum demand indication, and one that is insensitive to momentary peaks, is obtainable with the aid of a thermal bimetal. Passing the current to be indicated through the bimetal gives a thermal lag of a few minutes. For long-period indication (1 h or more) a separate heater is required.

Such instruments have been adapted for three-phase operation using separate heaters. A recent development permits a similar device to be used for two phases of a three-phase supply. The currents are summed *linearly*, and the maximum of the combined unbalanced currents maintained for 45 min is recorded on a kV-A scale marked in terms of nominal voltage.

## 11.5.7 Power factor

Power factor indicators have both voltage and current circuits, and can be interconnected to form basic electrodynamic or moving-iron direct-acting indicators. The current coils are fixed; the movement is free, the combined voltage- and current-excited field producing both deflecting and controlling torque. The electrodynamic form has the greater accuracy, but is restricted to a 90° deflection, as compared with 360° (90° lag and lead, motoring and generating) of the moving-iron type.

One electrodynamic form comprises two fixed coils carrying the line current, and a pair of moving volt coils set with their axes mutually at almost 90° (Figure 11.3). For one-phase operation the volt-coil currents are nearly in quadrature, being, respectively, connected in series with an inductor  $L$  and a resistor  $R$ . For three-phase working,  $L$  is

Figure 11.3 Single-phase electrodynamic power factor indicator

replaced by a resistor  $r$  and the ends of the volt-coil circuits taken, respectively, to the second and third phases. A three-phase moving-iron instrument for balanced loads has one current coil and three volt coils (or three current and one voltage); if the load is unbalanced, three current and three volt coils are required. All these power factor indicators are industrial frequency devices.

The one-phase electrodynamic wattmeter can be used as a phase-sensing instrument. When constant r.m.s. voltages and currents from two, identical-frequency, *sinusoidal* power supplies are applied to the wattmeter, then the phase change in one system produces power scale changes which are proportional to  $\cos \phi$ .

Many electronic phase-meters of the analogue and digital type are available which, although not direct-acting, have high impedance inputs, and they measure the phase displacement between any two voltages (of the same frequency) over a wide range of frequencies. Either the conventional solid state digital instruments generate a pulse when the two voltages pass zero, and measure and display the time between these pulses as phase difference, or the pulses trigger a multivibrator for the same period, to generate an output current proportional to phase (time) difference. These instruments provide good discrimination and, with modern high-speed logic switching, the instant for switch-on (i.e. pulse generation) is less uncertain: conversely, the presence of small harmonic voltages around zero could lead to some ambiguity.

## 11.5.8 Phase sequence and synchronism

A small portable form of *phase sequence* indicator is essentially a primitive three-phase induction motor with a disc rotor and stator phases connected by clip-on leads to the three-phase supply. The disc rotates in the marked forward direction if the sequence is correct. These instruments have an intermittent rating and must not be left in circuit.

The *synchroscope* is a power factor instrument with rotor slip-rings to allow continuous rotation. The moving-iron type is robust and cheap. The direction of rotation of the rotor indicates whether the incoming three-phase system is 'fast' or 'slow', and the speed of rotation measures the difference in frequency.

## 11.5.9 Frequency

Power frequency monitoring frequency indicators are based on the response of reactive networks. Both electrodynamic and induction instruments are available, the former having

the better accuracy, the latter having a long scale of  $300^\circ$  or more.

One type of indicator consists of two parallel fixed coils tuned to slightly different frequencies, and their combined currents return to the supply through a moving coil which lies within the resultant field of the fixed coils. The position of the moving coil will be unique for each frequency, as the currents (i.e. fields) of the fixed coils are different unique functions of frequency. The indications are within a restricted range of a few hertz around nominal frequency. A ratiometer instrument, which can be used up to a few kilohertz, has a permanent-magnet field in which lie two moving coils set with their planes at right angles. Each coil is driven by rectified a.c., through resistive and capacitive impedances, respectively, and the deflection is proportional to frequency.

*Conventional* solid state counters are versatile time and frequency instruments. The counter is based on a stable crystal reference oscillator (e.g. at 1 MHz) with an error between 1 and 10 parts in  $10^8$  per day. The displays have up to eight digits, with a top frequency of 100 MHz (or 600 MHz with heterodyning). The resolution can be 10 ns, permitting pulse widths of 1000 ns to be assessed to 1%; but a 50 Hz reading would be near to the bottom end of the display, giving poor discrimination. All counters provide for measurements giving the period of a waveform to a good discrimination.

## 11.6 Integrating (energy) metering

Integrating meters record the time integral of active, reactive and apparent power as a continuous summation. The integration may be limited by a specified total energy (e.g. prepayment meters) or by time (e.g. maximum demand). Meters for a.c. supplies are all of the induction type, with measuring elements in accordance with the connection of the load (one-phase or three- or four-wire three-phase). Manufacturing and testing specifications are given in BS 37. Instrument transformers for use with meters are listed in BS 3938 and BS 3941.

### 11.6.1 Single-phase meter

The rotor is a light aluminium disc on a vertical spindle, supported in low-friction bearings. The lower bearing is a sapphire cup, carrying the highly polished hemispherical hardened steel end of the spindle. The rotor is actuated by an induction driving element and its speed is controlled by an eddy current brake. The case is usually a high-quality black phenolic moulding with integral terminal block. The frame is a rigid high-stability iron casting which serves as the mounting, as part of a magnetic flux path, and as a shield against ambient magnetic fields.

The driving element has the basic form shown in *Figure 11.4*. It has two electromagnets, one voltage-excited and the other current-excited. The volt magnet, roughly of E-shape, has a nearly complete magnetic circuit with a volt coil on the central limb. Most of the flux divides between the outer limbs, but the *working* flux from the central limb penetrates the disc and enters the core of the current magnet. The latter, of approximate U-shape, is energised by a coil carrying the load current. With a condition of *zero* load current, the working flux from the volt magnet divides equally between the two limbs of the current magnet and returns to the volt magnet core through the frame, or through an iron path provided for this purpose. If the volt magnet flux is symmetrically disposed, the eddy current induced in the disc does not exert any net driving torque and the disc remains

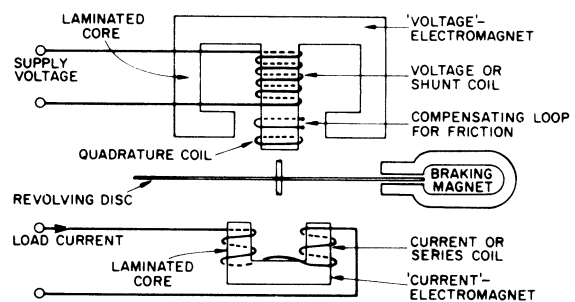

Figure 11.4 Essential parts of an induction meter

stationary. The volt magnet flux is approximately in phase quadrature with the applied voltage.

When a load current flows in the coil of the current magnet, it develops a co-phasal flux, interacting with the volt magnet flux to produce a resultant that 'shifts' from one current magnet pole to the other. Force is developed by interaction of the eddy currents in the disc and the flux in which it lies, and the net torque is proportional to the voltage and to that component of the load current in phase with the voltage—i.e. to the active power. The disc therefore rotates in the direction of the 'shift'.

The disc rotates through the field of a suitably located permanent isotropic brake magnet, and induced currents provide a reaction proportional to speed. Full-load adjustment is effected by means of a micrometer screw which can set the radial position of the brake magnet.

The volt magnet working flux lags the voltage by a phase angle rather less than  $90^\circ$  (e.g. by  $85^\circ$ ). The phase angle is made  $90^\circ$  by providing a closed *quadrature coil* on the central limb, with its position (or resistance) capable of adjustment.

The accuracy of the meter is affected on low loads by pivot friction. A *low-load adjustment*, consisting of some device that introduces a slight asymmetry in the volt magnet working flux, is fitted to mitigate frictional error. There are several methods of producing the required asymmetry: one is the insertion of a small magnetic vane into the path of the working flux. The asymmetry results in the development at zero load of a small forward torque, just sufficient to balance friction torque without causing the disc to rotate.

#### 11.6.1.1 Performance of single-phase meters

The limits of permissible error are defined in BS 37. In general, the error should not exceed  $\pm 2\%$  over most of the working range for credit meters. For prepayment meters,  $+2$  and  $-3\%$  for loads above  $1/30$  full load at unity power factor, at any price setting to be used, are the specified limits. Tests for compliance with this requirement at and below  $1/10$  marked current must be made with the coin condition that not less than one nor more than three coins of the highest denomination acceptable by the meter are prepaid.

It is usual for manufacturers to adjust their meters to less than one-half of the permissible error over much of the working range. The mean error of an individual meter is, of course, less than the maximum observable error, and the mean collective error of a large number of meters is likely to be much less than  $\pm 4\%$  at rated voltage and frequency. If no attempt is made during production testing to bias the error in one direction, the weighted mean error of many meters taken collectively is probably within  $0.5\%$ , and is likely to be positive (see *Figure 11.5(a)*).

**Figure 11.5** Typical performance of 240 V, 50 Hz, 20–80 A house-service meter (Ferranti Ltd)

#### 11.6.1.2 Temperature

The temperature error of a.c. meters with no temperature compensation is negligible under the conditions normally existing in the UK. In North America it is common practice to fix meters on the outside of buildings, where they are subjected to wide temperature ranges (e.g. 80°C), which makes compensation desirable. However, even in the UK it is common to provide compensation (when required) in the form of a strip of nickel-rich alloy encircling the stator magnet. Its use is advantageous for short-duration testing, as there is an observable difference in error of a meter when cold and after a 30 min run.

#### 11.6.1.3 Voltage and frequency

Within the usual limits of  $\pm 4\%$  in voltage and  $\pm 0.2\%$  in frequency, the consequent errors in a meter are negligible. Load-shedding, however, may mean substantial reductions of voltage and frequency. A significant reduction in voltage usually causes the meter to read high on all loads, as shown in *Figure 11.5(b)*. Reduction of the supply frequency makes the meter run faster on high-power-factor loads and slower on lagging reactive loads: an increase of frequency has the opposite effect (*Figure 11.5(c)*). The errors are cumulative if both voltage and frequency variations occur together.

## 11.7 Electronic instrumentation

The rapid development of large-scale integrated (l.s.i.) circuits, as applied to analogue and especially digital circuitry, has allowed both dramatic changes in the format of measurement instrumentation by designers and in the measurement test systems available for production or control applications.

A modern instrument is often a multipurpose assembly, including a microprocessor for controlling both the sequential measurement functions and the subsequent programmed assessment of the data retained in its store; hence, these instruments can be economical in running and labour costs by avoiding skilled attention in the recording and statistical computation of the data. Instruments are often designed to be compatible with standardised interfaces, such as the IEC bus or IEEE-488 bus, to form automatic measurement systems for interactive design use of feedback digital-control applications; typically a system would include a computer-controlled multiple data logger with 30 inputs from different parameter sensors, statistical

and system analysers, displays and storage. The input analogue parameters would use high-speed analogue-to-digital (A/D) conversion, so minimising the front-end analogue conditioning networks while maximising the digital functions (e.g. filtering and waveform analyses by digital rather than analogue techniques). The readout data can be assembled digitally and printed out in full, or presented through D/A converters in graphical form on X-Y plotters using the most appropriate functional co-ordinates to give an economical presentation of the data.

The production testing of the component subsystems in the above instruments requires complex instrumentation and logical measurements, since there are many permutations of these minute logic elements resulting in millions of high-speed digital logic operations—which precludes a complete testing cycle, owing to time and cost. Inspection testing of l.s.i. analogue or digital devices and subassemblies demands systematically programmed measurement testing sequences with varied predetermined signals; similar automatic test equipments (ATE) are becoming more general in any industrial production line which employs these modern instruments in process or quality-control operations. Some companies are specialising in computer-orientated measurement techniques to develop this area of ATE; economic projections indicate that the present high growth rate in ATE-type measurement systems will continue or increase during the next few years.

The complementary nature of automated design, production and final testing types of ATE leads logically to the interlinking of these separate functions for optimising and improving designs within the spectrum of production, materials handling, quality control and costing to provide an overall economic and technical surveillance of the product.

Some of the more important instruments have been included in the survey of electronic instrumentation in the following pages, but, owing to the extensive variety of instruments at present available and the rapid rate of development in this field, the selection must be limited to some of the more important devices.

*Digital instruments* usually provide an output in visual decimal or coded digit form as a discontinuous function of a smoothly changing input quantity. In practice the precision of a digital instrument can be extended by adding digits to make it better than an analogue instrument, although the final (least significant) digit must always be imprecise to  $\pm 0.5$ .

### 11.7.1 Digital voltmeters

These provide a digital display of d.c. and/or a.c. inputs, together with coded signals of the visible quantity, enabling the instrument to be coupled to recording or control systems. Depending on the measurement principle adopted, the signals are sampled at intervals over the range 2–500 ms. The basic principles are: (a) linear ramp; (b) charge balancing; (c) successive-approximation/potentiometric; (d) voltage to frequency integration; (e) dual slope; (f) multislope; and (g) some combination of the foregoing.

Modern digital voltmeters often include a multiway socket connection (e.g. BCD; IEC bus; IEEE-488 bus, etc.) for data/interactive control applications.

#### 11.7.1.1 Linear ramp

This is a voltage/time conversion in which a linear time-base is used to determine the time taken for the internally generated voltage  $v_s$  to change by the value of the unknown voltage  $V$ . The block diagram (*Figure 11.6(b)*) shows the use of comparison networks to compare  $V$  with the rising

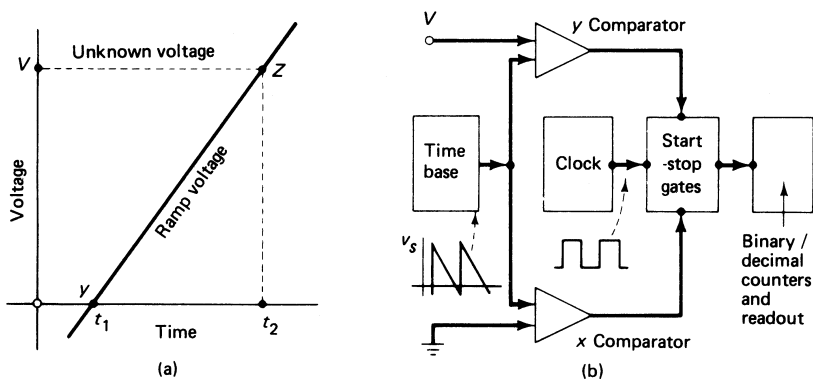

Figure 11.6 Linear ramp digital voltmeter. (a) Ramp voltage; (b) block diagram

(or falling)  $v_s$ ; these networks open and close the path between the continuously running oscillator, which provides the counting pulses at a fixed clock rate, and the counter. Counting is performed by one of the binary-coded sequences; the translation networks give the visual decimal output. In addition, a binary-coded decimal output may be provided for monitoring or control purposes.

Limitations are imposed by small non-linearities in the ramp, the instability of the ramp and oscillator, imprecision of the coincidence networks at instants  $y$  and  $z$ , and the inherent lack of noise rejection. The overall uncertainty is about  $\pm 0.05\%$  and the measurement cycle would be repeated every 200 ms for a typical four-digit display.

Linear 'staircase' ramp instruments are available in which  $V$  is measured by counting the number of equal voltage 'steps' required to reach it. The staircase is generated by a solid state diode pump network, and linearities and accuracies achievable are similar to those with the linear ramp.

### 11.7.1.2 Charge balancing

This principle<sup>5</sup> employs a pair of differential-input transistors used to charge a capacitor by a current proportional to the unknown d.c. voltage, and the capacitor is then discharged by a large number of small  $+\delta q$  and  $-\delta q$  quantities, the elemental discharges being sensed and directed by fast comparator/flip-flop circuits and the total numbers being stored. Zero is in the *middle* of the measurement range and the displayed result is proportional to the difference between the number of  $+\delta q$ ,  $-\delta q$  events.

The technique which, unlike dual-ramp methods, is inherently bipolar, claims some other advantages, such as improved linearity, more rapid recovery from overloads, higher sensitivity and reduced noise due to the averaging of thousands of zero crossings during the measurement, as well as a true *digital* auto-zero subtraction from the next measurement, as compared with the more usual capacitive-stored analogue offset p.d. being subtracted from the measured p.d.

Applications of this digital voltmeter system (which is available on a monolithic integrated circuit, Ferranti ZN 450) apart from d.c. and a.c. multimeter uses, include interfacing it *directly* with a wide range of conventional transducers such as thermocouples, strain gauges, resistance thermometers, etc.

### 11.7.1.3 Successive approximation

As it is based on the potentiometer principle, this class produces very high accuracy. The arrows in the block diagram

of Figure 11.7 show the signal-flow path for one version; the resistors are selected in sequence so that, with a constant current supply, the test voltage is created within the voltmeter.

Each decade of the unknown voltage is assessed in terms of a sequence of accurate stable voltages, graded in descending magnitude in accordance with a binary (or similar) counting scale. After each voltage approximation of the final result has been made and stored, the residual voltage is then automatically re-assessed against smaller standard voltages, and so on to the smallest voltage discrimination required in the result. Probably four logic decisions are needed to select the major decade value of the unknown voltage, and this process will be repeated for each lower decade in decimal sequence until, after a few milliseconds, the required voltage is stored in a coded form. This voltage is then translated for decimal display. A binary-coded sequence could be as shown in Table 11.2, where the numerals in **bold** type represent a logical *rejection* of that number and a progress to the next lower value. The actual sequence of logical decisions is more complicated than is suggested by the example. It is necessary to sense the initial polarity of the unknown signal, and to select the range and decimal marker for the read-out; the time for the logic networks to settle must be longer for the earlier (higher voltage) choices than for the later ones, because they must be of the highest possible accuracy; offset voltages may be added to the earlier logic choices, to be withdrawn later in the sequence; and so forth.

The total measurement and display takes about 5 ms. When noise is present in the input, the necessary insertion of filters may extend the time to about 1 s. As noise is more troublesome for the smaller residuals in the process, it is sometimes convenient to use some different techniques for the latter part. One such is the voltage-frequency principle (see below), which has a high noise rejection ratio. The

Figure 11.7 Successive-approximation digital voltmeter

**Table 11.2** Voltages obtained from residual (difference) currents across high-stability resistors

Unknown analogue voltage	3	9	.	2	0	6
Logic decisions in vertical binary	8	8		8	8	8
sequences and in descending 'order'	4	4		4	4	4
	2	2		2	2	2
	1	1		1	1	1
Decoded decimal display	3	9	.	2	0	6

reduced accuracy of this technique can be tolerated as it applies only to the least significant figures.

#### 11.7.1.4 Voltage-frequency

The converter (Figure 11.8) provides output pulses at a frequency proportional to the instantaneous unknown input voltage, and the non-uniform pulse spacing represents the variable frequency output. The decade counter accumulates the pulses for a predetermined time  $T$  and in effect measures the average frequency during this period. When  $T$  is selected to coincide with the longest period time of interfering noise (e.g. mains supply frequency), such noise averages out to zero.

Instruments must operate at high conversion frequencies if adequate discrimination is required in the final result. If a six-digit display were required within 5 ms for a range from zero to 1.000 00 V to  $\pm 0.01\%$ , then  $10^5$  counts during 5 ms are called for, i.e. a 20 MHz change from zero frequency with a 0.01% voltage-frequency linearity. To reduce the frequency range, the measuring time is increased to 200 ms or higher. Even at the more practical frequency of 0.5 MHz that results, the inaccuracy of the instrument is still determined largely by the non-linearity of the voltage-frequency conversion process.

In many instruments the input network consists of an integrating operational amplifier in which the average input voltage is 'accumulated' in terms of charge on a capacitor in a given time.

#### 11.7.1.5 Dual-slope

This instrument uses a composite technique consisting of an integration (as mentioned above) and an accurate measuring network based on the ramp technique. During the integration (Figure 11.9) the unknown voltage  $V_x$  is switched at time zero to the integration amplifier, and the initially uncharged capacitor  $C$  is charged to  $V_x$  in a known time  $T_1$ , which may be chosen so as to reduce noise interference. The ramp part of the process consists in replacing  $V_x$  by a reversed biased direct reference voltage  $V_r$  which produces a constant-current discharge of  $C$ ; hence, a known linear

voltage/time change occurs across  $C$ . The total voltage change to zero can be measured by the method used in the linear-ramp instrument, except that the slope is negative and that counting begins at maximum voltage. From the diagram in Figure 11.9(a) it follows that  $\tan \theta_x / \tan \theta_r = (T_2 - T_1) / T_1 = V_x / V_r$  so that  $V_x$  is directly proportional to  $T_2 - T_1$ . The dual-slope method is seen to depend ultimately on time-base linearity and on the measurement of time difference, and is subject to the same limitations as the linear-ramp method, but with the important and fundamental quality of inherent noise rejection capability.

Noise interference (of series-mode type) is principally due to e.m.f.s at power supply frequency being induced into the d.c. source of  $V_x$ . When  $T_1$  equals the periodic time of the interference (20 ms for 50 Hz), the charging p.d.  $v_c$  across  $C$  would follow the dotted path (Figure 11.9(a)) without changing the final required value of  $v_c$ , thus eliminating this interference.

#### 11.7.1.6 Multislope

At time  $T_1$  (above) the maximum dielectric absorption in  $C$  will coincide with  $v_c$  maximum; this effect degrades (a) the linearity of the run-down slope during  $T_2 - T_1$  and (b) the identification of zero p.d. One improved 'multislope' technique reduces dielectric absorption in  $C$  by inserting various reference voltages during the run-up period and, after subtraction, leaves a lower p.d.,  $v'_c$ , prior to run-down while storing the most significant digit of  $V_x$  during the run-up period. During run-down,  $C$  is discharged rapidly to measure the next smaller digit; the residue of  $v'_c$ , including overshoot, is assessed to give the remaining three digits in sequence using three  $v_r/t$  functions of slope  $+1/10$ ,  $-1/100$ ,  $+1/1000$  compared with the initial rapid discharge. Measurement time is reduced, owing to the successive digits being accumulated during the measurement process.<sup>6</sup>

#### 11.7.1.7 Mixed techniques

Several techniques can be combined in the one instrument in order to exploit to advantage the best features of each. One accurate, precise, digital voltmeter is based upon precision inductive potentiometers, successive approximation, and the dual-slope technique for the least significant figures. An uncertainty of 10 parts in  $10^6$  for a 3-month period is claimed, with short-term stability and a precision of about 2 parts in  $10^6$ .

#### 11.7.1.8 Digital multimeters

Any digital voltmeter can be scaled to read d.c. or a.c. voltage, current, immittance or any other physical property, provided that an appropriate transducer is inserted. Instruments scaled for alternating voltage and current

**Figure 11.8** Voltage-to-frequency digital converter

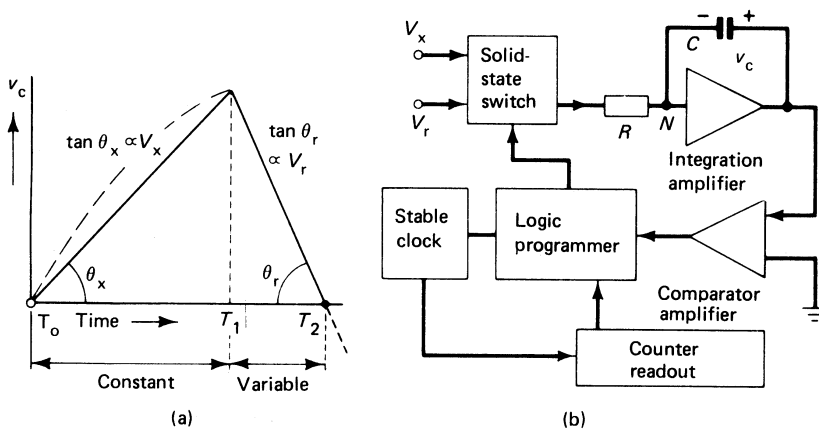

Figure 11.9 Dual-slope digital voltmeter. (a) Ramp voltage; (b) block diagram

normally incorporate one of the a.c./d.c. converter units listed in a previous paragraph, and the quality of the result is limited by the characteristics inherent in such converters. The digital part of the measurement is more accurate and precise than the analogue counterpart, but may be more expensive.

For systems application, programmed signals can be inserted into, and binary-coded or analogue measurements received from, the instrument through multiway socket connections, enabling the instrument to form an active element in a control system (e.g. IEC bus, IEEE-488 bus).

Resistance, capacitance and inductance measurements depend to some extent on the adaptability of the basic voltage-measuring process. The dual-slope technique can be easily adapted for two-, three- or four-terminal ratio measurements of resistance by using the positive and negative ramps in sequence; with other techniques separate impedance units are necessary. (See Table 11.3.)

#### 11.7.1.9 Input and dynamic impedance

The high precision and small uncertainty of digital voltmeters make it essential that they have a high input impedance if these qualities are to be exploited. Low test voltages are often associated with source impedances of several hundred kilo-ohms; for example, to measure a voltage with source resistance 50 kΩ to an uncertainty of  $\pm 0.005\%$  demands an instrument of input resistance 1 GΩ, and for a practical instrument this must be 10 GΩ if the loading error is limited to one-tenth of the total uncertainty.

The dynamic impedance will vary considerably during the measuring period, and it will always be lower than the quoted null, passive, input impedance. These changes in dynamic impedance are coincident with voltage 'spikes' which appear at the terminals owing to normal logic functions; this noise can adversely affect components connected to the terminals, e.g. Weston standard cells.

Input resistances of the order of 1–10 GΩ represent the conventional range of good-quality insulators. To these must be added the stray parallel reactance paths through unwanted capacitive coupling to various conducting and earth planes, frames, chassis, common rails, etc.

#### 11.7.1.10 Noise limitation

The information signal exists as the p.d. between the two input leads; but each lead can have unique voltage and

impedance conditions superimposed on it with respect to the basic *reference* or *ground* potential of the system, as well as another and different set of values with respect to a local *earth* reference plane.

An elementary electronic instrumentation system will have at least one ground potential and several earth connections—possibly through the (earthed) neutral of the main supply, the signal source, a read-out recorder or a cathode ray oscilloscope. Most true earth connections are at different electrical potentials with respect to each other, owing to circulation of currents (d.c. to u.h.f.) from other apparatus, through a finite earth resistance path. When multiple earth connections are made to various parts of a high-gain amplifier system, it is possible that a significant frequency spectrum of these signals will be introduced as electrical noise. It is this interference which has to be rejected by the input networks of the instrumentation, quite apart from the concomitant removal of any electrostatic/electromagnetic noise introduced by direct coupling into the signal paths. The total contamination voltage can be many times larger (say 100) than the useful information voltage level.

Electrostatic interference in input cables can be greatly reduced by 'screened' cables (which may be 80% effective as screens), and electromagnetic effects minimised by transposition of the input wires and reduction in the 'aerial loop' area of the various conductors. Any residual effects, together with the introduction of 'ground and earth-loop' currents into the system, are collectively referred to as *series* and/or *common-mode* signals.

#### 11.7.1.11 Series and common-mode signals

Series-mode (normal) interference signals,  $V_{sm}$ , occur in series with the required information signal. Common-mode interference signals,  $V_{cm}$ , are present in both input leads with respect to the reference potential plane: the required information signal is the difference voltage between these leads. The results are expressed as *rejection ratio* (in decibels) with respect to the *effective* input error signal,  $V_e$ , that the interference signals produce, i.e.

$$K_{sm} = 20 \log(V_{sm}/V_e) \text{ and } K_{cm} = 20 \log(V_{cm}/V_e)$$

where  $K$  is the rejection ratio. The series-mode rejection networks are *within* the amplifier, so  $V_e$  is measured with *zero* normal input signal as  $V_e$  = output interference

**Table 11.3** Typical characteristics of digital multimeters

\* Specifications often include 12-, 6-, and 3-month periods each with progressively smaller uncertainties of measurement down to 24-h statements for high precision instruments.

voltage  $\div$  gain of the amplifier appropriate to the bandwidth of  $V_e$ .

Consider the elementary case in *Figure 11.10*, where the input-lead resistances are unequal, as would occur with a transducer input. Let  $r$  be the difference resistance,  $C$  the cable capacitance, with common-mode signal and error voltages  $V_{cm}$  and  $V_e$ , respectively. Then the common-mode numerical ratio (c.m.r.) is

$$V_{cm}/V_e = R_{cm}/ri = R/2\pi fCr$$

assuming the cable insulation to be ideal, and  $X_C \gg r$ . Clearly, for a common-mode statement to be complete, it must have a stated frequency range and include the resistive imbalance of the source. (It is often assumed in c.m.r. statements that  $r = R$ .)

The c.m.r. for a digital voltmeter could be typically 140 dB (corresponding to a ratio of 10<sup>7</sup>/1) at 50 Hz with a 1 k $\Omega$  line imbalance, and leading consequently to  $C = 0.3$  pF. As the normal input cable capacitance is of the order of 100 pF/m, the situation is not feasible. The solution is to inhibit the return path of the current  $i$  by the introduction of a guard

network. Typical guard and shield parameters are shown in *Figure 11.11* for a six-figure digital display on a voltmeter with  $\pm 0.005\%$  uncertainty. Consider the magnitude of the common-mode error signal due to a 5 V, 50 Hz common-mode voltage between the shield earth  $E_1$  and the signal earth  $E_2$ :

*N–G not connected.* The a.c. common-mode voltage drives current through the guard network and causes a change of 1.5 mV to appear across  $r$  as a series-mode signal; for  $V_s = 4$  V this represents an error  $V_e$  of 0.15% for an instrument whose quality is  $\pm 0.005\%$ .

*N–G connected.* The common-mode current is now limited by the shield impedance, and the resultant series-mode signal is 3.1  $\mu$ V, an acceptably low value that will be further reduced by the noise rejection property of the measuring circuits.

#### 11.7.1.12 Floating-voltage measurement

If the d.c. voltage difference to be measured has a p.d. to  $E_2$  of 100 V, as shown, then with N–G open the change in p.d. across  $r$  will be 50  $\mu$ V, as a series-mode error of 0.005% for

Figure 11.10 Common-mode effect in an unbalanced network

Figure 11.11 Typical guard and shield network for a digital voltmeter

a 1 V measurement. With N–G connected the change will be 1  $\mu$ V, which is negligible.

The interconnection of electronic apparatus must be carefully made to avoid systematic measurement errors (and short circuits) arising from incorrect screen, ground or earth potentials.

In general, it is preferable, wherever possible, to use a *single* common reference node, which should be at zero signal reference potential to avoid leakage current through  $r$ . Indiscriminate interconnection of the shields and screens of adjacent components can increase *noise* currents by short-circuiting the high-impedance stray path between the screens.

#### 11.7.1.13 Instrument selection

A precise seven-digit voltmeter, when used for a 10 V measurement, has a discrimination of  $\pm 1$  part in  $10^6$  (i.e.  $\pm 10 \mu$ V), but has an uncertainty ('accuracy') of about  $\pm 10$  parts in  $10^6$  (i.e.  $\pm 100 \mu$ V). The distinction is important with digital read-out devices, lest a higher quality be accorded to the number indicated than is in fact justified. The quality of any reading must be based upon the time stability of the total instrument since it was last calibrated against *external* standards, and the cumulative evidence of previous calibrations of a like kind.

Selection of a digital voltmeter from the list of types given in Table 11.3 is based on the following considerations:

(1) No more digits than necessary, as the cost per extra digit is high.

- (2) High input impedance, and the effect on likely sources of the *dynamic* impedance.
- (3) Electrical noise rejection, assessed and compared with (a) the common-mode rejection ratio based on the input and guard terminal networks and (b) the actual inherent noise rejection property of the measuring principle employed.
- (4) Requirements for binary-coded decimal, IEEE-488, storage and computational facilities.
- (5) Versatility and suitability for use with a.c. or impedance converter units.
- (6) Use with transducers (in which case (3) is the most important single factor).

#### 11.7.1.14 Calibration

It will be seen from Table 11.3 that digital voltmeters should be recalibrated at intervals between 3 and 12 months. Built-in self-checking facilities are normally provided to confirm satisfactory operational behaviour, but the 'accuracy' check cannot be better than that of the included standard cell or Zener diode reference voltage and will apply only to *one* range. If the user has available some low-noise stable voltage supplies (preferably batteries) and some high-resistance helical voltage dividers, it is easy to check logic sequences, resolution, and the approximate ratio between ranges. In order to demonstrate traceability to national standards, a voltage source whose voltage is traceable to national standards should be used. This can either be done by the user or, more commonly, by sending the instrument to an accredited calibration laboratory.

### 11.7.2 Digital wattmeters<sup>7-9</sup>

Digital wattmeters employ various techniques for sampling the voltage and current waveforms of the power source to produce a sequence of instantaneous power representations from which the average power is obtained. One new NPL method uses high-precision successive-approximation A/D integrated circuits with the multiplication and averaging of the digitised outputs being completed by computer.<sup>10,11</sup> A different 'feedback time-division multiplier' principle is employed by Yokogawa Electric Limited.<sup>1</sup>

The NPL digital wattmeter uses 'sample and hold' circuits to capture the two instantaneous voltage ( $v_x$ ) and current ( $i_x$ ) values, then it uses a novel double dual-slope multiplication technique to measure the average power from the mean of numerous instantaneous ( $v_x i_x$ ) power measurements captured at precise intervals during repetitive waveforms. Referring to the single dual-ramp (Figure 11.9(a)) the a.c. voltage  $v_x$  (captured at  $T_0$ ) is measured as  $v_x T_1 = \frac{1}{2}(T_2 - T_1)$ . If a second voltage (also captured at  $T_0$ ) is proportional to  $i_x$  and integrated for  $T_2 - T_1$ , then, if it is reduced to zero (by  $V_T$ ) during the time  $T_3 - T_2$  it follows that  $i_x(T_2 - T_1) = \frac{1}{2}(T_3 - T_2)$ .

The instantaneous power (at  $T_0$ ) is  $v_x i_x = \frac{1}{4}(T_3 - T_2)$  and, by scaling, the mean summation of all counts such as  $T_3 - T_2$  equals the average power. The prototype instrument measures power with an uncertainty of about  $\pm 0.03\%$  f.s.d. (and  $\pm 0.01\%$ , between 50 and 400 Hz, should be possible after further development).

The 'feedback time division multiplier' technique develops rectangular waveforms with the pulse height and width being proportional, respectively, to the instantaneous voltage ( $v_x$ ) and current ( $i_x$ ); the average 'area' of all such instantaneous powers ( $v_x i_x$ ) is given (after 1.p. filtering) as a d.c. voltage measured by a DVM scaled in watts; such precision digital wattmeters, operating from 50 to 500 Hz, have  $\pm 0.05\%$  to  $\pm 0.08\%$  uncertainty for measurements up to about 6 kW.

### 11.7.3 Energy meters

A *solid state* single-phase meter is claimed to fulfil the specifications of its traditional electromechanical counterpart while providing a reduced uncertainty of measurement coupled with improved reliability at a similar cost. The instrument should provide greater flexibility for reading, tariff and data communication of all kinds, e.g. instantaneous power information, totalised energy, credit limiting and multiple tariff control. The instrument is less prone to fraudulent abuse.

### 11.7.4 Signal generators

Signal generators provide sinusoidal, ramp and square-wave output from fractions of 1 Hz to a few megahertz, although the more accurate and stable instruments generally cover a more restricted range. As voltage sources, the output power is low (100 mW–2 W). The total harmonic distortion (i.e. r.m.s. ratio between harmonic voltage and fundamental voltage) must be low, particularly for testing-quality amplifiers, e.g. 90 dB rejection is desirable and 60 dB ( $10^3:1$ ) is normal for conventional oscillators. Frequency selection by dials may introduce  $\pm 2\%$  uncertainty, reduced to 0.2% with digital dial selection which also provides 0.01% reproducibility. Frequency-synthesiser function generators should be used when a precise, repeatable frequency source is required. Amplitude stability and constant value over the whole frequency range is often only 1–2% for normal oscillators.

### 11.7.5 Electronic analysers

Analysers include an important group of instruments which operate in the frequency domain to provide specialised analyses, in terms of energy, voltage, ratio, etc., (a) to characterise networks, (b) to decompose complex signals which include analogue or digital intelligence, and (c) to identify interference effects and non-linear cross-modulations throughout complex systems.

The frequency components of a complex waveform (Fourier analysis) are selected by the sequential, or parallel, use of analogue to digital filter networks. A frequency-domain display consists of the simultaneous presentation of each separate frequency component, plotted in the  $x$ -direction to a base of frequency, with the magnitude of the  $y$ -component representing the parameter of interest (often energy or voltage scaled in decibels).

Instruments described as network, signal, spectrum or Fourier analysers as well as digital oscilloscopes have each become so versatile, with various built-in memory and computational facilities, that the distinction between their separate objectives is now imprecise. Some of the essential generic properties are discussed below.

#### 11.7.5.1 Network analysers

Used in the design and synthesis of complex cascaded networks and systems. The instrument normally contains a swept-frequency sinusoidal source which energises the test system and, using suitable connectors or transducers to the input and output ports of the system, determines the frequency-domain characteristic in 'lumped' parameters and the transfer function equations in both magnitude and phase: high-frequency analysers often characterise networks in 'distributed'  $s$ -parameters for measurements of insertion loss, complex reflection coefficients, group delay, etc. Three or four separate instruments may be required for tests up to 40 GHz. Each instrument would have a wide dynamic range (e.g. 100 dB) for frequency and amplitude, coupled with high resolution (e.g. 0.1 Hz and 0.01 dB) and good accuracy, often derived from comparative readings or ratios made from a built-in reference measurement channel.

Such instruments have wide applications in research and development laboratories, quality control and production testing—and they are particularly versatile as an automatic measurement testing facility, particularly when provided with built-in programmable information and a statistical storage capability for assessment of the product. Data display is by  $X$ – $Y$  recorder and/or cathode-ray oscilloscope (c.r.o.) and the time-base is locked to the swept frequency.

#### 11.7.5.2 Spectrum analysers

Spectrum analysers normally do not act as sources; they employ a swept-frequency technique which could include a very selective, narrow-bandwidth filter with intermediate frequency (i.f.) signals compared, in sequence, with those selected from the swept frequency; hence, close control of frequency stability is needed to permit a few per cent resolution within, say, a 10 Hz bandwidth filter. Instruments can be narrow range, 0.1 Hz–30 kHz, up to wide range, 1 MHz–40 GHz, according to the precision required in the results; typically, an 80 dB dynamic range can have a few hertz bandwidth and 0.5 dB amplitude accuracy. Phase information is not directly available from this technique. The instrument is useful for tests involving the output signals from networks used for frequency mixing, amplitude and frequency modulation or pulsed power generation. A steady

c.r.o. display is obtained from the sequential measurements owing to digital storage of the separate results when coupled with a conventional variable-persistence cathode-ray tube (a special cathode-ray tube is not required for a digital oscilloscope): the digitised results can, in some instruments, be processed by internal programs for (a) time averaging of the input parameters, (b) probability density and cumulative distribution, and (c) a comprehensive range of statistical functions such as average power or r.m.s. spectrum, coherence, autocorrelation and cross-correlation functions, etc.

### 11.7.5.3 Fourier analysers

Fourier analysers use digital signalling techniques to provide facilities similar to the spectrum analysers but with more flexibility. These 'Fourier' techniques are based upon the calculation of the discrete Fourier transform using the fast Fourier transform algorithm (which calculates the magnitude and phase of each frequency component using a group of time-domain signals from the input signal variation of the sampling rate); it enables the long measurement time needed for very-low-frequency ( $\ll 1$  Hz) assessments to be completed in a shorter time than that for a conventional swept measurement—together with good resolution (by digital translation) at high frequencies. Such specialised instruments are usable only up to 100 kHz but they are particularly suitable for examining low-frequency phenomena such as vibration, noise transmission through media and the precise measurement of random signals obscured by noise, etc.

### 11.7.6 Data loggers

Data loggers consist of an assembly of conditioning amplifiers which accept signals from a wide range of transducers or other sources in analogue or digital form; possibly a small computer program will provide linearisation and other corrections to signals prior to computational assessments (comparable to some features of a spectrum or other class of analyser) before presenting the result in the most economical manner (such as a graphical display). The data logger, being modular in construction, is very flexible in application; it is not limited to particular control applications and by the nature of the instrument can appear in various guises.

## 11.8 Oscilloscopes

The cathode-ray oscilloscope (c.r.o.) is one of the most versatile instruments in engineering. It is used for diagnostic testing and monitoring of electrical and electronic systems, and (with suitable transducers) for the display of time-varying phenomena in many branches of physics and engineering. Two-dimensional functions of any pair of repetitive, transient or pulse signals can be developed on the fluorescent screen of a c.r.o.

These instruments may be classified by the manner in which the *analogue* test signals are conditioned for display as (a) the 'analogue c.r.o.', using analogue amplifiers, and (b) the 'digital storage oscilloscope', using A/D converters at the input with 'all-digit' processing.

### 11.8.1 Cathode-ray tube

The cathode-ray tube takes its name from Pluecker's discovery in 1859 of 'cathode rays' (a better name would be 'electron beam', for J. J. Thomson in 1897 showed that the 'rays' consist of high-speed electrons). The developments by

Braun, Dufour and several other investigators enabled Zworykin in 1929 to construct the essential features of the modern cathode-ray tube, namely a small thermionic cathode, an electron lens and a means for modulating the beam intensity. The block diagram (*Figure 11.12*) shows the principal components of a modern cathode-ray oscilloscope. The tube is designed to focus and deflect the beam by means of structured electric field patterns. Electrons are accelerated to high speed as they travel from the cathode through a potential rise of perhaps 15 kV. After being focused, the beam may be deflected by two mutually perpendicular  $X$  and  $Y$  electric fields, locating the position of the fluorescing 'spot' on the screen.

#### 11.8.1.1 Electron gun and beam deflection

The section of the tube from which the beam emerges includes the heater, cathode, grid and the first accelerating anode; these collectively form the *electron gun*. A simplified diagram of the connections is given in *Figure 11.13*. The electric field of the relatively positive anode partly penetrates through the aperture of the grid electrode and determines on the cathode a disc-shaped area (bounded by the  $-15$  kV equipotential) within which electrons are drawn away from the cathode: outside this area they are driven back. With a sufficiently negative grid potential the area shrinks to a point and the beam current is zero. With rising grid potential, both the emitting area and the current density within it grow rapidly.

The diagram also shows the electron paths that originate at the emitting area of the cathode. It can be seen that those which leave the cathode at right angles cross the axis at a point not far from the cathode. This is a consequence of the powerful lens action of the strongly curved equipotential surfaces in the grid aperture. But, as electrons are emitted with random thermal velocities in all directions to the normal, the 'cross-over' is not a point but a small *patch*, the image of which appears on the screen when the spot is adjusted to maximum sharpness.

The conically shaped beam of divergent electrons from the electron gun have been accelerated as they rise up the steep potential gradient. The electrical potentials of the remaining nickel anodes, together with the post-deflection accelerating anode formed by the graphite coating, are selected to provide

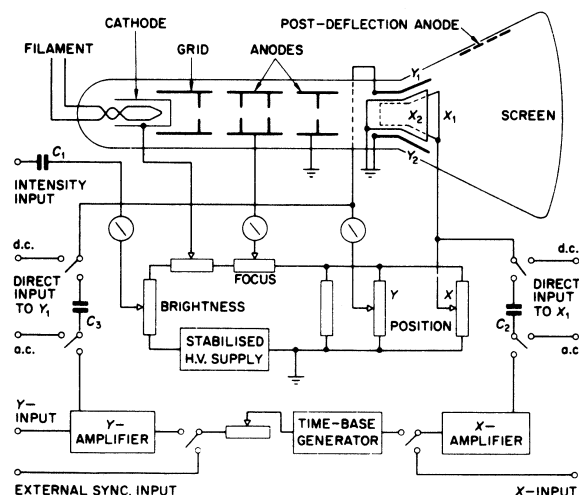

Figure 11.12 Analogue cathode-ray oscilloscope circuits

Figure 11.13 Electron beam in an electron gun

additional acceleration and, by field shaping, to refocus the beam to a spot on the screen. To achieve sharply defined traces it is essential that the focused spot should be as small as possible; the area of this image is, in part, dictated by the location and size of the 'point source' formed in front of the cathode. The rate at which electrons emerge from the cathode region is most directly controlled by adjustment of the negative potential of the grid; this is effected by the external *brightness control*. A secondary result of changes in the brightness control may be to modify, slightly, the shape of the point source. The slight de-focusing effect is corrected by the *focus control*, which adjusts an anode potential in the electron lens assembly.

#### 11.8.1.2 Performance (electrostatic deflection)

If an electron with zero initial velocity rises through a potential difference  $V$ , acquiring a speed  $u$ , the change in its kinetic energy is  $\frac{1}{2}mu^2$ , so that the speed is

$$u = \sqrt{(2Ve/m)} \simeq 6 \times 10^5 \sqrt{V} \text{ m/s}$$

using accepted values of electron charge,  $e$ , and rest-mass,  $m$ . The performance is dependent to a considerable extent on the beam velocity,  $u$ .

The deflection sensitivity of the tube is increased by shaping the deflection plates so that, at maximum deflection, the beam grazes their surface ( $Y_1Y_2$ ; Figure 11.12). The sensitivity and performance limits may be assessed from the *idealised* diagrams (and notation) in Figure 11.14. Experience shows that a good cathode-ray tube produces a beam-current density  $J_s$  at the centre of the luminous spot in rough agreement with that obtained on theoretical grounds by Langmuir, i.e.

$$J_s = k J_c \theta^2 V / T \quad (11.1)$$

where  $J_c$  is the current density at the cathode,  $V$  is the total accelerating voltage,  $T$  is the absolute temperature of the cathode emitting surface,  $\theta$  is one-half of the beam convergence angle, and  $k$  is a constant. If  $i_b$  is the beam current, then the apparent diameter of the spot is given approximately by  $\sqrt{(i_b/J_s)}$ .

The voltage  $V_d$  applied to the deflection plates produces an angular deflection  $\delta$  given by

$$V_d = \frac{1}{2} \delta V d / L_d \quad (11.2)$$

Figure 11.14 Deflection parameters

Deflection is possible, however, only up to a maximum angle  $\alpha$ , such that

$$\alpha L_d + \theta L = \frac{1}{2}d \quad (11.3)$$

From these three expressions, certain quantities fundamental to the rating of a cathode-ray tube with electric field deflection can be derived.

#### 11.8.1.3 Definition

This is the maximum sweep of the spot on the screen,  $D = 2\alpha L$ , divided by the spot diameter, i.e.  $N = D/s$ . In television  $N$  is prescribed by the number of lines in the picture transmission. In oscillography  $N$  is between 200 and 300. Better definition can be obtained only at the expense of deflection sensitivity.

#### 11.8.1.4 Specific deflection sensitivity

This is the inverse of the voltage that deflects the spot by a distance equal to its own diameter, i.e. the voltage which produces the smallest perceptible detail. The corresponding deflection angle is  $\delta_0 = \pi/L$ . Use of equations (11.1)–(11.3) gives for the specific deflection sensitivity

$$S = k_1 L / [(L/L_d + \alpha/\theta) \sqrt{(V_i b)}] \quad (11.4)$$

where  $k_1$  is a constant. Thus, the larger the tube dimensions the better the sensitivity at the smallest beam power consistent with adequate brightness of trace.

#### 11.8.1.5 Maximum recording speed

The trace remains visible so long as its brightness exceeds a certain minimum. The brightness is proportional to the beam power density  $VJ$ , to the luminous efficiency  $\sigma$  of the screen, and to the time  $s/U$  during which the beam sweeps at speed  $U$  over one element of the screen. Hence,

$$U = k_2 s J V \sigma \quad (11.5)$$

Recording speeds up to 40 000 km/s have been achieved with sealed-off tubes, permitting single-stroke photography of the trace.

#### 11.8.1.6 Maximum specified recording speed

Unless compared with the spot size  $s$ , the value of  $U$  does not itself give adequate information. The specific speed  $U_s = U/s$  is more useful: it is the inverse measure of the shortest time-interval in which detail can be recorded. Combining equations (11.5) and (11.1)

$$U_s = k_2 J V \sigma = k_3 (V\theta)^2 \quad (11.6)$$

The product  $\varsigma(V\theta)^2$  is the essential figure in the speed rating of a cathode-ray tube.

#### 11.8.1.7 Limiting frequency

A high recording speed is useful only if the test phenomena are recorded faithfully. The cathode-ray tube fails in this respect at frequencies such that the time of passage of an electron through the deflection field is more than about one-quarter of the period of an alternating quantity. This gives the condition of maximum frequency  $f_m$ :

$$f_m = 4.5 \times 10^5 \sqrt{V/L_d} \quad (11.7)$$

which means that the smallest tube at the highest acceleration voltage has the highest frequency limit. This conflicts with

the condition for deflection sensitivity. Combining the two expressions gives the product of the two:

$$(Sf_m) = k_4/[1 + (L_d/L)(\alpha/\theta)]\sqrt{i_b} \quad (11.8) \Leftarrow$$

Compromise must be made according to the specific requirement. It may be observed that the optimum current  $i_b$  is not zero as might appear, because for such a condition the convergence angle  $\theta$  is also zero. In general, the most advantageous current will not differ from that for which the electron beam just fills the aperture.

Limitation of cathode-ray-tube performance by space charge is an effect important only at low accelerating voltages and relatively large beam currents. For these conditions the expressions above do not give practical ratings.

### 11.8.1.8 Fluorescent screen

The kinetic energy of each incident electron is converted into light owing to the exchange of energy which occurs within the phosphors coated on the inside of the screen. The result, *luminescence*, is usually described as either fluorescence or phosphorescence. *Fluorescence* is the almost instantaneous energy conversion into light, whereas *phosphorescence* is restricted to the phosphors which 'store' the converted energy and release it, as light, after a short delay. The *afterglow* can last many seconds. The respective terms are applied to the phosphors in accordance with their dominant light-emitting behaviour; however, each property is always present in a phosphor. In most cathode-ray tubes fluorescent phosphors are used with a very short afterglow (40  $\mu$ s); a longer afterglow would blur a quickly changing display.

The most common fluorescent substances are silicates and sulphides, with calcium tungstate for photographic work. An excellent zinc silicate occurs naturally in the mineral willemite, but all other substances are prepared artificially. After purification, the substances are activated by the addition of very small quantities of suitable metals, and then ground to a powder of grain size 5–10  $\mu$ m (for sulphides 10–50  $\mu$ m).

In applying the powder to the glass several methods are used. Very finely ground silicates can be applied without a binder, by setting the powder from water, or an electrolyte. Sulphides are usually compounded with the glass wall by means of a binder such as sodium silicate; good results have been obtained also by baking them directly into the glass. In choosing the method two conflicting considerations must be taken into account. Baking or compounding gives good thermal contact, and prevents overheating of the powder particles by the electron beam. But at the same time good optical contact is established with the glass, with the result that light from the powder enters the glass also at angles exceeding the total reflection angle. This part of the light cannot escape at the viewing side, but is reflected and forms a luminous 'halo' which blurs the picture.

While silicates fluoresce usually green or blue-green, white fluorescence can be obtained by mixing cadmium sulphide and zinc cadmium sulphide in suitable proportions. The luminous efficiency of modern fluorescent powders is very high. Zinc silicate emits up to 2.5 cd/W of beam power, and some sulphides are even more effective. The luminous efficacy increases with voltage up to about 10 kV, beyond which it decreases, partly because fast electrons are not stopped by the crystal grains.

The range of phosphors is classified by 'P' numbers, as in Table 11.4.

The light persistence of the most widely used phosphor (P31) is 40  $\mu$ s; however, there are tubes available, using this phosphor, which have both variable persistence and 'mesh storage' facilities. Adjustable persistence enables very-low-frequency signals, lasting for a minute, to be viewed as a complete trace while retaining the normal 'writing' properties of the tube. Storage, at reduced brightness, is possible for up to 8 h.

Phosphor materials are insulators. The current circuit for all the incident beam electrons is completed by an equal number of low-energy electrons being attracted along various paths through the vacuum to the positive conducting-graphite coating. The result of secondary emission of electrons is to leave the screen with a positive charge only a little lower in potential than that of the graphite coating; thus, the surplus secondary emission electrons return to the phosphor-coated screen surface. This mechanism works perfectly at the voltages usually employed in oscillography and television (3–20 kV), also in small projection-tube sealed-off high-speed oscillographs (10–25 kV). Above 25 kV the mechanism is unsatisfactory and the dispersion of charge has to be supplemented by other means.

The power concentration in the luminous spot of a cathode-ray tube is very high. In direct-vision television tubes the momentary luminance may exceed 10 cd/mm<sup>2</sup>. A 3 mA 80 kV beam of a large-screen projection tube may be concentrated in an area of 0.1 mm<sup>2</sup>, representing a power density of 2 kW/mm<sup>2</sup>. (By comparison, melting tungsten radiates about 10 W/mm<sup>2</sup>.) The width of the trace in a conventional 10 kV cathode-ray tube with a beam current of 10  $\mu$ A is only 0.35 mm.

### 11.8.2 Deflection amplifiers (analogue c.r.o.)

Amplifiers are built into cathode-ray oscilloscope (c.r.o.) equipment to provide for time base generation and the amplification of small signals. The signals applied to the vertical (*Y*) deflecting plates are often repetitive time functions. To display them on a time base, the vertical displacements must be moved horizontally across the screen at uniform speed repeatedly at intervals related to the signal frequency, and adjusted to coincidence by means of a synchronising signal fed to the time base from the *Y* amplifier.

**Table 11.4** Classification of phosphors

Phosphor	Persistence	Colour of trace	Relative brightness	Application
P2	Medium/short	Yellow/green	6.5	Low repetition rates (general oscillography)
P4	Medium	White	5.0	High-contrast displays (monochrome television)
P7	Long	White or yellow/green	4.5	Long-persistence low-speed (radar)
P11	Medium/short	Blue	2.5	High writing speeds (photography)
P31	Medium/short	Green	10	High-brightness, general use

An additional constraint may be the requirement to start the time base from the left side of the screen at the instant the  $Y$ -plate signal is zero: a synchronising trigger signal is fed to the time base circuit to initiate each sweep. Finally, the spot must return (flyback) to the origin at the end of each sweep time. Ideally, flyback should be instantaneous: in practice it takes a few score nanoseconds. During flyback the beam is normally cut off to avoid return-trace effects, and this is the practice for television tubes.

Linear time bases are described in terms either of the sweep time per centimetre measured on the horizontal centre line of the graticule, or of the frequency. The repetition frequency range is from about 0.2 Hz to 2.5 MHz.

### 11.8.2.1 Ramp voltage (saw-tooth) generator

If a constant current  $I$  is fed to a capacitor  $C$ , its terminal voltage increases linearly with time. An amplified version of the voltage is applied to the  $X$  plates. Various sweep times are obtained by selecting different capacitors or other constant current values.

The method shown in Figure 11.15 employs a d.c. amplifier of high gain  $-G$  with a very large negative feedback coupled through an ideal capacitor  $C_f$ . The amplifier behaves in a manner dictated by the feedback signal to node B rather than by the small direct input voltage  $E_s$ . The resultant signal  $v_i$  is small enough for node B to be considered as virtually at earth potential. Analysing the network based on the 'virtual earth' principle, then  $v_i = 0$  and  $i_i = 0$ , the input resistance  $R_i$  being typically 1 M $\Omega$ . Then  $i_s + i_f = 0$ , whence

$$(E_s/R_s) = C_f(dv_o/dt) = 0 \text{ giving } v_o = -(1/C_f R_s) \int E_s \cdot dt$$

The output voltage  $v_o$  increases linearly with time to provide the ramp function input to the  $X$  amplifier.

### 11.8.2.2 Variable delay

When two similar  $X$  amplifiers, A and B, are provided, B can be triggered by A; if B is set for, say, five times the frequency of A and this had a variable delay facility, then any one-fifth of the complete A waveform display can be extended to fill the screen. Both complete and expanded waveforms can be viewed simultaneously by automatic switching of A and B to the  $X$  plates during alternate sweeps.

### 11.8.2.3 Signal amplifiers

The  $X$ - and  $Y$ -plate voltages for maximum deflection in a modern 10 cm cathode-ray tube may lie between 30 and 200 V. As many voltage phenomena of interest have amplitudes ranging between 500 V and a few millivolts, both

impedance matched attenuators and voltage amplifiers are called for. The amplifiers must be linear and should not introduce phase distortion in the working frequency range; the pulse response must be fast (e.g. 2 ns); and the drift and noise must be small (e.g. 3  $\mu$ V).

Amplifiers have d.c. and a.c. inputs. The d.c. coupling is conventional, to minimise the use of capacitors (which tend to produce low-frequency phase distortion). The d.c. inputs also permit the use of a reference line. The a.c. input switch introduces a decoupling capacitor.

Two separate  $Y$  amplifiers are often provided; in conjunction either with one switched or with two separate  $X$  amplifiers, they permit the examination of two voltages simultaneously. It is important to distinguish the dual-trace oscilloscope (in which a single beam is shared by separate signal amplifiers) and the true double-beam device (with a gun producing two distinct beams).

## 11.8.3 Instrument selection

A general purpose c.r.o. must compromise between a wide frequency range and a high amplification sensitivity, because high gain is associated with restricted bandwidth. An economically priced c.r.o. with solid state circuitry may have a deflection sensitivity of 5 mV/cm, bandwidth 10 MHz and a 3 kV accelerating voltage for a 10 cm useful display. For greater flexibility, many modern c.r.o.s comprise a basic frame unit with plug-in amplifiers; the frame carries the tube, all necessary power outlets and basic controls; the plug-in units may have linear or special characteristics. The tube must be a high-performance unit compatible with any plug-in unit. The cost may be higher than that of a single function c.r.o., but it may nevertheless be economically advantageous.

Many classes of measurement are catered for by specially designed oscilloscopes. In the following list, the main characteristic is given first, followed by the maximum frequency, deflection sensitivity and accelerating voltage, with general application notes thereafter.

**Low-frequency** (30 MHz, or 2 MHz at high gain; 0.1 mV/cm–10 V/cm; 3–10 kV). General purpose oscillography, for low-frequency system applications. Usually, high  $X$ -sweep speeds are needed for transient displays and complex transducer signals. Two traces available with two-beam or chopped single-beam tube. Single-shot facility.  $Y$ -amplifier signal delay useful for 'leading-edge' display. Rise times 10–30 ns.

**Medium-frequency** (100 MHz; 0.1 mV/cm; 8–15 kV). General-purpose, including wide-band precision types with a rise time of 3–10 ns.

**High-frequency** (non-sampling) (275 MHz; 10 mV/cm; 20 kV). May include helical transmission-line deflecting

Figure 11.15 Time-base operational amplifier

plates. Rise time 1.5 ns for testing digital system and computer displays.

*Variable persistence storage cathode-ray tube* for h.f. transients.

*Very-high frequency (sampling)* (12 000 MHz; 5 mV/cm; 20 kV). The v.h.f. waveforms are 'instantaneously' measured and optically stored,  $n$  times at  $n$  successively retarded instants during the period of each of  $n$  successive waveforms (with  $n$  typically 1000). The  $n$  spots accumulate in the correct time sequence as a single waveform derived from the  $n$  waveforms sampled.

*Large-screen* (20 MHz; 60 mV/cm; 28 kV). Screen area up to 0.25 m<sup>2</sup>. Useful for industrial monitoring, classroom display and computer graphics. (Magnetic deflection gives a shorter overall length of tube, probably with improved focusing towards the edges but with a lower maximum frequency.)

#### 11.8.3.1 Other features

With all c.r.o.s, the  $X$ - $Y$  cartesian coordinate display can be augmented by  $Z$ -modulation. This superimposes a beam-intensity control on the  $X$ - $Y$  signals to produce the illusion of three dimensions. The beam control may brighten one spot only, or gradually 'shape' the picture.

Oscilloscopes are supplemented by such accessories as special probes for matching and/or attenuating the signal to the signal/cable interface. Anti-microphony cables are available which minimise cable-generated noise and capacitance change. Many types of high-speed camera can be used, including single-shot cameras that can employ ultra-violet techniques to 'brighten' a record from a trace of low visual intensity.

### 11.8.4 Operational use

To avoid degradation of the signal source, a c.r.o. has a high input impedance (1 M $\Omega$ , 20 pF) and a good common-mode rejection (50 dB). The quality can be considerably impaired by impedance mismatch and incorrect signal/earth (or ground) connections.

#### 11.8.4.1 Impedance matching

Voltage signals are often presented to a c.r.o. through wires or coaxial cables terminated on crocodile clips. Although this may be adequate at low frequencies, it can behave like a badly matched transmission line, causing attenuation distortion and phase distortion. The earth screen of a coaxial cable is not fully effective, and in consequence the cable can pick up local radiated interference. In a normal cable the central conductor is not bonded to the insulation, and flexure of the cable may distort the signal waveform because of changes in the capacitance distribution, or generated noise. The cable capacitance of about 50 pF/m is additive to the c.r.o. input capacitance, and will distort the signal, particularly if the frequency and source impedance are high.

These adverse effects can be mitigated by use of fully screened probes and cables of low and constant capacitance associated with low loss. The probes may be *active* (including an impedance matching unity-gain amplifier) or *passive* (including resistance with adjustable capacitance compensation); attenuators are incorporated in each to reduce both the signal level and the capacitive loading of the source, the compensation being most effective for high-impedance sources. The active probe can be used to match the source to the standard 50  $\Omega$  input impedance of a high-frequency c.r.o. (100 MHz and above), an important matter in that a

quarter wavelength at 100 MHz is about 75 cm, and severe standing-wave effects may otherwise occur to invalidate the measurements.

#### 11.8.4.2 Earths and grounds

Ground planes (e.g. extended screens) and earth planes (e.g. trunking) constitute low-impedance paths through which interfering signals can circulate, of a wide variety of frequencies and waveforms. The arbitrary connection of screens to earth and ground terminals can have the unwelcome result of increasing noise, due to earth-loop currents. The latter must not enter the input signal lines of either the system or the c.r.o.; and the interference can be minimised by using a single ground/earth connection to serve the whole equipment, if this is possible. The common connection should be made at the zero-potential input signal lead.

### 11.8.5 Calibration

Operational specifications will include performance statements, typically: voltage accuracy,  $\pm 3\%$ ; time-base frequency  $\pm 3\%$ ;  $Y$ -amplifier linearity,  $\pm 3\%$ ; phase shift,  $1^\circ$ ; pulse response,  $\geq 5\%$  after 2 ns; sweep delay accuracy,  $\pm 2\%$ . The calibration facility provided usually consists of a 1 or 2 kHz square waveform with a 3  $\mu$ s rise time, with both the frequency and voltage amplitude within  $\pm 1\%$ .

The practical application of the c.r.o. as a test instrument includes (a) the general diagnostic display of waveforms, and (b) the testing of a product during development or manufacture in relation to its accuracy and quality control. For (a) the built-in calibration facility is adequate; but for (b) it is prudent (or essential) to make regular checks of the actual parameters of the self-calibration facility and of the basic characteristics of the instrument. Such tests would include assessments of the accuracy on alternating voltages, and the ratio and phase angle of the amplifiers and attenuators over the frequency range. The most important and critical test for a c.r.o., which will inevitably be used with modern digital networks, is its response to high frequency square waveforms. The rise time is quite easily measured, but the initial resonant frequency of the 'flat' part of the waveform and its rate of attenuation are important in assessing the actual duration of this part.

The quality and usefulness of these tests is ultimately related to the readability of the display, which would be no better than  $\pm 0.3\%$  in a 10 cm trace. The quality of the standard reference devices would, for example, be  $\pm 0.1\%$  for a variable-frequency alternating voltage source; hence, there would be a total measurement uncertainty of about 0.4% in the  $\pm 1\%$  waveform. It follows that the actual c.r.o. voltage source must be correct to within 0.6% if it is to be used with confidence as a  $\pm 1\%$  source. It is a fundamental requirement that the quality of all the reference standards be known from recent linearity and traceability tests.

### 11.8.6 Applications

The principal application is for diagnostic testing. In addition, the c.r.o. is used to monitor the transfer characteristics of devices and systems, as well as for numerical measurements. Among special uses are to be found the television camera, electron diffraction camera and electron microscope.

*Single-deflection measurements* The tube functions with a single pair of deflecting plates as a voltmeter or ammeter, with the advantages of being free from damping, unaffected by change of frequency or temperature or over-deflection,

and imposing only a minute load on the test circuit. Examples are the monitoring of signals in broadcast and recording studios, modulation checks, indication of motor peak starting currents, thickness measurement, null detection and the measurement of current and voltage in networks of very low power.

**Differential measurements** Similar or related phenomena are compared by use of both pairs of deflecting plates, the resulting Lissajous figure being observed. In this way phase difference can be measured, frequencies accurately checked against a standard, armature windings tested, modulation indicated by a stationary waveform, and the distortion measured in receivers, amplifiers and electro-acoustic equipment. Figure 11.16 is a Lissajous figure comparing two frequencies by counting the horizontal and vertical loops, giving the ratio 4/5. The diagram in Figure 11.17 shows the connections for testing the distortion of an amplifier: the oscillator is set to a known frequency, the two pairs of deflectors connected, respectively, to the input and output (with suitable attenuators). A straightline display indicates absence of distortion, while curvature or looping indicates distortion.

**Repetitive time base** Using a linear time base enables sustained waveforms to be displayed for machines, transformers and rectifiers, rapid operations to be timed, and surge phenomena to be shown with the aid of a recurrent-surge generator.

**Single sweep** Non-repetitive transients, such as those arising by lightning or switching, are most readily traced by use of the continuously evacuated tube, but sensitive sealed-off tubes can also be employed. In either case a non-repetitive time base is used consisting of the voltage of a capacitor discharged through a resistor and triggered by a gap. The transient discharge is normally obtained by use of a surge generator for power system plant testing, but other single transients, such as the small voltages of cardiac origin, may also require to be recorded.

**Independent bases** The c.r.o. is well suited to the display of quantities related by some variable other than time. The current due to an impressed voltage can be displayed on a frequency base as a resonance curve, radio receivers aligned, and  $B/H$  loops taken for steel samples. Transistor curve tracers are useful applications capable of giving a complete family of characteristics in a single display.

**Modified time bases** There are several modified forms of time base. If two voltages of the same amplitude and

Figure 11.16 Lissajous figure

Figure 11.17 Distortion test on amplifier

frequency are displaced in time phase by a quarter-period and applied, respectively, to the  $X$  and  $Y$  plates as in Figure 11.18, they will produce a circular trace. One application, in decade digital logic circuits, involves a  $Z$  modulation of the c.r.o. grid. To check that a frequency divider section is working correctly, the period of the circular time base is made 10 times that of the next higher count rate section. With the latter used to modulate, 10 equal bright and dark peripheral sectors should appear on the trace.

### 11.8.7 Digital storage oscilloscopes

Digital storage oscilloscopes (d.s.o.) (Figure 11.19) offer advantages over the analogue c.r.o. in some circumstances:

- (1) they allow long-term display of a transient quantity;
- (2) it is easy to produce a hard copy of the display;
- (3) they allow computation and signal processing within the d.s.o.;
- (4) they allow easy transfer of data to a computer; and
- (5) they use cheap cathode-ray-tube construction because the deflection is not at signal frequency but much lower than the maximum signal frequency.

The d.s.o. has become available for laboratory and industrial use because of the development of relatively cheap, accurate and fast A/D converters.

### 11.8.8 Digital oscilloscope characteristics

#### 11.8.8.1 Sampling rate

Clearly the sampling rate must be high enough to give a faithful representation of the applied signal. Nyquist's theorem states that a periodic signal must be sampled at more than twice the highest frequency component of the signal. In practice, because of the finite time available, a sample rate somewhat higher than this is necessary. A sample rate of 4 per cycle at oscilloscope bandwidth would be typical. Therefore, for single shot, a digital oscilloscope specification will give a bandwidth of 100 MHz or a sample rate of 400 megasamples/s. If the display is a dot display, then something like 20 samples per cycle is necessary if the eye is to interpret the display easily. Usually some form of interpolation is provided to aid interpretation. The simplest method is to draw straight lines between successive sample parts. Other interpolation methods are used such as sine interpolation, designed for fairly pure sine waves. This interpolation will give erroneous displays for non-sinusoidal inputs.

All this means that great care must be taken in interpreting a display when the input approaches the oscilloscope bandwidth, particularly if it has significant high frequency components such as a square wave. This is also true of course for an analogue c.r.o.

The d.s.o. in repetitive mode can build up the display over a number of sections of the displayed waveform, and so the sampling-rate problems are not so severe. Specifications will give bandwidth, single-shot bandwidth and sampling rate. If single-shot mode is to be used, then care must be taken to

Figure 11.18 Connections for circular time base

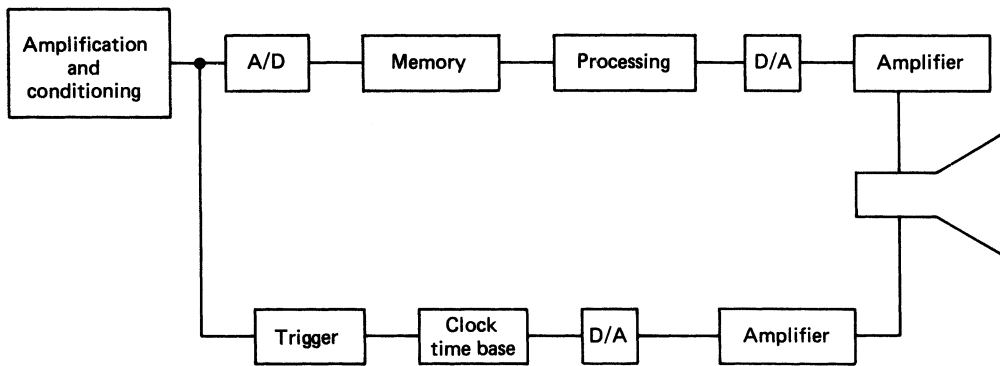

Figure 11.19 The digital storage oscilloscope

look for the adequacy of the single-shot bandwidth or the sampling rate.

For an analogue c.r.o., a rule of thumb relates the rise time of the c.r.o. to its bandwidth  $\text{rise time (s)} \times \text{bandwidth (Hz)} = 0.35$ . So, a 100 MHz oscilloscope has a rise time of 3.5 ns. A signal rise time approaching this cannot be faithfully displayed, as the fastest displayed rise time is that of the instrument itself. Usually the fastest rise time displayable is 8 times the c.r.o. rise time. So the fastest signal rise time  $= 2.8 \div \text{bandwidth}$ . For a 100 MHz c.r.o. this would be 28 ns.

A similar restriction occurs for the d.s.o. A fast signal pulse on an expanded time scale is shown in Figure 11.20. The worst case giving the slowest rise time is when one of the samples is in the middle of the edge. The time from 10% to 90% of the rise (the rise time) is given by  $(80/100) \times 2$  sample periods  $(= 4.6 \text{ sample periods})$ .

So for a 100 megasample/s d.s.o., the sampling interval is 10 ns and the displayed edge, regardless of the rise time of the applied signal, is at worst 16 ns. Again, in order to faithfully display the signal, and not the characteristics of the d.s.o., the fastest signal rise time should be about 8 times this limit, say 10 sample intervals. So, as a rule of thumb:

$$\text{Fastest signal rise time} = \frac{10}{\text{d.s.o. sampling rate}}$$

e.g. for 100 megasamples/s d.s.o. the fastest signal rise time is 100 ns. For a signal rise time faster than this it is likely

that the performance of the d.s.o. will show itself in the display of the signal.

### 11.8.8.2 Vertical resolution

Vertical resolution is another important parameter of the d.s.o. An important contribution to this is the number of bits of the A/D converter. The more bits, the greater the resolution. The minimum discernible level is

$$\frac{\text{Input voltage}}{2^n - 1}$$

where  $n$  is the number of bits of the A/D.

For example, for an input voltage of 1 V and an 8-bit A/D, the minimum discernible level is

$$\frac{1}{2^8 - 1} = \frac{1}{255} \text{ V } (\approx 4 \text{ mV})$$

This value is sometimes given as a percentage and in this case would be  $\pm 0.2\%$ .

So on a 1-V signal, noise of less than 4 mV will not be displayed. Increasing the number of bits in the A/D converter will help, but internally generated noise limits the advantage achieved. This leads to the concept of effective bits of the d.s.o., which is performance of a hypothetical idealised A/D converter which gives the same vertical resolution of the actual A/D converter with its noise limitation.

Figure 11.20 The effect of sampling rate on displayed rise time

## 11.9 Potentiometers and bridges

### 11.9.1 D.c. potentiometers

D.c. potentiometers may be used to measure a direct voltage by comparison with the known ratio of the e.m.f. of a Weston standard cell or electronic solid state reference device. The methods of achieving the linear ratio between the unknown p.d. and the standard-cell e.m.f. are by successive approximation to the balance condition (a) using groups of matched resistors, (b) using opposed m.m.f.s between matched windings and current-ratio resistors (comparator potentiometer), and (c) pulse-width modulation (ratio of time interval). The d.c. potentiometer is a ratio device of high precision with the uncertainty of the standard voltage source limiting the ultimate accuracy.

### 11.9.1.1 Weston standard cell

The highest quality saturated mercury/cadmium-mercury cell has an e.m.f. of about 1.018 620 V at 20°C. The net e.m.f./temperature coefficient is about  $-40 \mu\text{V}/^\circ\text{C}$ , arising from the two different coefficients of the limbs, each of the order of  $350 \mu\text{V}/^\circ\text{C}$ . It is, therefore, important to avoid a temperature differential across the cell by mounting it in oil or air within a constant temperature enclosure (e.g. for  $20^\circ\text{C} \pm 40 \text{ m}^\circ\text{C}$ , the uncertainty can be only  $\pm 0.4 \mu\text{V}$ ).

Standard cells are stable, the e.m.f. falling by, perhaps, 1  $\mu\text{V}$  per year. For accurate work, regular confirmation of the e.m.f. should be made at an accredited calibration laboratory.

The internal resistance is 600–800  $\Omega$ . The current drawn from a cell should ideally be zero: in practice it should be limited to a few nanoamperes for a few seconds.

Should a cell be compared with an electronic solid state voltage reference (below), the cell must be presented and removed while the electronic source is switched on.

### 11.9.1.2 Electronic solid state e.m.f. reference

These devices use the constant voltage property of Zener diodes to deliver highly stable d.c. voltages, usually at 1 V and 10 V levels for direct voltage meter calibrations, and 1.018 61 V to simulate a Weston cell for d.c. potentiometric standardisation. Up to four diodes (each stabilising at about 6.3 V) are used, having been carefully selected for stability, low noise and low temperature/voltage coefficient properties. After further ageing, these temperature-stabilised monolithic devices may be used either separately with a carefully designed operational amplifier, or connected in cascade in specialised networks to achieve the required output p.d. by potential division using highly stable resistors.

It would appear that these devices are excellent transportable standards of voltage (which should be reliable to within  $2 \mu\text{V}/\text{year}$ ) and they are much more convenient than Weston cells in this respect. Except for the most extreme requirements of accuracy, they could be used as laboratory standards, provided that at least three separate units are available for intercomparison. With more experience and/or minor refinement to these devices, they could shortly replace the Weston cell completely, since at present the Weston cell can be used as a transportable standard to less than  $0.5 \mu\text{V}$ , but only if very great care is exercised.

Typical electronic devices can deliver, say, 5 mA, 10 V from 2 m $\Omega$  and 1.0186 V from 2 k $\Omega$ .

### 11.9.1.3 Potentiometer principle (using groups of matched resistors)

In Figure 11.21 AB is a manganin wire of length a little greater than 1 m, through which the current  $I$  from a 2 V secondary cell may be varied by means of  $R$ . The current is adjusted so that the p.d. between points F and D, 1.0186 m apart, balances the e.m.f. of the Weston standard cell, the balance condition being obtained by use of the switch  $S$  and galvanometer  $G$ . The volt drop along the wire is now 1 mV per mm length. The switch  $S$  may now be set to apply the unknown voltage  $V_x$ , and a new balance point H found. Then the length DH in mm represents the unknown voltage in millivolts.

This very simple arrangement is inconvenient in practice. It suffers also from the disadvantage that the precision of the voltage measurement depends upon the precision with which the point of contact of the slider is known. For example, if the length DH is known only to the nearest millimetre, the precision of the voltage measurement would, in general,

Figure 11.21 Simple potentiometer

be less than 1 in 1000. Much greater precision than this is often required, and to obtain it (and to secure a more compact form of apparatus) some elaboration and refinement in the circuit elements is required. Many practical forms of d.c. potentiometer have been devised.

### 11.9.1.4 Practical potentiometer

The potentiometer in Figure 11.22 is supplied across AB from a 2 V secondary cell through a rheostat  $R$ . Resistors  $R_2$ ,  $R_3$  and  $R_4$  are connected in series between A and B, but the conditions first considered are with  $R_4$  short circuited by the switch at  $P_1$ . The resistor  $R_3$  is divided into equal sections with 19 tapings brought out to studs, and there is an additional stud connected to a tapping on  $R_2$ .

One terminal of the standard cell is connected to a tapping on the parallel resistor  $R_1$ , and the other terminal may be connected (when the switch  $S$  is in the left-hand position

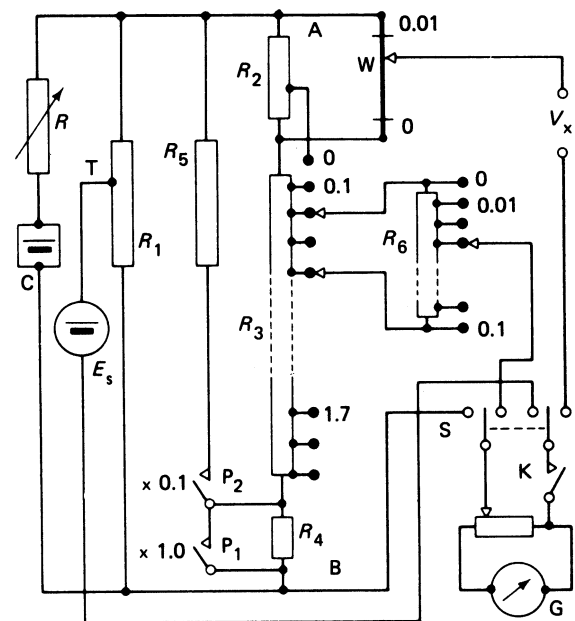

Figure 11.22 Practical potentiometer

and the key K is depressed) to the point B through galvanometer G. A balance may be obtained with the standard cell by adjusting the rheostat  $R$ , and the resistance values are such that the p.d. between successive studs on  $R_3$  is then precisely 0.1 V, and the voltage between A and B a little over 1.8 V. In parallel with the shunting resistor  $R_2$  is the slide wire W. The tapping on  $R_2$  enables a true zero, and small negative readings, to be obtained on W. By suitable choice of the resistance of  $R_2$  and W the voltage range covered by the whole slide wire is a little over 0.01 V.

$R_6$  is a tapped resistor with 10 equal sections and 11 studs. The total resistance of  $R_6$  is made equal to the resistance of two sections of  $R_3$ , and  $R_6$  always spans two sections by means of sliding contacts on the  $R_3$  switch as shown. The total resistance of  $R_6$  and two sections of  $R_3$  in combination is therefore always equal to a single section of  $R_3$  and the potential difference between successive tappings on  $R_6$  is then 0.01 V.

The unknown voltage  $V_x$  is applied to terminals connected through the galvanometer switch S to the sliding contact on W and to the tapping on the  $R_6$  switch. If the slide-wire dial has 100 divisions, each division represents 0.0001 V. Thus, for the switches in the positions shown,  $V_x$  might be 0.2376 V. The maximum  $V_x$  readable, assuming that there are some graduations provided beyond the 0.01 position on the slider dial, is  $1.7 + 0.1 + 0.0100 = 1.8100$  V.

The resistors  $R_4$  and  $R_5$  are introduced into the circuit by opening switch  $P_1$  and closing  $P_2$ ; this reduces the p.d.s in the potentiometer circuits to one-tenth of those marked. One division on the slider dial would then correspond with 0.00001 V or  $10 \mu\text{V}$ .

Medium- to high-precision potentiometers include a 'standard cell setter' so that the actual e.m.f. of the standard cell can be used for standardisation and, subsequently, for rechecking the standardisation during use *without* altering the measuring dials: this is more convenient, although less accurate than standardising against the dials. The contact T could be the slider of a 10-turn voltage divider with an indicated range, e.g. of 1.018 250 to 1.018 750 V in  $1\text{-}\mu\text{V}$  steps.

D.c. potentiometers of very high precision have a ratio non-linearity of  $\pm 5$  parts in  $10^6$ . A stable current of 50 mA must be provided by an electronic controller, and a high-gain low-noise detector is necessary: this may be a photo-cell galvanometer amplifier with a display sensitivity of 5000 mm/ $\mu\text{V}$  in a  $10\text{-}\Omega$  circuit.

#### 11.9.1.5 Comparator potentiometer (using m.m.f. balance)

The comparator potentiometer is one of a group of precision bridges employing mutual-coupled inductive ratio arms. The bridges exploit the high m.m.f. linearity and discrimination of a constant current in a variable number of turns.

A simplified network is shown in Figure 11.23. The measuring loop M is magnetically coupled to the balancing loop B by the turns  $N_m$  and  $N_b$ , respectively, on a magnetic core, which also carries a feedback winding with  $N_f$  turns. The feedback network includes an a.c. modulated sensor which actuates an a.c./d.c. electronic control network  $C_b$  to change the direct current  $I_b$  until a zero m.m.f. condition is achieved in the core.

#### 11.9.1.6 Operation and standardisation

If  $I_m$  and  $N_b$  are constant, then for an automatically maintained m.m.f. balance  $N_m I_m = N_b I_b$ , it follows that linear changes in  $N_m$  result in corresponding linear changes in  $I_b$ . As  $N_m$  has in effect a discrimination and linearity of about 1 in  $10^7$ , these properties are imposed also on  $I_b$ . To convert

this linear current scale to voltage across  $R_b$ , the instrument has to be standardised against a standard cell. The cell, of e.m.f.  $E_r$ , is connected (through S1) in opposition to the p.d. across  $R_m$ , and balance achieved by use of the adjustable direct-current controller  $C_m$ , which is then left to maintain this current level.

The equivalent cell e.m.f.  $I_m R_m$  is now connected (through S2) in opposition to  $I_b R_b$ , and  $N_m$  turns are selected to be numerically equal to  $E_r$ . The m.m.f. is balanced automatically by the feedback control system and by a small adjustment to  $N_b$  so that  $I_m R_m = I_b R_b = E_r$ , represented numerically by  $N_m$ . With switch S set to  $S_0$  the unknown p.d.  $V_x$  is presented through  $S_x$  and galvanometer  $G_1$  in opposition to  $I_b R_b$  and balance achieved by manual adjustment of  $N_m$ . Then  $N_m$  is numerically the unknown voltage.

Instruments of this kind are probably the most linear d.c. potentiometers available. They incorporate additional windings that enable the linearity to be checked by the operator. While the actual values of  $R_m$  and  $R_b$  are not of first importance, it is vital that they should be constant. Resistors are incorporated for subdivision of  $I_m$  for lower decades of  $N_m$  in order to simulate the  $10^7$  turns implied by a discrimination of 1 in  $10^7$ , but they do not contribute unduly to the overall non-linearity, which is about  $\pm 0.3 \times 10^{-6}$  of full scale. The system uncertainty must include that of the standard cell, at least  $\pm 1\text{--}2 \mu\text{V}$ .

#### 11.9.1.7 Pulse width modulation potentiometer<sup>12</sup>

This method subdivides a known stable d.c. voltage in terms of a time-period ratio. If a standard voltage source  $E_r$  is repeatedly connected to a low-pass filter through a very-high-speed semiconductor switch for a time  $t_1$ , and then disconnected for an additional time  $t_2$ , the high-frequency rectangular, chopped waveforms will, after smoothing, give an output  $E_0 = E_r t_1 / (t_1 + t_2)$  with  $t_1 + t_2 = T$ , a constant period. The time ratio can be precisely set using a variable time-interval counter for  $t_1$  and a fixed-period counter for  $T$ , with each counter being driven from a common highly stable crystal-controlled oscillator. An unknown voltage  $V_x$ , in opposition to  $E_0$  through a galvanometer, can be measured by variation of  $E_0$  (through the voltage-scaled setting of the  $t_1$  counter) until galvanometer zero balance is achieved. The e.m.f.  $E_r$  of the solid state source of steady voltage must be known accurately and the source must be capable of delivering small current surges into the low-pass filter without any significant change in voltage. Conversely,  $V_x$  and  $E_r$  could be interchanged when  $V_x > E_r$ .

One d.c. variable-voltage source uses the accurately determined voltage as input to constant gain d.c. amplifiers (designed for decade steps) to give a wide-range d.c. voltage standard source with  $\pm 50$  p.p.m. uncertainty (3-month stability) up to 1.2 kV with a  $25 \rightarrow 10$  mA (at 1 kV) current capability and  $0.5 \rightarrow 3.0$  s settling times.

#### 11.9.1.8 Applications

The d.c. potentiometer may be used to determine temperature by measuring the thermo-e.m.f.s in calibrated thermocouples. In conjunction with standard four-terminal resistors and shunts it is applied to the calibration of voltmeters, ammeters and wattmeters, and for the comparison of resistors. In Figure 11.24 the values  $V_x$ ,  $I_x$ ,  $R_x$  and  $P_x$  are unknowns, and  $E_p$  is measured by the potentiometer. Resistors  $R_1, \dots, R_7$  have known values. At (a) a voltage divider is used to measure  $V_x$ , and at (b) a shunt is employed to measure  $I_x$ . At (c)  $R_x$  is compared with  $R_4$  by means of

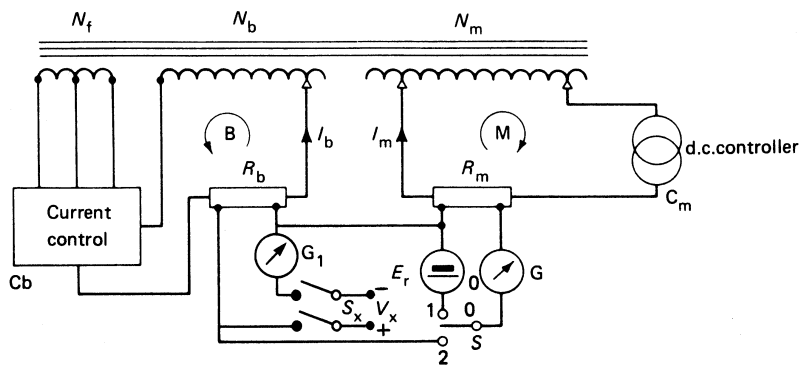

Figure 11.23 D.c. comparator potentiometer

Figure 11.24 D.c. potentiometer measurement of voltage, current, resistance and power

their respective p.d.s. The network (d) enables the power  $P_x = V_x I_x$  to be determined from  $V_x$  and  $I_x$ . The resistance of four-terminal resistors is known between the potential (inner) terminals, and *not* the current (outer) terminals, which minimises errors due to non-uniform current densities and contact resistances.

The National Physical Laboratory (NPL) designed 'Wilkins' resistor is a high-stability, four-terminal, a.c./d.c. resistor available in various decade and other values (Tinsley Co., London) which has an exceptionally low time constant for accurate a.c./d.c. comparator networks, etc.

### 11.9.2 A.c. potentiometers

The a.c. potentiometer may be used to measure the magnitude of an alternating voltage and its phase relative to a datum waveform. The measurements are normally restricted to sinusoidal waveforms, as the presence of harmonics makes a null balance impossible; and operation is usually confined to a single frequency. One recent instrument (Yorke) is capable of measurements up to audiofrequency, with an uncertainty approaching  $\pm 0.05\%$ . The general principles of the Larsen and Gall potentiometers are set out below.

#### 11.9.2.1 Larsen potentiometer

The primary winding of a variable mutual inductor is connected in series with a tapped resistor to a source of voltage  $V$ . The unknown voltage  $V_x$  is normally derived from the same source, because identity of frequency is essential. The supply current  $I$  is controlled by resistor  $R_1$  and indicated on an ammeter. The inductor secondary e.m.f. in series with

a tapped fraction of the volt drop across  $R$  is balanced against the unknown  $V_x$  (Figure 11.25) by means of the vibration galvanometer  $G$ , the sensitivity of which can be varied by resistor  $R_2$ . If  $M$  and  $R$  are the mutual inductance and resistance values at balance, then

$$V_x = \frac{I}{\omega} \sqrt{R^2 + \omega^2 M^2} \text{ and } \phi = \arctan(\omega M/R)$$

where  $\phi$  is the phase angle between  $V_x$  and  $I$ . In practice it may be necessary to reverse either or both of the component voltages to secure balance, and reversing switches are incorporated for this purpose. The mutual inductor should be astatic, to avoid pick-up errors.

#### 11.9.2.2 Gall potentiometer

The Gall potentiometer (Figure 11.26) provides two quadrature voltage components, summed and balanced against the unknown  $V_x$ . The supply voltage  $V$  is applied to the primaries of isolating transformers  $T_1$  and  $T_2$ . The secondary of  $T_1$  supplies a current, approximately in phase with  $V$ , to  $R_1$  which consists of a tapped resistor and slide wire in series. The current is adjusted by resistor  $R_3$  and read on an ammeter  $A$ , and passes through the primary of a fixed mutual inductor  $M$ . Any desired value of in-phase voltage (within the available range) is obtained from tappings on  $R_1$ . The primary of transformer  $T_2$  has a series resistor  $R_5$  and a variable capacitor  $C$ , and may be so adjusted that the current in  $R_2$  is in quadrature with that in  $R_1$ . The exact phase angle, and the calibration of the quadrature circuit, are achieved by balancing the secondary e.m.f. of the mutual inductor  $M$  against a fraction of the p.d. across  $R_2$ . Thus, variable voltages, phase and quadrature, can be obtained from  $R_1$  and  $R_2$ , respectively. These, in series, are balanced against the unknown  $V_x$  through the vibration

Figure 11.25 Larsen a.c. potentiometer

Figure 11.26 Gall coordinate a.c. potentiometer

galvanometer  $G$ . The reversing switches  $S_1$  and  $S_2$  facilitate balance and provide for a phase angle over a full  $360^\circ$ .

### 11.9.3 D.c. bridge networks

A bridge network has as its distinctive feature a 'bridge' connection between two nodes, with a null detector to sense the balance condition of zero p.d. between the nodes.

#### 11.9.3.1 Wheatstone bridge

The Wheatstone bridge is an arrangement in very wide use for the determination of one unknown resistance in terms of three known resistances. The network is shown in Figure 11.27, where  $R_1$ ,  $R_2$ ,  $R_3$  and  $R_4$  are resistors connected at the nodes  $a$  and  $b$  through a reversing switch  $S$  to a d.c. supply. The galvanometer  $G$ , with a shunting resistor to control its sensitivity, and the key  $K$  are connected to the nodes  $c$  and  $d$  as shown.  $R_1$  and  $R_3$  may be set at known fixed values.  $R_2$  is a variable resistor and  $R_4$  is the unknown resistance to be measured. The bridge is balanced by adjusting the value of  $R_2$  until the deflection of the galvanometer, set for maximum sensitivity, is brought to zero. The condition for balance is easily seen to be  $R_4/R_3 = R_2/R_1$  and is independent of the voltage applied to the bridge: whence the unknown is  $R_4 = (R_3/R_1)R_2$ . The bridge may be built up as a single unit with, for example,  $R_1$  and  $R_3$  each able to be set at one of the resistance values 1, 10, 100 or 1000  $\Omega$ . The bridge ratio  $R_3/R_1$  may therefore have a range of values from 1000/1 to 1/1000. In this case  $R_2$  might conveniently be adjustable, by means of dial switches, in steps of 1  $\Omega$  from 1 to 1110  $\Omega$ .

The bridge resistors are wound from manganin wire, since manganin is an alloy with a low temperature coefficient of resistance and a low thermoelectric e.m.f. to copper. Any thermoelectric e.m.f.s in the bridge connections which did not on average cancel themselves out could give a false result. Errors from this cause are eliminated by taking a balance for each position of the changeover switch  $S$  and using the mean of two observed values of  $R_2$ .

Figure 11.27 Wheatstone bridge

High-precision Wheatstone bridges are capable of measuring resistances between 1  $\Omega$  and 100 M $\Omega$  with uncertainties which vary between 5 and 100 in  $10^6$  of the reading over this range of values. Modern resistors are very stable devices and they should not change in value by more than a few parts in  $10^6$  per year; however, it is prudent to check the linearity of resistive bridges regularly, particularly if they are being used to the limit of the original specification. Some bridges have trimming facilities available with the principal resistors, although corrections can always be applied which although tedious, can avoid imposing new resistance drifts on the bridge as a consequence of changing stable resistors.

Various forms of high-quality bridges are used for measuring the changes which occur in resistive transducers. The Smith and Mueller bridges, used for measurements with precision platinum resistance thermometers, can yield 0.001 $^\circ$ C discrimination in readings. For strain gauge transducers there are portable bridges that can detect changes of 0.05% or less.

#### 11.9.3.2 Kelvin double bridge

The Kelvin double bridge is an adaptation of the Wheatstone bridge which may be used for the accurate measurement of very low resistances, such as four-terminal shunts or short lengths of cable. In the network (Figure 11.28)  $R_x$  is the unknown and  $R_s$  is a standard of approximately the same ohmic value. The two are connected in series in a heavy-current circuit (e.g. 50 A for  $R_s = 40$  m $\Omega$ , giving 0.5 V drop and adequate sensitivity). Suitable values for  $R_1$ ,  $R_2$ ,  $R_3$  and  $R_4$  are in each case a few hundred ohms. To use the bridge,  $R_1$  and  $R_2$  are made equal; then  $R_3$  and  $R_4$  are adjusted (keeping  $R_3 = R_4$ ) until balance is achieved. Then the balance condition is  $R_x/R_s = R_4/R_2 = R_3/R_1$ . Provided that it is short and of adequate cross-section, the connection between  $R_x$  and  $R_s$  does not affect the measurement.

Good-quality commercial bridges claim an uncertainty of about  $\pm 0.05\%$  for unknowns between 1  $\Omega$  and a few micro-ohms. Near the latter level a small constant resistance becomes a limitation. As  $R_1, \dots, R_4$  constitute a Wheatstone bridge network, a Kelvin bridge is often extended to measure two-terminal resistances up to 1 M $\Omega$  with an uncertainty of  $\pm 0.02\%$ .

#### 11.9.3.3 Digital d.c. low resistance instruments

Digital milliohm-meter/micro-ohmmeter instruments have built-in d.c. supplies; they are auto-ranging and make four-terminal measurements by internal comparator-ratio techniques to give, e.g.  $4\frac{1}{2}$ -digit displays in the case of the Tinsley 5878 micro-ohmmeter with 0.1  $\mu\Omega$  best resolution and uncertainty  $\pm 0.1\% \rightarrow 0.3\%$  of reading. Also, a IEEE 488 bus attachment is available for use in automated test systems. Thermal e.m.f. balance is incorporated as well as lead compensation.

Figure 11.28 Kelvin double bridge

### 11.9.3.4 Comparator resistance bridge

The comparator resistance bridge is a variant of the comparator potentiometer (Figure 11.23). In this case the network connections and adjustments are such that, at balance,

$$I_m R_m = \frac{R_b}{N_b} \text{ and } I_m N_m = \frac{R_b}{N_b}, \text{ whence } R_m = \frac{R_b}{N_b} \left( \frac{N_m}{N_b} \right)$$

where  $R_b$  is the known standard four-terminal resistor and  $N_b$  has been adjusted to make  $R_b/N_b$  an exact decade value. The unknown four-terminal resistance  $R_m$  is found in terms of a number of turns  $N_m$  and a decade factor.

The two resistors can be compared at different current levels, so that, for example, the rated current can be used with the test resistor, while the standard resistor can be used at a current well below the level at which self-heating effects would change its resistance value. The actual comparison uncertainty with this class of bridge is less than 1 in  $10^6$ , to which must be added the basic uncertainty in  $R_b$ , probably 2 in  $10^6$  if it is a class 'S' (or 'Wilkins') standard four-terminal resistor known to be stable.

### 11.9.4 A.c. bridge networks

A.c. network parameters (impedance, admittance, phase angle, loss angle, etc.) can be measured in the following ways:

- (1) Single-purpose or multipurpose a.c. bridge networks, with four or six arms or with inductive ratio arms.
- (2) Analogue and digital networks developed for special applications and consisting of frequency-selective or resonant or filter networks; they are associated usually with measurements at radiofrequencies and high audio-frequencies.
- (3) Digital multimeter instruments for measuring the modulus of the unknown parameter (but not other qualities).

The treatment in this subsection is confined largely to (1).

#### 11.9.4.1 Balance conditions

In the four-arm bridge of Figure 11.29, the arms comprise impedance operators  $Z_1$ ,  $Z_2$ ,  $Z_s$  and  $Z_x$ . The network is supplied at nodes a and b from a signal generator, and a sensitive null detector is connected between nodes c and d. If  $Z_1$  and  $Z_2$  (fixed standards) and  $Z_s$  (variable standard) are so adjusted that the p.d. between c and d is zero, then the unknown impedance  $Z_x$  depends on whether  $Z_1$  and  $Z_2$  are adjacent as in Figure 11.29(a), or in opposite arms as in Figure 11.29(b); in either case the balance condition is that the product of pairs of opposite arms is equal, giving

- (a) ratio bridge:  $Z_x = \frac{Z_1}{Z_2} Z_s$ ;  
 (b) product bridge:  $Z_x = \frac{Z_1}{Z_2} Z_s$

where  $Y_s = 1/Z_s$ . These are complex expressions, so that the equality involves both magnitude and phase angle; alternatively, both phase ('real') and quadrature ('imaginary')

**Figure 11.29** Basic four-arm a.c. bridge. (a) Ratio bridge; (b) product bridge

components. Thus, equation (a) above can be written in terms of magnitudes in either of the following ways:

$$Z_x \angle \phi_x = \frac{Z_1}{Z_2} \angle (\phi_s + \phi_1 - \phi_2) \Leftarrow$$

$$R_x + jX_x = (R_s + jX_s)(R_1 + jX_1)/(R_2 + jX_2) \Leftarrow$$

The bridge arms will include intentional or stray inductance and capacitance, and the corresponding reactances are functions of frequency. Most practical bridges are so chosen that only two or three final adjustments are necessary to obtain the optimum null condition of the detector.

#### 11.9.4.2 Signal source

The bridge supply can be from a screened power-frequency instrument transformer, but more probably from a fixed- or variable-frequency signal generator (see Section 11.7.4). A voltage up to 30 V may be required, but a few volts is normally adequate, especially for radiofrequency bridges. The maximum power of a signal generator is of the order of 1000 mW, so that to avoid overload and distortion it is important that the appropriate voltage be set and a reasonable match be obtained between the generator and the effective input impedance of the bridge network.

#### 11.9.4.3 Detector

A moving-coil vibration galvanometer may be used at discrete frequencies over the range of 10 Hz–1.2 kHz. The galvanometer has a taut suspension mechanically tuned to the operating frequency. The method is sensitive, and effectively filters harmonics, but it is often more convenient to employ the electronic detectors included in most commercial bridges. These include tuned-resonance amplifier networks or broad band high-gain electronic amplifiers; both give a rectified out-of-balance display on a d.c. instrument, with 'magic eye' or c.r.o. as possible alternatives. In some portable instruments it was the practice to use head-telephone sets, which are highly sensitive in the audio range of 0.8–1.0 kHz.

#### 11.9.4.4 Bridge-arm components

Precision a.c. resistance boxes can be designed with very low time constants. They are available with switched or plugged groups of ten resistors in decade values between 0.1  $\Omega$  and 1 M $\Omega$ . Careful construction and screening enable some of these devices to be used at frequencies up to 1.2 MHz before the residual reactance becomes significant. An overall uncertainty of  $\pm 0.05\%$  is possible, but 0.1–1.0% is more conventional. (See also Section 11.9.1.8.)

Multi-dial switched mica capacitors are available with good stability and low loss tangent. Single- and double-screen capacitors have respectively, three and four terminals, and care is needed to avoid unwanted stray capacitance, the screens being maintained at the proper potentials with respect to the equipment and the environment.

Continuously variable calibrated air-dielectric capacitors with ranges between 20 and 1200 pF are used for small adjustment, and ranges of fixed or variable mutual inductors are available. For high-voltage bridges the standard capacitors are of fixed value, and designed with air or compressed gas as dielectric for 300 kV and above.

#### 11.9.4.5 Low-frequency and audiofrequency bridges

A selection is given of the more important bridges, many of which form the basis of commercial instruments; for example, the inductance bridges of Maxwell and Hay, the modified de Sauty bridges for capacitance, the Schering

bridge for capacitance and loss tangent at low and high voltages, and the Wien bridge for frequency and a.c. resistance. These bridges are commonly made to give results with a  $\pm 1\%$  uncertainty, but can be designed for  $\pm 0.1\%$ .

All bridges should be checked occasionally to show that the reference standard components have not changed and that the range and ratio division has not drifted; also, if the bridge is frequency sensitive, the frequency of the oscillator and the drift rate should be investigated. Naturally, superior standard components must be available which have recent 'traceability' certification, in addition to accurately known decade-ratio measurement techniques. Where bridge measurements are implicit in contract specifications, it may be prudent or necessary to justify the claims by referring the instrument to a calibration service standards laboratory.

#### 11.9.4.6 Mutual inductance

Figure 11.30(a) shows the simple Felici–Campbell bridge for the measurement of an unknown mutual inductance  $M_x$  in terms of a variable standard  $M$ . For balance on the null detector D, then  $M_x = M$ , on the assumption that the inductors are perfect, i.e. that the secondary e.m.f. is in phase quadrature with the primary current. Each, however, has a small in-phase component that can be represented by an equivalent resistance  $\sigma$ . The modification in Figure 11.30(b) shows Hartshorn's arrangement, which enables the impurities to be measured: at balance by adjustment of  $M$  and  $r$ , the conditions are  $M_x = M$  and  $\sigma_x = r + \sigma$ .

#### 11.9.4.7 Inductance

Inductance may be measured by Wien's modification of the Maxwell bridge (Figure 11.31(a)). If the unknown inductor has an inductance  $L_x$  and an equivalent series resistance  $R_x$ , balance gives

$$L_x = R_2 R_3 C_1; \quad R_x = R_2 R_3 / R_1; \quad Q_x = \omega L_x / R_x = \omega C_1 R_1$$

The advantage is that inductance is measured in terms of a high-quality and almost loss-free capacitor. The bridge can measure a wide range of inductance values with  $Q$  factors less than 10. High  $Q$  factors require excessively large values of  $R_1$ , and by creating the same effective phase characteristic by means of a low-valued resistor  $R_1$  in series with  $C_1$ , the Hay bridge of Figure 11.31(b) is obtained. The balance conditions for it are

$$Q_x = \omega C_1 R_1; \quad R_x = R_2 R_3 / R_1 (1 + Q_x^2);$$

$$L_x = R_2 R_3 C_1 / (1 + Q_x^2)$$

A disadvantage is the need to measure the frequency.

A commercial instrument using the Maxwell and Hay bridges has built-in supplies at frequencies of 50 Hz, 1 kHz and 10 kHz, and an inductance range from 0.3  $\mu\text{H}$  to 21 kH with an accuracy within  $\pm 1\%$ . The loss resistance is known to about  $\pm 5\%$ , and it is possible to introduce a d.c. bias.

Figure 11.30 Mutual inductance bridges. (a) Felici–Campbell; (b) Hartshorn

Figure 11.31 Inductance bridges. (a) Maxwell–Wein; (b) Hay

#### 11.9.4.8 Capacitance at low voltage

Relatively pure capacitors can be measured by the de Sauty bridge (Figure 11.32(a)), the balance condition for which is  $C_x = \epsilon_s (R_4 / R_3)$ . Imperfect capacitors can be compared by the arrangement shown in Figure 11.22(b), in which the imperfection is represented by a series resistance  $r$ . To obtain balance, adjustment of all four resistors  $R$  is necessary:

$$C_x = \epsilon_s (R_4 / R_3) = \epsilon_s [(R_2 + r_s) / (R_1 + r_x)] \leftarrow$$

For the loss tangent,

$$\tan \delta_x = \tan \delta_s + \omega C_s [R_2 - (R_1 R_4 / R_3)] \leftarrow$$

Portable commercial capacitance testers, with battery-driven 1 kHz oscillators and rectified d.c. or headphone detectors, use a modified de Sauty bridge network so that loss tangent can be estimated and the capacitance measured to an uncertainty of about  $\pm 0.25\%$ .

#### 11.9.4.9 Capacitance at high voltage

Dielectric tests at high voltages, particularly of the loss tangent, can be made with the Schering bridge (Figure 11.33). The bridge is in wide use for precision measurements on solid and liquid dielectrics, and for insulation testing of cables, high-voltage machine windings and capacitor bushings. The capacitance of the high-voltage standard capacitor  $C_s$  is calculable, and with an air or gas dielectric can be assumed to have zero loss. A typical standard capacitor for 150 kV is shown in Figure 11.34; for higher voltages the clearances necessary for avoiding corona and breakdown are large, but the dimensions can be reduced by a construction in which the dielectric gas is under pressure.

The test capacitor in Figure 11.33 is represented by  $C_x$  and a series loss resistance  $r_x$ .  $R_3$  is a variable resistor, and the fourth arm comprises a variable low-voltage capacitor  $C_4$  in parallel with a resistor  $R_4$  (which may be fixed). Then, for balance

$$C_x = \epsilon_s (R_4 / R_3) \leftarrow \text{and} \quad \tan \delta_x = \omega C_4 R_4$$

The loss tangent is a valuable and sensitive indication of the quality of the test insulation. If periodical tests reveal a gradual increase in the loss tangent, then deterioration is

Figure 11.32 Capacitance bridges. (a) De Sauty; (b) modified de Sauty

Figure 11.33 Schering bridge

Figure 11.34 Air capacitor

occurring, the loss power is increasing and breakdown in service is probable.

To avoid electric field coupling between bridge components—in particular, between the high-voltage electrodes and the connecting leads—that would affect accuracy, components  $R_3$ ,  $R_4$  and  $C_4$  are enclosed in metal screens connected to the earthed point A. Again, to avoid errors due to intercapacitive currents between the centre low-voltage electrode and the guard electrode of  $C_s$ , these electrodes should be brought to the same potential by aid of the auxiliary branches  $C_g$  and  $R_g$ . Balance is achieved with the detector switched to this combination, in addition to the main balance. If the test capacitor  $C_x$  is a cable with an earthed sheath, or a capacitor bushing on site and not readily insulated from earth, then the bridge node A must be isolated: careful screening is now even more necessary. Figure 11.35 shows the arrangement for a portable Schering bridge equipment for testing an earthed bushing. It will be seen that an earthed screen isolates the bridge from the transformer primary, and a second screen connected to point A keeps capacitive currents from the high-voltage connections out of the bridge arms.

**Discharge bridge** This has been developed to detect the onset of void breakdown in cables and bushings. The network (Figure 11.36) can be used to test an unearthed component—for example, the bushing  $C_x$ ; the arrangement resembles that of the Schering bridge. The stray capacitances of the guards and screening of  $C_s$  act as the capacitance  $C_4$ , which, however, at the discharge frequencies concerned, is greater than that required for balance. Hence, it is necessary to provide the variable capacitor  $C_3$ . The bridge output is fed to a rectifier milliammeter D through a filter and amplifier designed to pass, e.g. the band 10–20 kHz, so that the indication is a measure of the discharge current. On the supply side of the bridge is connected some

Figure 11.35 Schering bridge and earthed bushing

Figure 11.36 Discharge bridge

artificial source of discharge voltage, such as the neon tube N, which serves initially to balance the detector D.

#### 11.9.4.10 Wagner earth

Capacitance between bridge arms and earth in the Schering bridge causes disturbing currents to flow so that false balance conditions may result. If, as in Figure 11.37, the bridge supply is not earthed but the nodes c and d are at earth potential, then the detector is also at earth potential and no stray capacitance currents can flow in it. Further, all branch capacitances to earth are stabilised. The Wagner earth method secures this condition by the use of the additional impedances  $Z_5$  and  $Z_6$ , the junction of which is solidly earthed.  $Z_5$  and  $Z_6$  must be of the same type as either  $Z_1$  and  $Z_2$ , or  $Z_3$  and  $Z_4$ . If balance is achieved for both positions of the switch, then nodes c and d must have the same potential as the earthed junction, which is zero. Stray capacitance at a and b is innocuous as it merely 'loads' the supply.

The Wagner earth is usually applied to commercial Schering bridges, but the technique is applicable to any bridge and can be particularly helpful at higher frequencies.

#### 11.9.4.11 Inductive ratio-arm bridge

The principle is explained by reference to the simplified diagram in Figure 11.38(a), the essential features being the coupled windings of, respectively,  $N_x$  and  $N_s$  turns. If the voltage per turn is  $v$ , then the two windings have the voltages  $V_x = N_x v$  and  $V_s = N_s v$ , respectively. Let  $V_x = \frac{1}{\omega C_s}$ ; then the current  $I_x$  through the unknown capacitive admittance  $Y_x$  can be made equal to the current  $I_s$  by variation of the parallel standards (conductance  $G_s$  and capacitance  $C_s$ ),

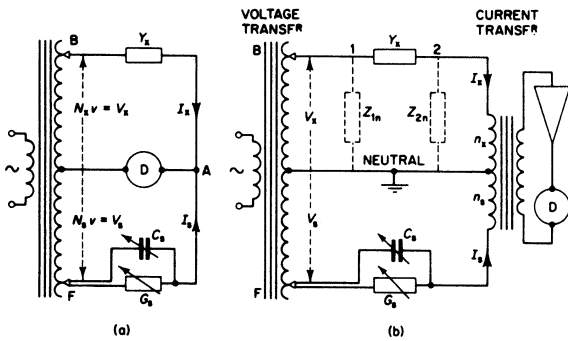

Figure 11.37 Wagner earth arrangement

**Figure 11.38** Inductive ratio-arm bridge. (a) Basic principle; (b) with isolated detector

until the detector shows a null reading. For this condition the standard admittances represent the *parallel* equivalent network values of  $Y_x$ . If  $Y_x$  is inductive, the  $C_s$  connection at F is transferred to B to avoid the use of standard inductors, which are very inferior to standard capacitors.

The voltage linearity of the input transformer is of fundamental importance to this class of bridge. With modern techniques and magnetic core materials, it is possible to wind toroidal cores to produce an extremely uniform reactive distribution (leakage inductive reactance and turn-to-turn capacitance) with a resultant non-linearity of about 1 in  $10^7$  in the magnitude of the mutually induced e.m.f. per turn.

In one well-known bridge (Wayne Kerr) the primary winding of a current transformer is inserted at A and the detector removed to the secondary winding as in *Figure 11.38(b)*. The two parts of the primary winding ( $n_s$  and  $n_x$  turns) are wound in opposite senses and the detector can indicate the zero m.m.f. condition in the windings.

In general,  $N_s$  differs from  $N_x$  and  $n_s$  from  $n_x$ , so that  $I_x n_x = I_s n_s$  for balance; further, the primary of the current transformer is at the ground (or earth) potential of the neutral if the trivial resistance drop of the windings is ignored, so that  $I_x = (N_s/n_s) Y_x$  and  $I_s = (N_x/n_x) Y_s$ . Combining these results gives

$$Y_x = \frac{N_s}{N_x} \left( \frac{n_s}{n_x} \right) Y_s$$

The double turns ratio product can be used to permit *one* accurate standard resistor or capacitor to be switched to any  $N_s$  turns of value 1–10 to simulate *ten* accurate standard components by the precise selection of turns. Moreover, wide-range multiplication of the simulated standard is achieved by decade tappings on  $N_x$  and  $n_x$ .

An important advantage with this class of bridge is the possibility of connecting the neutral to earth; then small leakage currents from  $Y_x$  to earth are almost completely eliminated, since the current transformer is at earth potential and any *small* leakage currents from the high-voltage side of  $Y_x$  merely cause a slight *uniform* reduction in  $v$  but does not alter the turns ratio. Hence, determinations such as the following are possible:

- (1) One-port low-capacitance measurement in the presence of a large shunt capacitance due to connecting leads.
- (2) One-port *in situ* impedance measurement, the effect of the remainder of the network (shown dotted in *Figure 11.38*) is neutralised.
- (3) Three-terminal impedance transfer functions for correctly terminated networks.

The results of measurements appear in *parallel admittance* form, and may require elementary computation to

render them into *series impedance* form, with due regard to frequency. With medium to high values of impedance, resistance and capacitance are unaffected, but for inductance measurement (involving a ‘resonance’ balance) a reciprocal  $\omega^2$  correction is needed. For low-impedance networks, resistance and inductance are unchanged but capacitance readings require correction.

#### 11.9.4.12 Characteristics

Universal bridges of the inductive ratio-arm type measure over a wide range of values, at an angular frequency of, e.g., 10 krad/s from a built-in oscillator, or at other frequencies up to 10 MHz using external signal generators and tuned electronic detectors. The measurement uncertainty can be within  $\pm 0.1$ –1.0%, provided that the standard component values are trimmed against superior standards and that the actual frequency is measured when frequency sensitive parameters are measured.

The Wayne Kerr precision bridge operates at 1591.55 Hz ( $\omega = 40$  krad/s) and the six-figure display has a minimum uncertainty of 0.01%. The instrument uses an electronic null-seeking process to assist the *automatic* balancing procedure. With external source the bridge has a frequency range of 0.2–20 kHz with manual balancing.

Admittance bridges are commercially available to operate up to 100 MHz. At this frequency lumped parameter measurements are being displaced by distributed-parameter network characteristics.

#### 11.9.4.13 Current comparator bridge

The a.c. current comparator instrument uses current transformers only in the load network. It is based on the principle, of m.m.f. (i.e. ampere-turn) balance on an ideal magnetic circuit, in which the current ratio is the inverse turns ratio.

The two basic current coils, P and S in *Figure 11.39*, are wound in opposing senses on a common magnetic core with a high initial permeability. The null m.m.f. condition is sensed by winding M and manual selection of the turns ratio  $N_p/N_s$ . The ideal balance condition can be closely approached in practice by shielding the detector from magnetic leakage by a laminated magnetic screen and by a compensation winding  $W_c$ . The shield must not form a short-circuited turn; but it does aid magnetic energy transfer between windings P and S. This is advantageous in current-transformer calibration, as it enables an external burden B to be supported under balance conditions. Any change in the capacitive error due to B can be neutralised by  $W_c$  connected on one side of the separate centre-tapped transformer  $W_b$ . By careful design the capacitance distribution is uniform.

**Figure 11.39** Current comparator with capacitive and burden compensation

The internal p.d. of the major winding can be neutralised by a parallel compensation winding  $W_c$  wound within the magnetic shield, so reducing capacitive currents, as it can be held at earth or reference ground potential.

The commercial range of comparators include d.c. potentiometers, direct voltage and current ratios, d.c. and a.c. four-terminal resistance comparison, voltage- and current-transformer errors, and high-voltage capacitor comparison. All the instruments derived from d.c. and a.c. comparators possess very linear properties, excellent discrimination and good stability. When certified they can be used as comparative reference standards.

#### 11.9.4.14 H.V. capacitance comparator bridge

Standard capacitors used with high-voltage bridges (such as the Schering and comparator types) use compressed gas construction up to a maximum of 1000 pF, although 100 pF is more common. Measurement of such capacitors is based on the principle that a stable alternating voltage to two capacitors produces a current ratio equal to the capacitance ratio. The variable turns ratio of the comparator bridge can be used to balance an unknown capacitor up to 1000 times as large as the standard. By cascading, the range can be extended still further.

#### 11.9.4.15 Substitution

In any active network the equivalent parameters of a component may be measured if variable reference standards can be either substituted for the component or connected in parallel with it—provided always that the standards can be adjusted so that no final change occurs in the voltage, current, phase or harmonic content of the waveforms in the network. The substitution principle can be applied to any type of bridge, or other class of network; resonant networks often provide the best discrimination between the two conditions. It is important that the stray capacitance, inductance and resistance paths, to earth and between components, should be unchanged by the act of substitution; hence, for the substitution test there should be (ideally) no change in the geometrical layout of leads and components. This can be easily achieved with low-loss changeover switches or coaxial connectors.

For the measurement of radiofrequency components, where shunt capacitance effects are prominent, the substitution principle is particularly valuable. Typical applications are discussed below.

#### 11.9.4.16 Parallel-T network

Figure 11.40(a) shows a general parallel-T network, with an a.c. source as input and a detector across the output terminals. The balance condition (of zero output) in terms of the impedance operators is

$$Z_1 + Z_2 + (Z_1 Z_2 / Z_3) + Z_4 + Z_5 + (Z_4 Z_5 / Z_6) = 0$$

Figure 11.40 Parallel-T networks

Suppose that  $Z_1$  and  $Z_2$  are pure reactances of like sign, e.g.  $-jX_1$  and  $-jX_2$ , and that  $Z_3$  is purely resistive, then

$$Z_1 Z_2 / Z_3 = -(X_1 X_2 / R_3) \leftarrow$$

which is equivalent to a negative resistance and capable of balancing out a positive resistance in  $Z_4$  or  $Z_5$ . An example is shown in Figure 11.40(b). The source is a modulated signal generator and the detector is, in effect, a radio receiver tuned to the 'carrier' frequency. Balance is achieved by variation of  $C_3$  and  $C_6$  with the test terminals open-circuited. If an unknown admittance  $G_x + jB_x$  is now connected across the test terminals and the disturbed balance restored by altering  $C_3$  and  $C_6$  to  $C'_3$  and  $C'_6$ , respectively, then

$$B_x = \omega(C_3 - C'_3) \text{ and } G_x = \omega^2 C^2 (C'_6 - C_6) P / C_4$$

Bridge screening is simplified because the common source and detector terminal can be earthed. The use of a variable resistor as a balance arm can often be avoided, a considerable simplification for radiofrequency measurement.

#### 11.9.4.17 Bridged-T network

This can be used at frequencies up to about 50 MHz. Figure 11.41(a) shows the schematic arrangement, and Figure 11.41(b) illustrates a common application. If the unknown impedance  $Z_x = R + j\omega L$  is such that  $R^2$  is negligible compared with  $\omega^2 L^2$ , then for balance

$$1/\omega^2 LC = 2 \quad \text{and} \quad R = S/4$$

whence  $R$  and  $L$  can be obtained if the angular frequency  $\omega$  is known.

## 11.10 Measuring and protection transformers

Measuring (instrument) transformers are used primarily for changing currents and voltages in power networks to values more suited to the range of conventional indicators. Protection transformers are employed in systems of fault protection. Both types are dealt with in BS 3938 (*Current transformers*) (IEC 185) and BS 3941 (*Voltage transformers*) (IEC 186 and 186A).

### 11.10.1 Current transformers

Air-cooled current transformers (c.t.) are used in circuits of voltage up to 660 V and currents up to 75 kA. The *bar primary* form employs the actual cable or bus-bar of the main circuit as the primary winding. The core is built of high-grade steel laminations in rectangular or circular shape. The secondary has the appropriate number of complete turns uniformly around the annular core or on all four sides of

Figure 11.41 Bridged-T networks

the rectangular core. The assembly of core and secondary encloses the bar primary, which is equivalent to a single turn.

For lower primary currents it is necessary to provide a conventional primary winding. This gives a better primary/secondary coupling and a greater accuracy.

Current transformers must be insulated to withstand the service voltage, which may be up to 400 kV. Oil immersion may be necessary, in which case the core and coils are clamped to the top cover to facilitate removal as a complete unit.

#### 11.10.1.1 Burden and output

Primary currents have preferred values between 1 A and 75 kA, with rated secondary currents of 5 A and 1 A (also 2 A). The *rated burden* is the ohmic impedance  $Z_T$  of the secondary circuit when carrying the rated current  $I_s$  at a stated power factor. The *rated output* is the volt-ampere product  $(I_s Z_T) I_s$ . The rated output, the limiting value for which accuracy statements apply, appears in selected preferred values between 1.5 and 30 VA. The normal operating mode of a c.t. is as a low-impedance device; hence, a short-circuiting switch is provided for the secondary winding for use when a low-impedance load (e.g. an ammeter) is not connected to the secondary terminals.

#### 11.10.1.2 Errors

In an ideal c.t. the primary/secondary current ratio is precisely the same as the secondary/primary turns ratio, and the currents produce equal m.m.f.s in exact antiphase. In a practical c.t. the current ratio diverges from the turns ratio, and the phase angle differs by a small defect from opposition. These *ratio* and *phase angle errors* arise from that component of the primary current required to magnetise the core and provide for core loss, and from the e.m.f. necessary to circulate the secondary current through its burden. In transformers intended for accurate measurement and for metering, these errors must be small.

#### 11.10.1.3 Classification

The limits of error define the 'class' of transformer. BS 3938 defines six classes for measuring and three for protective c.t.

**Measuring c.t.** The classes in descending order of accuracy are designated AL, AM, BM, CM, C and D. The limits of ratio error vary from  $\pm 0.1\%$  for AL to  $\pm 5\%$  for D; and the phase error from  $\pm 5$  min in AL to  $\pm 120$  min ( $2^\circ$ ) in types CM and C, with no limits quoted for type D.

**Protective c.t.** The classes are termed S, T and X. The limits of ratio error for S and T are, respectively,  $\pm 3$  and  $5\%$ , and the corresponding phase limits are  $3^\circ$  and  $6^\circ$  approximately. Limits for type X are not stated explicitly. In testing S, T and X classes it is necessary to distinguish between low- and high-impedance types.

#### 11.10.1.4 Measurement

Errors are normally measured by comparison with a c.t. of higher class. By convention, a phase error is positive when the secondary current phasor leads that of the primary current.

#### 11.10.1.5 Arnold method

In Figure 11.42 C is the c.t. under test and B is a standard of the same nominal ratio and having known, very small

Figure 11.42 Arnold method for measurement of current-transformer errors

errors. The working burden of the test c.t. is  $Z$ . The network is such that the difference between the secondary currents  $I_b$  and  $I_c$  flows in the non-reactive resistor  $R$  and is measured by means of the mutual inductor  $M$  and slide wire  $r$  fed by the auxiliary c.t.  $F$  (conveniently of ratio 5/5 A). Phase balance is achieved by adjusting  $M$  (positive or negative), and ratio balance by selection of  $r$  around the centre-tap of  $P$ . From the phasor diagram, the components of the difference current  $I$  are approximately  $I_b - I_c$  and  $-jI_c(\beta_c - \beta_b)$  because the phase angles are actually very small. At balance the condition is given by  $I_b(r - j\omega M) = RI$ . Equating the 'real' parts gives  $I_c/I_b = 1 - (r/R)$ ; whence in terms of the current ratios  $k_c = I_p/I_c$  and  $k_b = I_p/I_b$ , where the primary current is common to both c.t.s,

$$k_c = k_b(I_c/I_b) = k_b/[1 - (r/R)] \simeq k_b[1 + (r/R)] \Leftarrow$$

provided that  $r \ll R$ . Equating the 'imaginary' parts gives

$$\beta_c - \beta_b = (\omega M/R)(I_b/I_c) \simeq \omega M/R$$

The bridge readings give the errors directly by comparison with those of the reference transformer.

#### 11.10.1.6 Kusters method

This is a comparator method (Figure 11.43) in which C is the c.t. under test with its rated burden  $Z$ , and B is an a.c. comparator with the same nominal ratio as C but possessing negligible errors. The errors of C can be deduced directly from the balance settings of the arms of the parallel  $G - C_1$  network.

### 11.10.2 Voltage transformers

Magnetically coupled voltage transformers (v.t.) resemble power transformers in basic principle, and have recommended primary voltages up to  $396/\sqrt{3}$  kV. Oil-immersion

Figure 11.43 Kusters method for measurement of current-transformer errors

is necessary for these levels. The preferred secondary voltages lie between  $110/\sqrt{3}$  and 220 V/ph.

#### 11.10.2.1 Burden and output

The preferred rated output burdens lie between 10 and 200 VA/ph, and the rated burden is normally the limit for which stated accuracy limits apply.

#### 11.10.2.2 Errors

Five classes are listed in descending order of accuracy, namely AL, A, B, C and D. The voltage ratio error limit varies between 0.25 and 5% and applies for *small* voltage changes ( $\pm 40\%$ ) around the rated voltage; and the phase error limits are  $\pm 40$  min to  $\pm 60$  min from class AL to class C. The phase error of D is not defined.

For dual purpose v.t. (i.e. for both measuring and protective application) additional classes E and F are defined which quote the permitted limits of error for classes A, B and C when used at voltages between 0.05 and 1.9 times rated voltage. The v.t. is then denoted by both relevant class letters. The extended error limits are  $\pm 3=5\%$  and  $\pm 2=5\%$ .

#### 11.10.2.3 Measurement

By convention, a phase error is positive when the secondary voltage phasor  $V_s$  leads the primary voltage phasor  $V_p$ . The ratio error is  $(k_r V_s - V_p)/V_p$ , where  $k_r$  is the nominal rated transformation ratio. The rated output is stated in volt-amperes at unity power factor for the specified class accuracy.

#### 11.10.2.4 Dannatt method

This deduces the error in terms of network parameters (Figure 11.44). The v.t. primary is fed from a supply to which is also connected the standard air capacitor  $C_s$  in series with a low-valued resistor  $R_s$ . The v.t. secondary is loaded with the rated burden  $Z$  in parallel with a series-parallel network comprising high-valued resistors  $R_1$  and  $R_2$ , a capacitor  $C_1$  and the primary of a mutual inductor  $M$ . The secondary voltage of the mutual inductor is balanced against the volt drop across  $R_s$ . To ensure that the guard and guarded electrodes of  $C_s$  are held at the same potential, a variable resistance  $R_g$  is connected so that balance is obtained with either position of the switch  $S$ . The balance condition is such that the ratio and phase errors are given very closely by

Figure 11.44 Dannatt method for measurement of voltage-transformer errors

$$M/C_s R_s (R_1 + R_2) \leftarrow \text{and } \omega(L - C_1 R_1^2)/(R_1 + R_2)$$

where  $L$  is the self-inductance of the mutual inductor primary.

#### 11.10.2.5 Kusters method

The a.c. comparator bridge can be applied. The capacitance ratio of two gas-filled high-voltage capacitors supplied by a common secondary voltage is measured with the currents passing through the separate balancing windings. If one high-voltage capacitor and its series-connected balancing winding are now fed from the primary supply of the v.t., then the voltage ratio can be found by rebalancing the comparator when the two capacitors are connected, respectively, to the primary and secondary voltages.

#### 11.10.2.6 Capacitor-divider voltage transformer

For high-voltage transformers for 100 kV and above, a more economical and satisfactory voltage division for measurement and protective purposes is given by use of the capacitor-divider system (Figure 11.45). The reduced intermediate voltage appears across the protecting gap  $G$  as the input to a tuned transformer. Changes in the secondary burden  $Z$ , which would adversely affect the errors, are minimised by adjusting the transformer leakage reactance and/or that of a series inductor  $L$  to resonate with the input capacitance  $(C_1 + C_2)$  effectively across the primary. There is a consequent sensitivity to frequency.

The classification is the same as for magnetic transformers, except that AL does not apply and there is an additional limitation on frequency. The transient performance is naturally significantly different from that of the normal v.t.

## 11.11 Magnetic measurements

Because of the non-homogeneity of bulk ferromagnetic materials, magnetic metrology is relatively inaccurate and imprecise. The fields of interest lie in the basic physics of magnetism, the distribution of the magnetic field, the assessment of magnetic parameters, and the measurement of core loss.

**Physical basis** The origin of magnetic phenomena lies in the statistical quantum-mechanical behaviour of electrons and particles. Additional information can be obtained by photography of domain formation.

**Field distribution** Two-dimensional field distributions in air-gaps are readily traced by current-field analogues such as conducting paper or the electrolytic tank. The tank can also be employed for restricted three-dimensional fields, and tests around models or actual equipments can be

Figure 11.45 Capacitor-divider voltage transformer

based on various types of small sensor working into calibrated instruments (fluxmeter or ballistic galvanometer) or a Hall effect device.

*Parameters* The 'static' magnetisation characteristic, the relative permeability and the hysteresis loop are the principal parameters of interest.

*Core loss* The loss in a core is a matter of considerable technological importance. It is, however, very difficult to measure directly the losses in such a way that the results can be directly applied to machine constructions other than transformers.

### 11.11.1 Instruments

The most simple fundamental standard of magnetic flux density is based on the accurately known dimensions of a long, uniformly wound solenoid carrying a known current. Alternatively, a uniformly wound toroid can be used, although in this case the flux density will not be quite uniform across the core section. The measurement of flux and flux density can be carried out by means of the ballistic galvanometer or fluxmeter for the former, and the Hall effect instrument for the latter.

#### 11.11.1.1 Ballistic galvanometer

The moving coil of a galvanometer with a long periodic time gives a first swing proportional to the time integral of the current through it (i.e. the charge) provided that the duration is very short. The charge results from a time integral of voltage (i.e. magnetic linkage) impressed on a known resistance. The moving coil is connected in series with a search coil and a resistor, and is immersed in the magnetic field due to a known current. When this current is *rapidly* reversed, the total change of linkage is presented to the galvanometer as an impulsive charge, and the first deflection of the instrument is used for calibration against a known (or calculable) linkage change, or for measuring an unknown linkage. The main limitations to accuracy are the observation of the scale and the uncertainty in the current measurement. A typical high sensitivity ballistic galvanometer has a period of 20 s, a moving-coil resistance of 850  $\Omega$ , and a sensitivity of 8.5 m $\mu$ C on a scale distant 1 m from the coil using a lamp and mirror technique.

#### 11.11.1.2 Fluxmeter

The fluxmeter is a permanent-magnet instrument with a moving coil of low inertia and negligible control torque. Its damping is made high by use of a relatively thick aluminium former, so that the period is long. It is immaterial whether the time taken to change the linkage in a search coil connected to the moving coil is long or short, and in consequence the instrument is useful in iron testing, where the time taken for a flux to collapse or reverse may be several seconds. The deflection is read from the initial position of a pointer on a quadrant scale when the pointer reaches its maximum deflection; after this the pointer drifts slowly back to a zero position. A typical full-scale deflection would be given by a change of 10  $\mu$ Wb-t.

Strong air-gap flux densities can be measured by an alternative method in which a small coil is rotated at a high and known speed, the induced e.m.f. being proportional to the local flux density.

#### 11.11.1.3 Hall effect instrument

The Hall effect applies to conductors generally, but its application is normally associated with semiconductor materials. These should be of low resistance so that, even for small signals, the thermal (Johnson) noise effects will be low. Bulk materials, indium arsenide and indium antimonide, have low resistances and good output voltage coefficients, with the InSb voltage larger than that of InAs; however, InAs is usually selected, as its temperature coefficient is one-tenth that of InSb. Thin-film InSb is used for switching applications where the higher output e.m.f. is the prime consideration. The Hall effect response is very fast, being usable up to the megahertz range. Bulk material InAs elements are more effective than thin-film elements, owing to the much lower resistances obtainable.

In commercial instruments the current  $I_c$  in the sensing element can be a direct current chopped at audio frequency; the resultant audiofrequency Hall voltage  $E_H$ , after linear amplification and demodulation, can be displayed on a taut-band d.c. moving coil indicator against a calibrated scale of flux density. Typical ranges have full-scale deflections between 0.1 mT and 5 T for steady fields. Pulsating fields can be measured with d.c. instruments at frequencies up to 500 Hz with a cathode-ray-oscilloscope detector. Instruments for alternating fields only are available for frequencies of about 30 kHz, with ranges similar to those of d.c. instruments.

An instrument and probe can be checked by use of stable reference magnets, which may have uncertainties of 0.5–1.0%. The overall uncertainty of a scale reading is typically  $\pm 3\%$  of the full-scale deflection for the range.

The sensing elements are protected by epoxy glass-fibre or similar enclosures, and are available in a variety of forms for probing transverse, coaxial or tangential fields. The flat form is most common, typically with the dimensions 0.5 mm  $\times$  4 mm  $\times$  25 mm. Incremental measurements, using two matched probes and backing-off networks, enable perturbations as small as 0.1  $\mu$ T to be observed either in the presence of, say, a given 0.1 T field or as a difference between two separate 0.1 T field systems. Hall effect instruments have many obvious applications where the magnitude and direction of the field distribution is required such as air gaps of machines and instruments, magnetron magnets, mass spectrometer fields, residual interference fields, etc.; in addition, the Hall-effect principle can be used in a variety of transducer applications by making  $I_c$  and  $B$  proportional to separate physical functions, and measuring the instantaneous or average results of this product. One example is a wide band, 50 kHz wattmeter in which  $I_c$  and  $B$  are made, respectively, proportional to the scalar values of the load current and voltage.

### 11.11.2 Magnetic parameters

The d.c. magnetisation curve, hysteresis loop and relative permeability can be obtained by use of a fluxmeter or calibrated ballistic galvanometer, using a method substantially the same as for calibration. The magnetic test material constitutes the core of the toroid, or is built in strips to form a hollow square. The a.c. cyclic magnetisation loop differs from the 'static' loop, and is still further modified when a d.c. bias m.m.f. is superposed. The a.c. loop can be viewed on a c.r.o. displaying the  $B$  and  $H$  functions on the  $Y$  and  $X$  axes, respectively. The  $H$  function can be obtained from the volt drop across a small resistor carrying the magnetising current, and the  $B$  function from the time integral of the search-coil voltage obtained with the aid of an operational amplifier.

### 11.11.2.1 Core loss

In a low-frequency test the loop area of the  $B/H$  relation is directly proportional to the core loss per cycle of magnetisation, which provides a simple comparative test for specimen material. A more convenient method employs low power factor wattmeters, but care is needed to exclude instrument and connection losses. Selected samples of sheet steel intended for the cores of inductors and power transformers are prepared for testing in the form of strips (e.g. 30 cm × 3 cm) assembled in bundles and butted or interleaved at the corners to form a hollow square. The sides are embraced by magnetising and search coils of known dimensions. Input power and current, and mean and r.m.s. voltages, are read at various frequencies and voltages to assess the overall power loss within the material and (if required) an approximate indication of the eddy and hysteresis loss components. The Lloyd-Fisher and Epstein squares are commonly used forms, the latter being referred to in BS 601 (*Sheet steel*).

The magnetic properties of bars, forgings and castings are derived from galvanometer or fluxmeter measurements (BS 2454). A.c. potentiometer and bridge methods are also used, especially for low-loss materials at frequencies in the audio range. With ferrite and powder cores, as with  $Q$ -value tests of a coil with and without a slug core, r.f. resonance methods are convenient.

Production and quality control test equipment for core-loss and coil-turns instruments include a 'coil-turns tester' (Tinsley 5812D) with a four-digit display of the number of turns in non-uniform and uniform windings, by using an inductive comparative measurement against a standard winding; the same range of 'magnetic type' instrumentation includes a 'shorted-turns tester' which will detect single and multiple shorted circuited turns in coils of any shape or number of windings; while a 'core tester' can check transformer core characteristics of EI stacks, C cores and toroids including hysteresis loop output for a cathode-ray-oscilloscope display.

### 11.11.3 Bridge methods

Two examples of bridges for audiofrequency tests are given. The non-linear magnetic characteristics of materials introduce harmonics at higher flux densities, imposing limitations because the bridge must be balanced at fundamental frequency.

#### 11.11.3.1 Campbell method

The specimen, shown as a toroid, is uniformly wound with  $N_2$  secondary turns, overlaid with  $N_1$  primary turns (*Figure 11.46(a)*). The magnetising current  $I_1$  passes through the primary of the mutual inductor  $M$  and the resistor  $r$ .

**Figure 11.46** Bridges for magnetic measurements. (a) Campbell; (b) Owen

At balance indicated on detector D, the power factor and power loss are given by

$$\cos \phi = \frac{r}{\sqrt{r^2 + \omega^2 M^2}} \quad \text{and} \quad P = \frac{1}{2} I_1^2 r (N_1/N_2)^2$$

The corresponding magnetising force and flux density are found from

$$H = (I_1 N_1 / l) \sin \phi \quad \text{and} \quad B_m = \frac{1}{4} \mu_0 I_1 N_2$$

where  $l$  is the mean length of the magnetic path in the toroid,  $a$  is its cross-sectional area, and  $V$  is the mean voltage as measured on the high-impedance average voltmeter  $V$ .

#### 11.11.3.2 Modified Owen method

The toroidal specimen (*Figure 11.46(b)*), has  $N_1$  a.c. magnetising turns, and an additional winding  $N_2$  through which a steady polarising d.c. excitation can be superposed. The d.c. supply is taken from a battery through a high-valued inductor to minimise induced alternating current from  $N_1$ . The Wagner earth arrangement  $R_5 C_5 C_6$  may be added to eliminate earth capacitance errors from the main bridge arms by balancing in both positions of the switch S. The high-impedance voltmeter  $V$  measures the r.m.s. voltage  $V$  across  $R_3$ . The a.c. magnetising force  $H_a$  due to the current  $V/R_3$  in  $N_1$ , the d.c. magnetising force  $H_d$  due to  $I_d$  in  $N_2$ , the power loss in the specimen (including the  $I^2 R$  loss in the winding  $N_1$  which can be allowed for separately) and the peak flux density  $B_m$  are given by

$$H_a = \frac{1}{2} N_1 / R_3 l; \quad H_d = \frac{1}{2} N_2 / l; \quad P = \frac{1}{2} (C_4 / C_3 R_3) \omega^2 V^2$$

$$B_m = \sqrt{2} V (C_4 / \omega C_2 a N_1) \sqrt{(1 + \omega^2 C_2^2 R_2^2)}$$

where  $a$  is the cross-sectional area of the specimen, and it is assumed that all time-varying quantities have sinusoidal waveform and angular frequency  $\omega$ .

## 11.12 Transducers

In instrumentation systems a transducer is a device that can sense changes of one physical kind and transpose them systematically into a different physical kind compatible with a signal processing system. The compatible signals considered here are generally electrical or magnetic. Transducers can sense most non-electrical quantities (e.g. humidity, pressure, temperature and force) and, so far as the electrical response is concerned, can be classified as 'active' or 'passive', as follows:

**Passive.** The output response produces proportional changes in a passive network parameter such as resistance, inductance and capacitance.

**Active.** Transducers act as generators, the class including piezoelectric, magnetoelectric and electrochemical devices.

The 'Code for Temperature Measurement' is included in BS 1041. The sensors and instruments for the purpose are classified according to temperature range:

- (1) Specialised thermometers for measurements near absolute zero. One such, based on the magnetic susceptibility of certain paramagnetic salts, is suitable for temperatures below 1.5 K; another, employing an acoustic resonant-cavity technique, can be used up to 50 K. The associated

instruments are a mutual inductance bridge for the former, and electronic measurement of length for the latter.

- (2) Ge, Si and GaAs p-n junction diode and carbon resistor thermometers are used with d.c. potentiometers and Wheatstone bridges for temperatures up to 100 K.
- (3) Vapour pressure thermometers are used for standard readings below 5 K and for general measurements up to 370 K.
- (4) Thermistor (resistance) and quartz (resonance) methods, with Wheatstone bridge and electronic counter, respectively, cover the range 5–550 K.
- (5) Electrical resistance sensors (usually of Pt) are used with d.c. bridges throughout the range 14–1337 K.
- (6) Thermocouple e.m.f.s are measured by d.c. potentiometer. The method, widely employed in industry, has ranges between 100 and 3000 K with various combinations of metals.
- (7) The expansion of mercury in glass or steel capillary tubes is applied to measurements from 230 to 750 K. The range is 80–300 K if the mercury is replaced by toluene.
- (8) Radiation and optical thermometers employ thermopiles, photodiodes or photomultipliers for measurements up to 5000 K, using d.c. potentiometric or optical balance methods. These provide the only practical methods for very high temperatures.

Mercury-in-glass and optical thermometers are indicating instruments only, but the remainder can be made to furnish graphical records. The electrical resistance and thermoelectrical thermometers are especially suitable for multipoint recording as for heated solid surfaces, points in a mass, or inaccessible places in electrical machines.

### 11.12.1 Resistive transducers for temperature measurement

A resistive sensor based on a substantially linear resistance/temperature coefficient should have small thermal capacity for rapid response and avoidance of local temperature gradient. Hence, materials of high resistivity (giving small volume) and temperature coefficient are desirable. Thermistors are made to fulfil these requirements.

#### 11.12.1.1 Pure-metal sensors

Pure conductors such as Pt, Ni and W have low resistance/temperature coefficients but these are stable and fairly linear. Pt is generally adopted for precision measurements and, in particular, for the definitive experiment within the range 100–903.5 K of the International Practical Temperature Scale. Platinum and other metals can be deposited on ceramics to produce metal-film resistors suitable (if individually calibrated) for temperature measurement.

#### 11.12.1.2 Platinum resistance thermometer

To a reasonable approximation the resistance  $R$  of a platinum wire at temperature  $\theta$  (in degrees Celsius) in terms of its resistance  $R_0$  at 0°C is

$$R = R_0(1 + k\theta) \quad \text{where} \quad k = (R_{100} - R_0)/100R_0$$

The temperature  $\theta_p$  for a given value  $R$  is

$$\theta_p = 100(R - R_0)/(R_{100} - R_0)$$

Figure 11.47 Temperature-sensor network

and is known as the *platinum temperature*. Conversion to true temperature is found from the difference formula

$$\theta_{\zeta} - \theta_p = \delta_{\zeta}[(\theta/100)^2 - (\theta_p/100)^2]$$

The value of  $\delta_{\zeta}$  depends upon the purity of the metal. It is obtained by measurement of the resistance of the sensor at 0, 100 and 444.67°C, the last being the boiling point of sulphur. The value of  $\delta_{\zeta}$  is typically 1.5.

A practical sensor usually consists of a coil of pure platinum wire wound on a mica or steatite frame, the coil being protected by a tube of steel or refractory material. The resistance measurement is carried out by connecting the coil in a Wheatstone bridge network or to a potentiometer. In the former case the bridge usually has equal ratio-arms and a pair of compensating leads is connected in the fourth arm. These leads run in parallel to the actual leads from the sensor coil and compensate for their resistance changes. If the initial resistance and coefficient  $k$  of the sensor are large, the compensating leads may not be required. Figure 11.47 shows the method of connecting three such coils in turn in a Wheatstone bridge network, so as to measure the temperatures at three different locations. In this case the bridge is not balanced; the out-of-balance current through the galvanometer gives the temperature directly. Initial setting is done by adjustment of the battery current until some definite deflection is obtained, when a standard resistance replaces the sensors in the bridge circuit.

#### 11.12.1.3 Thermocouple sensors

Thermocouple sensors are active transducers exploiting the Seebeck effect developed between two dissimilar metals when two junctions are at different temperatures. The International Practical Temperature Scale is defined in terms of a (0.9 Pt + 0.1 Rh)/Pt thermocouple over the range 903.5–1336 K. Readings between 100 and 3000 K are possible with Au/CoCu at the lower and W/Re at the higher end. Conventional materials for intermediate ranges include

copper/constantan (670 K)	iron/constantan (1030 K)
chrome/constantan (1270 K)	chromel/alumel (1640 K)

the figures giving the upper limits. The thermo-e.m.f. varies between 10 and 80  $\mu\text{V/K}$ . To make an instrument direct-reading for the temperature at one junction, the second ('cold') junction must be kept at a reference temperature. The cold junction can be maintained at 0°C by immersion within chipped, melting ice in a thermos flask, or by using a commercial ice-point apparatus working upon the Peltier effect. When high temperatures are being measured, the terminals of the detector can sometimes be used as the 'cold' junction, but compensating leads should be connected between the thermocouple and the detector. The most accurate method for measuring the e.m.f. is with a d.c. potentiometer.

The e.m.f.  $e$  for a hot-junction temperature  $\theta$  (in degrees Celsius) with the cold junction at  $0^\circ\text{C}$  is of the form  $\log(e) = A \log(\theta) + B$ , where the constants  $A$  and  $B$  have, for example, the values 1.14 and 1.36 for copper/constantan, with  $e$  in microvolts.

The small thermal capacity of thermocouples makes them suitable for the measurement of rapidly changing temperatures and for the temperatures at particular points in a piece of apparatus. One useful application is the measurement of surface temperatures, in which case the thermocouple consists of the two metals in the form of a flat flexible strip with a welded junction at the centre, this strip being applied to the surface under test.

### 11.12.2 Thermistors

Thermistors are semiconductor sensors which are made from the sintered compounds of metallic oxides of Cu, Mn, Ni and Co formed into beads, rings and discs. A high resistivity is achieved with a large resistance/temperature coefficient. The units can have resistances at  $20^\circ\text{C}$  from  $1\ \Omega$  to several mega-ohms. The thermal-inertia time-constant is not more than 1 s for small beads, but rather more for discs and coated specimens. The outstanding property is the negative resistance/temperature coefficient of several parts in  $10^2$  per degree Celsius. Thermistors can be used over the range 200–550 K. One consequence of the current/voltage characteristic is self-heating if the thermistor carries appreciable current.

Wheatstone bridge networks are widely used, with the thermistor in one arm and the out-of-balance detector current as an indication of temperature. Although the characteristics are strongly non-linear, it is possible to obtain thermistors in matched pairs, which can be applied to differential temperature measurement. Another application, not directly a temperature measurement, is to the indication of air flow in pipe, or as anemometers: one thermistor is embedded in a metal block, acting as a thermal reservoir, the other senses the air speed as a cooling effect.

### 11.12.3 p–n Junctions

Certain semiconductor diodes are suitable for temperature measurement over a wide range; Ge, for example, is useful below 35 K. One differential thermometer has two matched p–n diodes which, when linearly amplified, give a discrimination better than  $0.0001^\circ\text{C}$ . Such instruments have several indirect applications, such as sensing thermal gradients in ‘constant-temperature’ enclosures or vats, monitoring load changes, and displaying the input–output liquid temperature differences in fluid pumps.

### 11.12.4 Pyrometers

Radiation thermometers respond to the total radiation (heat and light) of a hot body, while optical thermometers make use only of the visible radiation. Both forms of *pyrometer* are specially suited to the measurement of very high temperatures, because they do not involve contact with the source of heat.

*Radiation thermometers* Both the Fery variable-focus and the Foster fixed-focus types comprise a tube containing at the closed end a concave mirror which focuses the radiation on to a sensitive thermocouple. In use the tube is ‘sighted’ on to the hot body. The sighting distance is not critical,

provided that the image formed is large enough to cover the thermocouple surface. Calibration is by direct sighting on to a body of known surface temperature.

*Optical thermometers* The commonest form is the disappearing-filament type, which consists of a telescope containing a lamp, the filament brightness of which can be so adjusted by circuit resistance that, when viewed against the background of the hot body, the filament vanishes. The lamp current passes through an ammeter scaled in temperature. The telescope eyepiece contains a monochromatic glass filter to utilise the phenomenon that the light of any one wavelength emitted by the hot body depends on its temperature. Although calibration is based on the assumption that the hot body is a uniform radiator, departure from this condition involves less error than in the radiation pyrometer.

### 11.12.5 Pressure

The piezoelectric effect is the separation of electronic charge within a material when applied pressure deforms the crystal structure. Conversely, the application of charge to the crystal will cause changes in the dimension of the crystal. Quartz is the only *natural* crystal in general use as a sensor. It is important that the crystal be prepared by slicing along the plane most sensitive for the particular application. Quartz is used in oscillators as the stable frequency-reference element. The self-resonant frequency is temperature-dependent, so constant temperature (e.g.  $35^\circ\text{C}$ ) ovens are required for very stable oscillators: this application of quartz is not as a sensor, but the same temperature dependence of resonant frequency is applied for very-low-temperature measurement (below 35 K) where the temperature change can be interpreted by changes in frequency. Numerous ceramic crystals have been developed based upon barium titanate with controlled added impurities; the piezoelectric properties have to be applied by a special polarising treatment during the cooling period following the sintering process in a kiln.

Active four-arm strain gauge bridges, diffused into a single crystal silicon diaphragm, form the basic sensor for a wide range of sensitive pressure elements which are encapsulated in solid state transducers/transmitters (e.g. Druck Limited, Groby, Leicestershire, England). Minimum to maximum pressures can be measured, from venous or arterial values in physiology, to aerospace applications in engines and satellites, and to high-pressure industrial processes. The sensors have 10 V d.c. or a.c. input, with  $15\text{ mV} \rightarrow 10\text{ V}$  outputs, 0.1% non-linearity working into a  $4\frac{1}{2}$ -digit multichannel indicator/BCD-recorder which, when coupled with a  $5\frac{1}{2}$ -digit, 0.04% calibrator, provides traceability through a low-cost primary standard.

### 11.12.6 Acceleration

Accelerometers can be used for velocity measurement by integration of the output signal. The acceleration force of a mass is made to increase or decrease the spring pressure on a ceramic or quartz crystal to produce proportional piezoelectric effect. The device is insulated and hermetically sealed, with care taken to avoid loss of signal through parallel insulation paths of resistance comparable with that of the crystal itself (e.g. 1000 M $\Omega$ ). Conditioning of the signal involves matching to the much lower input impedance of conventional amplifiers by use of an emitter–follower

network. 'Integrated circuit' forms of the network can be located actually within the transducer unit.

The signal amplifier can be a voltage amplifier or a charge amplifier (i.e. an operational amplifier with capacitive feedback). The latter is preferred because the equivalent feedback capacitive effect is large and dominates the input capacitance associated with varying lengths of coaxial cable.

Other accelerometers are based either on changes in the reluctance of differential transformers or on variations in the resistance of a strain gauge. Slow changes in acceleration can be sensed by connecting the seismic mass to a wiper on a resistance voltage divider.

The upper frequency of the output is limited by the natural frequency of the transducer, while the minimum is almost zero. If the lowest useful frequency of an a.c. electronic amplifier is 20 Hz, the analysis of very-low-frequency signals may be achieved by first recording them on a precision frequency-modulated tape-recorder, which is then replayed at high speed for amplification and analysis.

Constant bandwidth frequency analysers are convenient for stable periodic complex waveforms. Constant per cent bandwidth types suit cases such as machines in which there is some small fluctuation in the nominal periodic behaviour. Truly random vibrations of a stochastic nature may more profitably be analysed in terms of the power spectral density function. Analysers are available for measuring many properties of random signals—e.g. 'probability density function' devices based on instantaneous signal amplitudes (see Section 11.7.5).

### 11.12.7 Strain gauges

Electrical strain gauges are devices employed primarily for detecting and measuring small dimensional variations in the surfaces to which they are attached, particularly where direct measurement is difficult. The gauge essentially converts mechanical displacement into a change in some electrical quantity (usually resistance). The essential feature is that strain shall be communicated to the gauge without fatigue or inertia effects.

#### 11.12.7.1 Resistance-wire, p-n junction and carbon gauges

A grid of resistance wire is cemented between two insulating films. The grid is usually smaller than 30 mm × 15 mm, and has a resistance in the range 60–2000 Ω. When the gauge is cemented to the surface under test, the change  $\Delta R$  in total resistance  $R$  due to a displacement  $\Delta L$  in a length  $L$  is converted into strain  $\epsilon$  by means of the gauge factor

$$k_g = (\Delta R/R)(L/\Delta L) = (\Delta R/R)/\epsilon$$

If  $F$  represents the force and  $E$  the elastic modulus (i.e. the stress/strain ratio), then

$$F = k_g E a R / \Delta R$$

where  $a$  is the area normal to the direction of the applied force. Resistance-wire strain gauges have been in use for many years. Recent developments include metal-foil strain gauges based upon printed circuit and photoetching techniques: these can be made smaller. Thin-film techniques have been developed to apply the gauges directly to very small surface areas.

Semiconductor *silicon junction* strain gauges are perhaps 30 times more sensitive than the resistive gauge; however,

their stress and temperature ranges are more restricted, and they are more difficult to 'cement' in position. The inherent non-linearity of the response by sensors can be offset by special bridge techniques using compensation networks.

Gauges consisting of a layer of *carbon*, which responds to strain in a manner similar to that of a carbon microphone, have a gauge factor typically of 20, considerably higher than for metals but much less than for p-n junctions. The inherent disadvantage is sensitivity to temperature and humidity.

#### 11.12.7.2 Strain-gauge measurement techniques

**Strain** An 'active' gauge is cemented to the workpiece, and a similar 'compensating' gauge is left free. The gauges form two arms of a bridge (Figure 11.48(a)), which is inherently self-compensating for temperature. Balance is achieved initially by adjusting  $R_1$ , the load is applied and the bridge rebalanced. For multiple-gauge arrangements, 100-channel instruments with zero-balancing facilities are available, giving a printed read-out. Alternatively, after initial balance, the residual bridge voltage is measured, or applied to a cathode-ray-oscilloscope for recording. Dynamic strain may be measured by the circuit of (Figure 11.48(b)), usable with a flat-response amplifier over the range 0.5–1000 Hz. As in any structural stress analysis it is important to know the time relation as well as the amplitude of stress, the amplifier must have either a negligible phase shift or one directly proportional to frequency over the required working range.

**Torque** For a circular-section shaft in torsion, the principal stresses lie at 45° to the axis. If four gauges are applied as in Figure 11.49, and connected to a bridge through suitable slip-ring gear (usually silver ring surfaces and silver graphite brushes), the bridge unbalance is four times that of a single gauge. The arrangement is inherently temperature compensated. For engine testing it is normal to make up a special length of shaft with gauges and slip-rings, to be fitted between the engine and the brake or driven unit. With automatic recorders it is possible to record simultaneous data such as torque, pressure variation, temperature, etc., to give all phenomena on a time base display.

**Thrust** Various other measurements of mechanical power transmission can be measured. The arrangement in Figure 11.50 is for thrust. Four axial (A) and four circumferential (C) gauges are disposed symmetrically and connected as indicated in a bridge network, with  $r$  as balancing adjustment at zero load. The monitoring system (which can be used with other strain-gauge applications) consists of a self-balancing potentiometer with chart (Ch), digital (Dg) and indicator (Id) readouts. The speed of a self-balancing potentiometer is restricted to about one reading per second.

**Principal stresses** The direction and magnitude of principal stresses can be determined from a *rosette* of three or

Figure 11.48 Strain-gauge networks

Figure 11.49 Strain-gauge torque measurement

Figure 11.50 Strain-gauge thrust measurement

Figure 11.51 Typical strain-gauge rosettes

more strain gauges arranged with suitable orientations (Figure 11.51). Commercial rosettes are available in several geometrical formations. As it is unlikely that the principal strain will be on the axis of any one gauge, note must be taken of the sensitivity of the gauges in a direction at right angles to the axis if accurate results are required. The correction is not likely to exceed 3%.

### 11.12.8 Magnetostrictive transducers

Magnetostriction is the dimensional change that occurs in a ferromagnetic material when subjected to magnetisation, and an inverse effect of change in magnetisation when the physical dimensions are altered by the application of external force. The dimensional changes are very small (e.g. 30 parts in  $10^6$ ), but if the magnetic field alternates at a frequency corresponding to one of the natural frequencies of vibration of the material in some form, such as a bar, resonance increases the vibration amplitude considerably to perhaps 1 part in  $10^3$ .

Materials vary widely in the magnitude and sign of the magnetostrictive effect, which also depends on the magnetic field intensity. Pure iron may have positive or negative magnetostriction: the addition of nickel makes the effect positive at all frequencies. With 30% Ni the longitudinal magnetostriction falls to zero, a property utilised in invar-nickel alloys to give very low coefficients of thermal expansion, because the latter is neutralised by the magnetostrictive contraction. In nickel alloys there is a peak dimensional change when the Ni content is about 45% and at about 63% the most sensitive magnetostrictive condition is reached.

#### 11.12.8.1 Sensors

For the purpose of detecting surface and submarine ships, magnetostriction transducers have been employed using

under-water supersonic vibrations. The compression stresses generated by the transmitter are reflected by the submerged object and are picked up by a detector utilising the inverse effect—i.e. change of magnetic properties under mechanical stress.

The presence of flaws, air pockets or impurities can similarly be detected in some opaque substances (e.g. rubber) which should normally be homogeneous. The phase displacement between the incident and reflected waves can be interpreted to indicate the position of the obstruction.

Liquid level can be controlled by a sensor probe just above the required level and connected to an oscillator network. As the level of the liquid reaches the probe, the oscillation ceases because of the greatly increased damping. For the measurement of mechanical stress (Figure 11.52) the bridge is balanced when the sensor and compensating elements are equally stressed, the compensating element eliminating thermal errors. If the stress in the sensor element is increased, its permeability is reduced, and the out-of-balance current is indicated on the detector D, which can be calibrated in stress units. If the stress is rapidly varying, D can be replaced by a cathode-ray oscilloscope.

### 11.12.9 Reactance sensors

Many transducers use the properties of inductive and capacitive reactance. The inductance of an iron-cored inductor varies very rapidly with the length of an included air gap. The basic network in Figure 11.53 employs a bridge with inductors 1 and 2, one with a fixed gap and the other with a gap variable in accordance with some physical quantity such as pressure, strain, thickness, acceleration, etc. The detector D is calibrated appropriately for direct indication. Reliable readings of displacement down to about  $3 \times 10^{-5}$  mm are readily secured with a properly designed instrument. If the displacement fluctuates, it will modulate the supply waveform, and the modulation waveform can be filtered out from the carrier.

Capacitive reactance can also be used, but as the magnitude of its change with displacement is very small, the capacitor sensor is made to be part of the capacitance in an

Figure 11.52 Magnetostriction stress sensor circuit

Figure 11.53 Reactance bridge electric gauge

oscillatory circuit, the frequency of which can be related to the displacement. One type of capacitor pressure sensor consists of two flexible parallel plates with a 'vacuum' dielectric. A cylindrical capacitor suitable for sensing high pressures has as electrodes an inner deforming cylinder and an outer ring section: dimensional changes in the radial gap occur when the axial force on the inner cylinder causes a change in its diameter. The change of capacitance is well within the range of commercial strain-gauge bridges.

#### 11.12.9.1 Angular velocity sensors

Measurements can be read from the output of a permanent-magnet d.c. tachometer for speeds up to 3000 rev/min. The instrument is direct-reading, but a proportional direct output voltage can be used as an electrical transducer. For low speeds the commutator ripple can be excessive and an a.c. tachometer with full-wave rectification will provide a more uniform output, particularly if the instrument is of the multi-tooth variable-reluctance type. These instruments act as loads on the source and they are unable to assess the fine detail of the angular velocity such as superimposed small amplitude oscillations, or non-uniform accelerations and retardations due to changes in load. Simple optical solutions to the problem involve the use of a stroboscope or photosensor coupled with digital counters, and each method avoids any loading of the machine.

### 11.12.10 Stroboscope

The stroboscope generates high-intensity impulsive flashes of light at controllable repetition frequency. If the repetition frequency corresponds to the time of one revolution of a rotating object or to one complete excursion of a reciprocating object (or any multiple thereof), the object appears to be at rest. If the period is a submultiple  $1/n$ , then the object appears stationary in  $n$  different positions. It is desirable for the repetition frequency to exceed 30 Hz in order to avoid visual flicker.

From the flash frequency and observation, the character of velocity perturbations can be viewed and counted and dynamic distortion effects seen. Electrical stroboscopes may involve special neon lamps connected to the secondary side of an induction coil, the primary of which is interrupted by a driven tuning fork. In modern instruments the lamp is a xenon gas discharge tube emitting white light. The flashing frequency is adjusted by means of a transistorised multi-vibrator-shaper circuit producing pulses of constant energy and fast rise time. Each trigger pulse initiates the discharge of a capacitor to create the flash. Capacitor recharging limits the upper frequency to about 1.5 kHz with a 200 lux illumination level. High frequencies up to 10 kHz can be obtained from a Z-modulated cathode-ray tube as a low-level light source.

### 11.12.11 Photosensors

In this context, 'light' usually means radiation at wavelengths covering the visible spectrum from the near infrared to the near ultraviolet. Light transducers can be identified by three basic forms of physical behaviour: photovoltaic, photoresistive/photojunction and photoemissive.

#### 11.12.11.1 Photovoltaic

Photovoltaic sensors are p-n junction devices with the normal barrier layer potential present between the two materials. When illuminated, the higher-energy photons

raise electrons from the valence into the conduction band to create electron-hole pairs. The consequent continual charge separation is enough to drive current through a resistive load without any external source.

**Selenium cell** This has a linear current/illumination characteristic for load resistances up to 100  $\Omega$ , but the relation is progressively more non-linear for higher resistance, and reaches an open-circuit e.m.f. of 0.6 V. The peak spectral response is in the centre of the visible band (0.57  $\mu\text{m}$ ), but the energy efficiency is only 0.5%.

**Silicon p-n junction cell** The energy conversion is 10–15%, which is adequate for solar cell use in space vehicles. As the time response (a few microseconds) is very fast, silicon photocell arrays are used for reading punched-card and tape, and for optical tracking. The output of a single sensor is typically 70  $\mu\text{A}$  for 5000 lux, the current being constant up to 200 mV. When they are reverse-biased, silicon photosensors behave as photoresistive devices.

#### 11.12.11.2 Photoresistive

A photoresistive sensor consists of a single homogeneous semiconductor material such as n-type cadmium sulphide or cadmium selenide. The material is doped to permit of a large electron charge amplification by the selective absorption of holes, and a spectral response that can simulate that of the eye. This type of sensor is well known as a photographic exposure meter. The CdS sensor is not quite linear over wide illumination ranges, and its response time (100 ms), is slow compared with that (10 ms) of the CdSe type.

The sensors can be used in series with a source and a relay, the latter operating when illumination reduces the sensor resistance to about 1 k $\Omega$ . The power dissipation by the sensor can be minimised if the slow resistance changes are used to alter the state of a conventional Schmitt trigger circuit (Figure 11.54). The required illumination level is set by  $R_1$ ; when the illumination is reduced, the cell resistance rises to switch on  $T_1$ , which causes  $T_2$  to switch off and  $T_3$  then saturates. The relay operates when the Zener diode conducts at about 12 V. The sensor is useful for alarm circuits, street-lighting control and low-rate counting.

#### 11.12.11.3 Photojunction

Normal diodes and transistors are light-shielded. In the photojunction devices controlled light is admitted to enhance the light effect.

**Photodiodes** These are normally of silicon unless the greater infra-red response of germanium is needed. Time constants of 10–100 ns are normal. Silicon planar p-type/intrinsic/n-type photodiodes can respond to laser pulses of 1 ns, and are usable at very low light level equivalent to a

Figure 11.54 Photoresistive cell in Schmitt trigger circuit

current of about 100 pA. Special low-noise transistor amplifiers are required.

**Phototransistors** The normal form is the n-p-n silicon planar transistor, with conventional bias except for the reverse-biased photodiode between base and collector. It behaves as a common-collector transistor amplifier with a photocurrent generator between base and collector. The maximum cut-off frequency is 50 kHz. A derivative of the field effect transistor, the 'photofet', is more sensitive and the gain-bandwidth product is higher.

#### 11.12.11.4 Photoemissive

Photoemissive sensors are vacuum or gas-filled phototubes. The emission of electrons from the cathode occurs when light falls on it, to be collected by a positive anode. Vacuum phototubes have been superseded for light measurement by photodiodes. In the *photomultiplier* tube the vacuum emission is enhanced by secondary emission at a succession of anodes to give an electron multiplication of  $10^8$  or  $10^9$ , providing significant output for flashes of very short duration. The photomultiplier is used as a *scintillation* sensor by viewing the weak light emissions that occur in selected phosphors exposed to  $\alpha$ ,  $\beta$  or  $\gamma$  radiation. These scintillation 'counters' have wide application in spectrophotometry, flying-spot scanning, photon counting and whenever a very weak light signal is to be amplified. An alternative device is the Bendix magnetic multiplier. This consists of a single layer of resistive film with the emissive cathode at one end; by suitable accelerating p.d.s applied along the film, together with shaped magnetic fields, the electrons are multiplied by secondary emission and bounced along the strip to accumulate on an anode to give an overall electron gain of  $10^9$ . With different emissive materials, ultraviolet rays and X-rays can be amplified for subsequent analysis.

*Gas filled phototubes* are low-frequency devices but have a high signal/noise ratio. They are used for film sound-track sensing, and have been applied to monitor natural gas flames (which emit considerable ultraviolet radiation) to avoid danger from unburnt gas.

#### 11.12.11.5 Selection

Photovoltaic cells do not require an external supply, but they are generally less sensitive than photoresistive types, which do. Photodiodes can be selected for a range of optimum spectral sensitivities and are fast-operating, particularly so for the silicon planar p-i-n type. Phototransistors provide amplification at the cost of a relatively slow response (minimum 20  $\mu$ s). Photomultiplier tubes provide high amplification, even for single photons.

Integrated-circuit chips about 4 mm<sup>2</sup> in area, produced with progressively more complex networks, can include scores of photodiode arrays, with amplifiers, logic counting networks, scanning circuits, etc., to give such outputs as digital pulse rates proportional to illumination, logic for character recognition and punched-card reading, and as replacements for photomultipliers. These devices find a wide range of application in transducer instrumentation for control and communication.

### 11.12.12 Nuclear radiation sensors

Radiation sensors are required in particle physics research, for monitoring reactions in nuclear power stations, as gauges for industrial processes, and for measurements

employing radioactive isotopes. The emanations used for industrial processes include  $\alpha$ ,  $\beta$  and  $\gamma$  rays with X-rays for special applications such as the examination of welds; the sensor characteristics largely determine the radiation to be processed. The devices include the following.

*Low-pressure gas ionisation chambers* to measure  $\alpha$ -particles by accumulating the electrons released by their collisions with gas molecules, and without subsequent multiplication.

*Proportional counters*, similar to the foregoing but with a higher accelerating voltage (500–800 V) to give cumulative gas amplification (Townsend avalanche) and an electron gain of  $10^5$ – $10^6$ . The use is for counting  $\alpha$ -particles in the presence of  $\beta$ -particles and  $\gamma$  rays.

*Geiger counters* operating at 800–1500 V, or at low voltage, for  $\beta$  and  $\gamma$  ray detection. The complete ionisation must be quenched between counts, and the dead time restricts the counting rate to about 1000/s.

*Scintillation sensors* (or 'counters') for  $\alpha$ ,  $\beta$  or  $\gamma$  detection. There are also semiconductor sensors for the same application and for X-rays.

$\alpha$ -,  $\beta$ - and  $\gamma$ -Ray sensors require to be followed by electronic pulse amplifiers and counters. A counter may accumulate a total/fractional scaled count, or it may give a rate-meter display. These outputs, together with pulse height analysers, are used to assess the energy spectra of the received signals. Coincidence counters have multiple input sensors so arranged that only the required type of emanation is measured during any selected period.

The detectors can form the bases for industrial gauges and monitors when used with radioisotope sources. The selective absorption of materials enables  $\beta$ -radiations through paper to indicate the uniformity of the product; liquid-level gauges give correcting signals when the rise of level absorbs the radiation; radioisotope tracers with short half-lives can be introduced into liquid and gas channels to indicate flow rate, uniformity of mixing and the detection of leakages.

### 11.13 Data recording

Chart recorders responsive to signals at frequencies up to a maximum of 25 kHz include: (1) a.c. ultraviolet, (2) X–Y, and (3) analogue and digital strip-chart forms. All provide records of related phenomena that need to be preserved in graphical form.

The visual discrimination of the best-quality trace, when stated as a fraction of the chart width, should not be significantly different from the accuracy and linearity of the display; this condition dictates the width of the chart paper. Many different types of treated chart paper are needed in order to be compatible with the various writing systems mentioned below. Paper is provided in rolls or overlapping folds, the latter being very convenient for quick retrieval of data.

Conventional pens for ink-feed methods use felt, ball-point or nylon disposable tips. The ink cartridges are easily replaced, and the supply is drawn to the tip by capillary action. The nylon pen is suitable for higher writing speeds; to retain a uniform trace, a variable pressure is automatically applied to the ink cartridge. In multiple-display applications, the possibility of easy trace separation by colour is a unique convenience of ink writing.

Many alternative writing methods have been developed in an attempt to overcome the inertia (response time) limitation of conventional ink writing, as well as to improve the quality of the trace. These include: (a) a heated stylus and sensitive plastic-coated paper; (2) mechanical pressure on

chemically treated paper; (3) ultraviolet light beams directed on to photographic paper, the trace appearing and becoming fixed within a few seconds of exposure to natural light; (4) the passage of current through treated metallised paper causing the chemical reduction process to develop a black imprint; and (5) electrostatic copying, in which a flat capacitor is formed from conductive paper with a dielectric coating—a very small area can be charged, and particles are attracted to the charged area to provide the visible trace, which may require treatment to make it permanent.

## 12.1 Introduction

### 12.1.1 Definition of terms

Accurate measurement of process variables such as flow, pressure and temperature is an essential part of any industrial process. This chapter describes methods of measuring common process variables.

Like most technologies, instrumentation has a range of common terms with precise meanings.

*Measured variable* and *process variable* are both terms for the physical quantity that is to be measured on the plant (e.g. the level in tank 15). The *measured value* is the actual value in engineering units (e.g. the level is 1252 mm).

A *primary element* or *sensor* is the device which converts the measured value into a form suitable for further conversion into an instrumentation signal, i.e. a sensor connects directly to the plant. An orifice plate is a typical sensor. A *transducer* is a device which converts a signal from one quantity to another (e.g. a PT100 temperature transducer converts a temperature to a resistance). A *transmitter* is a transducer which gives a standard instrumentation signal (e.g. 4–20 mA) as an output signal, i.e. it converts from the process measured value to a signal which can be used elsewhere.

### 12.1.2 Range, accuracy and error

The *measuring span*, *measuring interval* and *range* are terms which describe the difference between the lower and upper limits that can be measured, (e.g. a pressure transducer which can measure from 30 to 120 bar has a range of 90 bar). The *rangeability* or *turndown* is the ratio between the upper limit and lower limits where the specified accuracy can be obtained. Assuming the accuracy is maintained across the range, the pressure transmitter above has a turn-down of 4:1. Orifice plates and other differential flow meters lose accuracy at low flows, and their turn-down is less than the theoretical measuring range would imply.

The *error* is a measurement of the difference between the measured value and the true value. The *accuracy* is the maximum error which can occur between the process variable and the measured value when the transducer is operating under specified conditions. Error can be expressed in many ways. The commonest are absolute value (e.g.  $\pm 2^\circ\text{C}$  for a temperature measurement), as a percentage of the actual value, or as a percentage of full scale. Errors can occur for several reasons; calibration error, manufacturing tolerances and environmental effects are common.

Many devices have an inherent coarseness in their measuring capabilities. A wire wound potentiometer, for example, can only change its resistance in small steps and digital devices such as encoders inherently measure in discrete steps. The term *resolution* is used to define the smallest steps in which a reading can be made.

In many applications the accuracy of a measurement is less important than its consistency. The consistency of a measurement is defined by the terms *repeatability* and *hysteresis*.

*Repeatability* is defined as the difference in readings obtained when the same measuring point is approached several times from the same direction.

*Hysteresis* occurs when the measured value depends on the direction of approach as *Figure 12.1*. Mechanical backlash or stiction are common causes of hysteresis.

The accuracy of a transducer will be adversely affected by environmental changes, particularly temperature cycling, and will degrade with time. Both of these effects will be seen as a *zero shift* or a change of sensitivity (known as a *span error*).

**Figure 12.1** Hysteresis, also known as backlash. The output signal is different for an increasing or decreasing input signal

### 12.1.3 Dynamic effects

A sensor cannot respond instantly to changes in the measured process variable. Commonly the sensor will change as a first order lag as *Figure 12.2* and represented by the equation:

$$T \frac{dx}{dt} + x = a$$

Here  $T$  is called the time constant. For a step change in input, the output reaches 63% of the final value in time  $T$ . *Table 12.1* shows the change at later times.

It follows that a significant delay may occur for a dynamically changing input signal.

A second order response occurs when the transducer is analogous to a mechanical spring/viscous damper. The response of such a system to a step input of height  $a$  is given by the second order equation:

$$\frac{d^2x}{dt^2} + 2b\omega_n \frac{dx}{dt} + \omega_n^2 x = a$$

where  $b$  is the damping factor and  $\omega_n$  the natural frequency. The final steady state value of  $x$  is given by:

$$x = \frac{a}{\omega_n^2}$$

The step response depends on both  $b$  and  $\omega_n$ , the former determining the overshoot and the latter the speed of

**Figure 12.2** Response of a first order lag to a step input signal

**Table 12.1**

Time	% Final value
$T$	63
$2T$	86
$3T$	95
$4T$	98
$5T$	99

**Figure 12.3** Response of a second order lag to a step input signal for various values of damping factor

response as shown on *Figure 12.3*. For values of  $b < 1$  damped oscillations occur. The case where  $b = 1$  is called *critical damping*. For  $b > 1$ , the system behaves as two first order lags in series.

Intuitively one would assume that  $b = 1$  is the ideal value. This may not always be true. If an overshoot to a step input signal can be tolerated a lower value of  $b$  will give a faster response and settling time within a specified error band. The signal enters the error band then overshoots to a peak which is just within the error band as shown on *Figure 12.4*. Many instruments have a damping factor of 0.7 which gives the fastest response time to enter, and stay within, a 5% settling band. *Table 12.2* shows optimum damping factors for various settling bands. The settling time is in units of  $1/\omega_n$ .

**Table 12.2**

Settling band	Optimum ' $b$ '	Settling time
20%	0.45	1.8
15%	0.55	2
10%	0.6	2.3
5%	0.7	2.8
2%	0.8	3.5

**Figure 12.4** Overshoot on a second order system and definition of settling time

### 12.1.4 Signals and standards

The signals from most primary sensors are very small and in an inconvenient form for direct processing. Commercial transmitters are designed to give a standard output signal for transmission to control and display devices.

The commonest electrical standard is the 4–20 mA loop. As its name implies this uses a variable current with 4 mA representing one end of the signal range and 20 mA the other. This use of a current (rather than a voltage) gives excellent noise immunity as common mode noise has no effect and errors from different earth potentials around the plant are avoided. Because the signal is transmitted as a current, rather than a voltage, line resistance has no effect.

Several display or control devices can be connected in series provided the total loop resistance does not rise above some value specified for the transducer (typically 250 to 1 k $\Omega$ ).

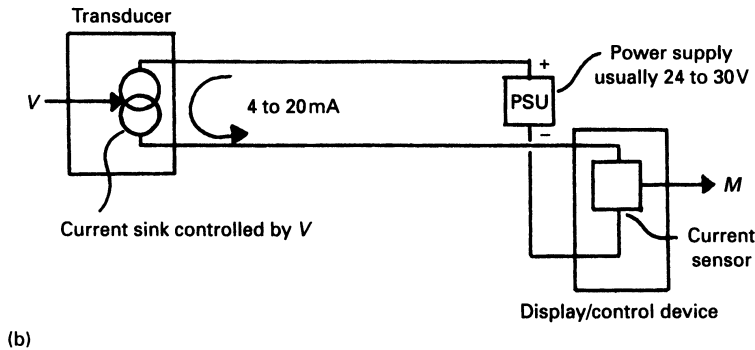

Transducers using 4–20 mA can be current sourcing (with their own power supply) as *Figure 12.5(a)* or designed for two wire operation with the signal line carrying both the supply and the signal as *Figure 12.5(b)*. Many commercial controllers incorporate a 24 V power supply designed specifically for powering two wire transducers.

The use of the offset zero of 4 mA allows many sensor or cable faults to be detected. A cable break or sensor fault will cause the loop current to fall to zero. A cable short circuit will probably cause the loop current to rise above 20 mA. Both of these fault conditions can be easily detected by the display or control device.

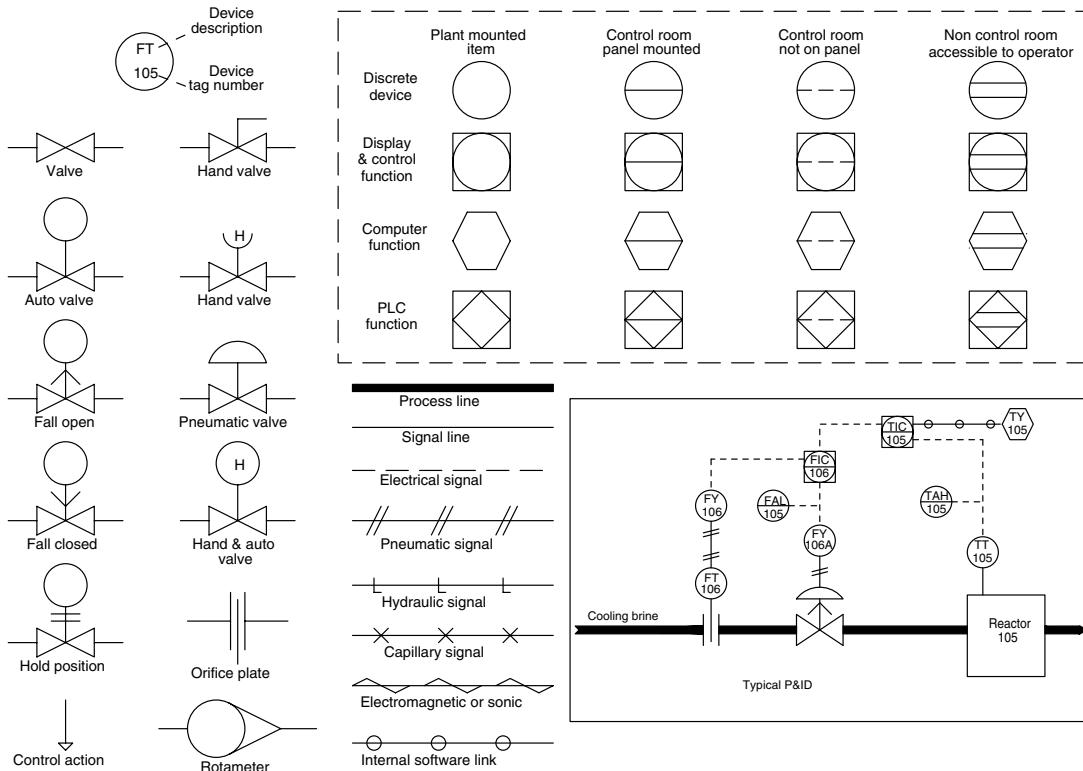

### 12.1.5 P&ID symbols

Instruments and controllers are usually part of a large control system. The system is generally represented by a *Piping & Instrumentation drawing* (or P&ID) which shows the devices, their locations and the method of interconnection. The description *Process & Instrumentation diagram* is also used by some sources. The letters P&ID should not be confused with a PID controller described in Chapter 13. The basic symbols and a typical example are shown on *Figure 12.6*.

The devices are represented by circles called balloons. These contain a unique tag which has two parts. The first is two or more letters describing the function. The second

**Figure 12.5** Current loop circuits. (a) Current sourcing with a self powered transducer; (b) Current sinking with a loop powered (two wire) transducer

**Figure 12.6** Common Piping & Instrumentation Diagram (P&ID) symbols and simple schematic

part is a number which uniquely identifies the device, for example FE127 is flow sensor number 127.  
The meanings attached to the letters are:

First letter	Second and subsequent letters
A	Analysis Alarm (often followed by H for high or L for low)
B	Burner
C	Conductivity
D	Density
E	Voltage or misc. electrical Primary element (sensor)
F	Flow
G	Gauging
H	Hand
I	Current
J	Power
K	Time
L	Level Light. Also Low (with A = alarm)
M	Moisture
O	Orifice
P	Pressure
Q	Concentration or Quantity Integration (e.g. flow to volume)
R	Radioactivity
S	Speed
T	Temperature
U	Multivariable
V	Viscosity
W	Weight, force
X	Signal to signal conversion
Y	Relay
Z	Position

It is good engineering practice for plant devices to have their P&ID tag physically attached to them to aid maintenance.

12.2 Temperature

12.2.1 General

Accurate knowledge and control of temperature is required in the majority of industrial processes.

12.2.2 Thermocouples

If two dissimilar metals are joined together as shown in *Figure 12.7(a)* and one junction is maintained at a high temperature with respect to the other, a current will flow which is a function of the two temperatures. This current, known as the *Peltier effect*, is the basis of a temperature sensor called a thermocouple. In practice, it is more convenient to measure the voltage difference between the two wires rather than current. The voltage, typically a few mV, is again a function of the temperatures at the meter and the measuring junction.

In practice the meter will be remote from the measuring point. If normal copper cables were used to link the meter and the thermocouple, the temperature of these joints would not be known and further voltages, and hence errors, would be introduced. The thermocouple cables must therefore be run back to the meter. Two forms of cable are used; *extension cables* which are essentially identical to the thermocouple cable or *compensating cables* which match the thermocouple characteristics over a limited temperature range. Compensating cables are much cheaper than extension cables.

Because the indication is a function of the temperature at both ends of the cable, correction must be made for the local meter temperature. A common method, called *Cold Junction Compensation*, measures the local temperature by some other method, (such as a resistance thermometer) and adds in a correction as *Figure 12.7(b)*.

Thermocouples are non-linear devices and the voltage can be represented by an equation of the form:

$$V = a + bT + cT^2 + dT^3 + eT^4 + \dots \Leftarrow$$

where a, b, c, d etc. are constants (not necessarily positive) and *T* is the temperature. Linearising circuits must be provided in the meter if readings are to be taken over an extended range.

Although a thermocouple can be made from any dissimilar metals, common combinations have evolved with

Figure 12.7 Thermocouple circuits. (a) Basic thermocouple; (b) Cold junction compensation

**Table 12.3** Common thermocouple types

Type	+ve Material	–ve Material	$\mu\text{V}/^\circ\text{C}$	Usable Range	Comments
E	Chromel 90% Nickel, 10% Chromium	Constantan 57% Copper 43% Nickel	68.00	0–800°C	Highest output thermocouple
T	Copper	Constantan	46.00	–187 to 300°C	Used for cryogenics and mildy oxidising or reducing atmospheres. Often used for boiler flues
K	Chromel	Alumel	42.00	0 to 1100°C	General purpose. Widely used
J	Iron	Constantan	46.00	20 to 700°C	Used with reducing atmospheres. Tends to rust
R	Platinum with 13% Rhodium	Platinum	8.00	0 to 1600°C	High temperatures (e.g. iron foundries and steel making). Used in UK in preference to type ‘S’
S	Platinum with 10% Rhodium	Platinum	8.00	0 to 1600°C	As Type R. Used outside the UK
V	Copper	Copper/Nickel	—		Compensating cable for type K to 80°C
U	Copper	Copper/Nickel	—		Compensating cable for types ‘R’ and ‘S’ to 50°C

$\mu\text{V}/^\circ\text{C}$  is typical over range.

Alumel is an alloy comprising 94% Nickel, 3% Manganese, 2% Aluminium and 1% Silicon.

well documented characteristics. These are identified by single letter codes. *Table 12.3* gives details of common thermocouple types.

Thermocouple tables give the thermocouple voltage at various temperatures when the cold junction is kept at a defined reference temperature, usually 0°C. A typical table for a type K thermocouple is shown on *Table 12.4*. This has entries in 10°C steps, practical tables are in 1°C steps.

Thermocouple tables are used in two circumstances: for checking the voltage from a thermocouple with a millivoltmeter or injecting a test voltage from a millivolt source to test an indicator or controller. Because a thermocouple is essentially a differential device with a non-linear response, in each case the ambient temperature must be known. In the examples below the type K thermocouple from *Table 12.4* is used.

To interpret the voltage from a thermocouple there are four steps:

- (1) Measure the ambient temperature and read the corresponding voltage from the thermocouple table. For an ambient temperature of 20°C and reference voltage of 0°C a type K thermocouple this gives 0.798 mV

- (2) Measure the thermocouple voltage. Let us assume it is 12.521 mV
- (3) Add the two voltages;  $12.521 + 0.798 = 13.319$  mV
- (4) Read the temperature corresponding to the sum. The thermocouple table shows that the voltage corresponding to 330°C is 13.040 mV and interpolation with  $41.9 \mu\text{V}/^\circ\text{C}$  gives a temperature of just over 336°C.

To determine the correct injection voltage there are three steps:

- (1) As before measure the ambient temperature at the instrument or controller terminals and read the corresponding voltage from the tables. As before we will assume an ambient of 20°C which gives a voltage of 0.798 mV
- (2) Find the table voltage corresponding to the required test temperature, say 750°C which gives 31.213 mV
- (3) Subtract the ambient voltage from the test temperature voltage. The result of 30.415 mV is the required injection voltage. As before the  $\mu\text{V}/^\circ\text{C}$  slope can be used to work out voltages for temperatures between the 10°C steps of *Table 12.4*.

**Table 12.4** Voltages for a type K thermocouple, voltages in micro volts with reference junction at 0°C

Deg C	0	–10	–20	–30	–40	–50	–60	–70	–80	–90	$\mu\text{V}/^\circ\text{C}$

1100	45119	45497	45873	46249	46623	46995	47367	47737	48105	48473	37.2
1200	48838	49202	49565	49926	50286	50644	51000	51355	51708	52060	35.7
1300	52410	52759	53106	53451	53795	54138	55479	54819			

Note that if the local input terminals at the meter are shorted together, the local ambient temperature (from the cold junction compensation) should be displayed. This is a useful quick check.

The tables show that the voltage from a thermocouple is small, typically less than 10 mV. High gain, high stability amplifiers with good common mode rejection are required and care taken in the installation to avoid noise.

In critical applications a high resistance voltage source is connected across the thermocouple so that in the event of a cable break the meter will indicate a high temperature.

### 12.2.3 Resistance thermometers

If a wire has resistance  $R_0$  at  $0^\circ\text{C}$  its resistance will increase with increasing temperature giving a resistance  $R_t$  at temperature  $T$  given by:

$$R_t = R_0(1 + aT + bT^2 + cT^3 + \dots) \Leftarrow$$

where  $a$ ,  $b$ ,  $c$  etc. are constants. These are not necessarily positive.

This change in resistance can be used to measure temperature. Platinum is widely used because the relationship between resistance and temperature is fairly linear. A standard device is made from a coil of wire with a resistance of  $100\ \Omega$  at  $0^\circ\text{C}$ , giving rise to the common name of a *Pt100 sensor*. These can be used over the temperature range  $-200^\circ\text{C}$  to  $800^\circ\text{C}$ . At  $100^\circ\text{C}$  a Pt100 sensor has a resistance of  $138.5\ \Omega$ , and the  $38.5\ \Omega$  change from its resistance at  $0^\circ\text{C}$  is called the *fundamental interval*.

The current through the sensor must be kept low to avoid heating effects. Further errors can be introduced by the resistance of the cabling to the sensor as shown on *Figure 12.8(a)*. Errors from the cabling resistance can be overcome by the use of the three and four wire connections of *Figure 12.8(b, c and d)*. Three wire connections are usually used with a bridge circuit and four wire connections with a constant current source.

A *thermistor* is a more sensitive device. This is a semiconductor crystal whose resistance changes dramatically with

temperature. Devices are obtainable which decrease or increase resistance for increasing temperature. The former (decreasing) is more common.

The relationship is very non linear, and is given by:

$$R = R_0 \exp \left( B \left( \frac{1}{T} - \frac{1}{T_0} \right) \right)$$

where  $R_0$  is the defined resistance at temperature  $T_0$ ,  $R$  the resistance at temperature  $T$  and  $B$  is a constant called the *characteristic temperature*. A typical device will go from  $300\ \text{k}\Omega$  at  $0^\circ\text{C}$  to  $5\ \text{k}\Omega$  at  $100^\circ\text{C}$ .

Although very non-linear, they can be used for measurement over a limited range. Their high sensitivity and low cost makes them very useful for temperature switching circuits where a signal is required if a temperature goes above or below some preset value. Electric motors often have thermistors embedded in the windings to give early warning of motor overload.

### 12.2.4 Pyrometers

A heated object emits electromagnetic radiation. At temperatures below about  $400^\circ\text{C}$  this radiation can be felt as heat. As the temperature rises the object starts to emit visible radiation passing from red through yellow to white as the temperature rises. Intuitively we can use this radiation to qualitatively measure temperature as below:

Temperature	Colour
$500^\circ\text{C}$	Barely visible dull red glow
$800^\circ\text{C}$	Bright red glow
$950^\circ\text{C}$	Orange
$1000^\circ\text{C}$	Yellow
$1200^\circ\text{C}$	White
$1500^\circ\text{C}$	Dazzling white, eyes naturally avert

Pyrometers use the same effect to provide a non contact method of measuring temperature.

**Figure 12.8** The effect of line resistance on RTDs. (a) Simple two wire circuit introduces an error of  $2r$ ; (b) Three wire circuit places line resistance into both legs of the measuring bridge; (c) Alternative three wire circuit; (d) Four wire circuit

Figure 12.9 The principle of an optical pyrometer

A pyrometer is, in theory, a very simple device as shown on Figure 12.9. The object whose temperature is to be measured is viewed through a fixed aperture by a temperature measuring device. Part of the radiation emitted by the object falls on the temperature sensor causing its temperature to rise. The object's temperature is then inferred from the rise in temperature seen by the sensor. The sensor size must be very small, typically of the order of 1mm diameter. Often a circular ring of thermocouples connected in series (called a *thermopile*) is used. Alternatively a small resistance thermometer (called a *bolometer*) may be used. Some pyrometers measure the radiation directly using photo-electric detectors.

A major (and surprising) advantage of pyrometers is the temperature measurement is independent of distance from the object provided the field of view is full. As shown on Figure 12.10 the source is radiating energy uniformly in all directions, so the energy received from a point is proportional to the solid angle subtended by the sensor. This will decrease as the square of the distance. There is, however, another effect. As the sensor moves away the scanned area also increases as the square of the distance. These two effects cancel giving a reading which is independent of distance.

Although all pyrometers operate on radiated energy there are various ways in which the temperature can be deduced from the received radiation. The simplest measures the total energy received from the object (which is proportional to  $T^4$  where  $T$  is the temperature in kelvin). This method is susceptible to errors from lack of knowledge of the emissivity of the object's surface. This error can be reduced by using filters to restrict the measuring range to frequencies where the object's emissivity approaches unity.

An alternative method takes two measurements at two different frequencies (i.e. two different colours) and compares the relative intensities to give an indication of temperature. This method significantly reduces emissivity errors.

Pyrometers have a few major restrictions which should be appreciated. The main problem is they measure surface temperature and only surface temperature. Lack of knowledge of the emissivity is also a major source of error.

## 12.3 Flow

### 12.3.1 General

The term 'flow' can generally be applied in three distinct circumstances:

*Volumetric flow* is the commonest and is used to measure the volume of material passing a point in unit time (e.g.  $\text{m}^3 \cdot \text{s}^{-1}$ ). It may be indicated at the local temperature and pressure or normalised to some standard conditions using the standard gas law relationship:

$$V_n = \frac{P_m V_m T_n}{P_n T_m}$$

where suffix 'm' denotes the measured conditions and suffix 'n' the normalised condition.

*Mass flow* is the mass of fluid passing a point in unit time (e.g.  $\text{kg} \cdot \text{s}^{-1}$ ).

*Velocity of flow* is the velocity with which a fluid passes a given point. Care must be taken as the flow velocity may not be the same across a pipe, being lower at the walls. The effect is more marked at low flows.

### 12.3.2 Differential pressure flowmeters

If a constriction is placed in a pipe as Figure 12.11 the flow must be higher through the restriction to maintain equal mass flow at all points. The energy in a unit mass of fluid has three components:

- (1) Kinetic energy given by  $mv^2/2$ ;
- (2) Potential energy from the height of the fluid; and
- (3) Energy caused by the fluid pressure, called, rather confusingly, *flow energy*. This is given by  $P/\rho$  where  $P$  is the pressure and  $\rho$  the density.

In Figure 12.11 the pipe is horizontal, so the potential energy is the same at all points. As the flow velocity increases through the restriction, the kinetic energy will increase and, for conservation of energy, the flow energy (i.e. the pressure) must fall.

$$\frac{mv_1^2}{2} + \frac{P_1}{\rho_1} = \frac{mv_2^2}{2} + \frac{P_2}{\rho_2}$$

This equation is the basis of all differential flow meters.

Flow in a pipe can be smooth (called *streamline* or *laminar*) or *turbulent*. In the former case the flow velocity is not equal across the pipe being lower at the walls. With turbulent flow the flow velocity is equal at all points across a pipe.

Figure 12.10 The effect of object distance on a pyrometer. The energy per unit area *decreases* with the square of the distance, however the scanned area *increases* as the square of the distance. Neglecting other influences (such as atmospheric absorption) these effects cancel as the pyrometer reading is independent of distance

**Figure 12.11** The basis of a differential flow meter. Because the mass flow must be equal at all points (i.e.  $Q_1 = Q_2$ ) the flow velocity must increase in the region of  $A_2$ . As there is no net gain or loss of energy, the pressure must therefore decrease at  $A_2$

For accurate differential measurement the flow must be turbulent.

The flow characteristic is determined by the *Reynolds number* defined as:

$$Re = \frac{vD\rho}{\eta\varsigma}$$

where  $v$  is the fluid velocity,  $D$  the pipe diameter,  $\rho$  the fluid density and  $\eta\varsigma$  the fluid viscosity. Sometimes the *kinematic viscosity*  $\rho/\eta\varsigma$  is used in the formula. The Reynolds number is a ratio and has no dimensions. If  $Re < 2000$  the flow is laminar. If  $Re > 10^5$  the flow is fully turbulent.

Calculation of the actual pressure drop is complex, especially for compressible gases, but is generally of the form:

$$Q = K\sqrt{\Delta P} \quad (12.1)$$

where  $K$  is a constant for the restriction and  $\Delta P$  the differential pressure. Methods of calculating  $K$  are given in British Standard BS 1042 and ISO 5167:1980. Computer programs can also be purchased.

The commonest differential pressure flow meter is the orifice plate shown on *Figure 12.12*. This is a plate inserted

**Figure 12.12** Mounting of an orifice pipe between flanges with  $D-D/2$  tapping

into the pipe with upstream tapping point at  $D$  and downstream tapping point at  $D/2$  where  $D$  is the pipe diameter. The plate should be drilled with a small hole to release bubbles (liquid) or drain condensate (gases). An identity tag should be fitted showing the scaling and plant identification.

The  $D-D/2$  tapping is the commonest, but other tappings shown on *Figure 12.13* may be used where it is not feasible to drill the pipe.

Orifice plates suffer from a loss of pressure on the downstream side (called the *head loss*). This can be as high as 50%. The venturi tube and Dall tube of *Figure 12.14(b)* have lower losses of around 5% but are bulky and more expensive. Another low loss device is the pitot tube of *Figure 12.15*. Equation 12.1 applies to all these devices, the only difference being the value of the constant  $K$ .

Conversion of the pressure to an electrical signal requires a differential pressure transmitter and a linearising square root unit. This square root extraction is a major limit on the turndown as zeroing errors are magnified. A typical turndown is 4:1.

The transmitter should be mounted with a manifold block as shown on *Figure 12.16* to allow maintenance. Valves B and C are isolation valves. Valve A is an equalising valve and is used, along with B and C, to zero the transmitter. In normal operation A is closed and B and C are open. Valve A should always be opened before valves B and C are closed prior to removal of the transducer to avoid high pressure being locked into one leg. Similarly on replacement, valves B and C should both be opened before valve A is closed to prevent damage from the static pressure.

Gas measurements are prone to condensate in pipes, and liquid measurements are prone to gas bubbles. To avoid these effects, a gas differential transducer should be mounted above the pipe and a liquid transducer below the pipe with tap off points in the quadrants as shown later in Section 12.4.6.

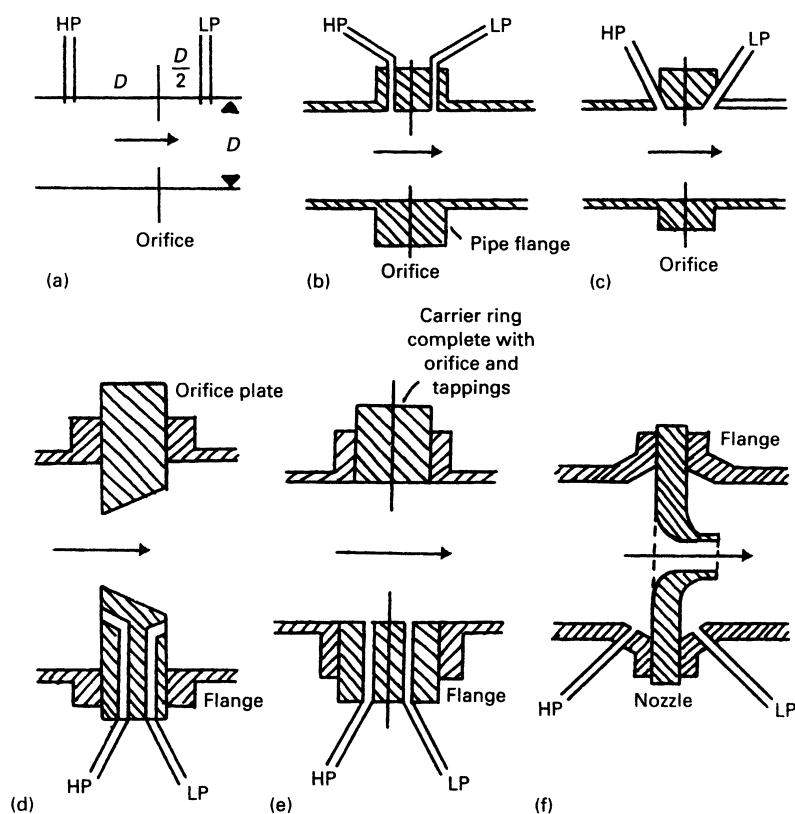

Although the accuracy and turndown of differential flowmeters is poor (typically 4% and 4:1) their robustness, low cost and ease of installation still makes them the commonest type of flowmeter.

### 12.3.3 Turbine flowmeters

As its name suggests a turbine flowmeter consists of a small turbine placed in the flow as *Figure 12.17*. Within a specified flow range, (usually with about a 10:1 turndown for liquids, 20:1 for gases,) the rotational speed is directly proportional to flow velocity.

The turbine blades are constructed of ferromagnetic material and pass below a variable reluctance transducer producing an output approximating to a sine wave of the form:

$$E = A\omega \sin(N\omega t)$$

**Figure 12.13** Common methods of mounting orifice plates. (a)  $D-D/2$ , probably the commonest; (b) Flange taps used on large pipes with substantial flanges; (c) Corner taps drilled through flange; (d) Plate taps, tappings built into the orifice plate; (e) Orifice carrier, can be factory made and needs no drilling on site; (f) Nozzle, gives smaller head loss

**Figure 12.14** Low loss differential pressure primary sensors. Both give a much lower head loss than an orifice plate but at the expense of a great increase on pipe length. It is often impossible to provide the space for these devices. (a) Venturi tube; (b) Dall Tube

Figure 12.15 An insertion pitot tube

where  $A$  is a constant,  $\omega$  is the angular velocity (itself proportional to flow) and  $N$  is the number of blades. Both the output amplitude and the frequency are proportional to flow, although the frequency is normally used.

The turndown is determined by frictional effects and the flow at which the output signal becomes unacceptably low. Other non linearities occur from the magnetic and viscous drag on the blades. Errors can occur if the fluid itself is swirling and upstream straightening vanes are recommended.

Turbine flowmeters are relatively expensive and less robust than other flowmeters. They are particularly vulnerable to damage from suspended solids. Their main advantages are a linear output and a good turndown ratio. The pulse output can also be used directly for flow totalisation.

### 12.3.4 Vortex shedding flowmeters

If a bluff (non-streamlined) body is placed in a flow, vortices detach themselves at regular intervals from the down-

Figure 12.16 Connection of a differential pressure flow sensor such as an orifice plate to a differential pressure transmitter. Valves B and C are used for isolation and valve A for equalisation

stream side as shown on Figure 12.18. The effect can be observed by moving a hand through water. In flow measurement the vortex shedding frequency is usually a few hundred Hz. Surprisingly at Reynolds numbers in excess of  $10^3$  the volumetric flow rate,  $Q$ , is directly proportional to the observed frequency of vortex shedding  $f$ , i.e.

$$Q = Kf$$

where  $K$  is a constant determined by the pipe and obstruction dimensions.

Figure 12.17 A turbine flow meter. These are vulnerable to bearing failures if the fluid contains any solid particles

Figure 12.18 Vortex shedding flowmeter

The vortices manifest themselves as sinusoidal pressure changes which can be detected by a sensitive diaphragm on the bluff body or by a downstream modulated ultrasonic beam.

The vortex shedding flowmeter is an attractive device. It can work at low Reynolds numbers, has excellent turndown (typically 15:1), no moving parts and minimal head loss.

### 12.3.5 Electromagnetic flowmeters

In Figure 12.19(a) a conductor of length  $l$  is moving with velocity  $v$  perpendicular to a magnetic field of flux density  $B$ . By Faraday's law of electromagnetic induction a voltage  $E$  is induced where:

$$E = B \cdot l \cdot v \quad (12.2)$$

This principle is used in the electromagnetic flowmeter. In figure 12.19(b) a conductive fluid is passing down a pipe with mean velocity  $v$  through an insulated pipe section. A magnetic field  $B$  is applied perpendicular to the flow. Two electrodes are placed into the pipe sides to form, via the fluid, a moving conductor of length  $D$  relative to the field where  $D$  is the pipe diameter. From Equation 12.2 a voltage will occur across the electrodes which is proportional to the mean flow velocity across the pipe.

Equation 12.2 and Figure 12.19(b) imply a steady d.c. field. In practice an a.c. field is used to minimise electrolysis and reduce errors from d.c. thermoelectric and electrochemical voltages which are of the same order of magnitude as the induced voltage.

Electromagnetic flowmeters are linear and have an excellent turndown of about 15:1. There is no practical size limit and no head loss. They do, though provide a few installation problems as an insulated pipe section is required,

with earth bonding either side of the meter to avoid damage from any welding which may occur in normal service. They can only be used on fluids with a conductivity in excess of  $1 \text{ mS m}^{-1}$  which permits use with many, (but not all), common liquids but prohibits their use with gases. They are useful with slurries with a high solids content.

### 12.3.6 Ultrasonic flowmeters

The Doppler effect occurs when there is relative motion between a sound transmitter and receiver as shown on Figure 12.20(a). If the transmitted frequency is  $f_t$  Hz,  $V_s$  is the velocity of sound and  $V$  the relative velocity, the observed received frequency,  $f_r$  will be:

$$f_r = f_t \frac{(V + V_s)}{V}$$

A Doppler flowmeter injects an ultrasonic sound wave (typically a few hundred kHz) at an angle  $\theta$  into a fluid moving in a pipe as shown on Figure 12.20(b). A small part of this beam will be reflected back off small bubbles, solid matter, vortices etc. and is picked up by a receiver mounted alongside the transmitter. The frequency is subject to two changes, one as it moves upstream against the flow, and one as it moves back with the flow. The received frequency is thus:

$$f_r = f_t \frac{(V_s + V \cos(\theta))}{(V_s - V \cos(\theta))}$$

which can be simplified to

$$\Delta f = \frac{2f_t}{V_s} V \cos(\theta)$$

The Doppler flowmeter measures mean flow velocity, is linear, and can be installed (or removed) without the need to break into the pipe. The turndown of about 100:1 is the best of all flowmeters. Assuming the measurement of mean flow velocity is acceptable it can be used at all Reynolds numbers. It is compatible with all fluids and is well suited for difficult applications with corrosive liquids or heavy slurries.

Figure 12.19 Electromagnetic flowmeter. (a) Electromagnetic induction in a wire moving in a magnetic field; (b) The principle applied with a moving conductive fluid

**Figure 12.20** An Ultrasonic Flowmeter. (a) Principle of operation; (b) Schematic of a clip on ultrasonic flowmeter

### 12.3.7 Hot wire anemometer

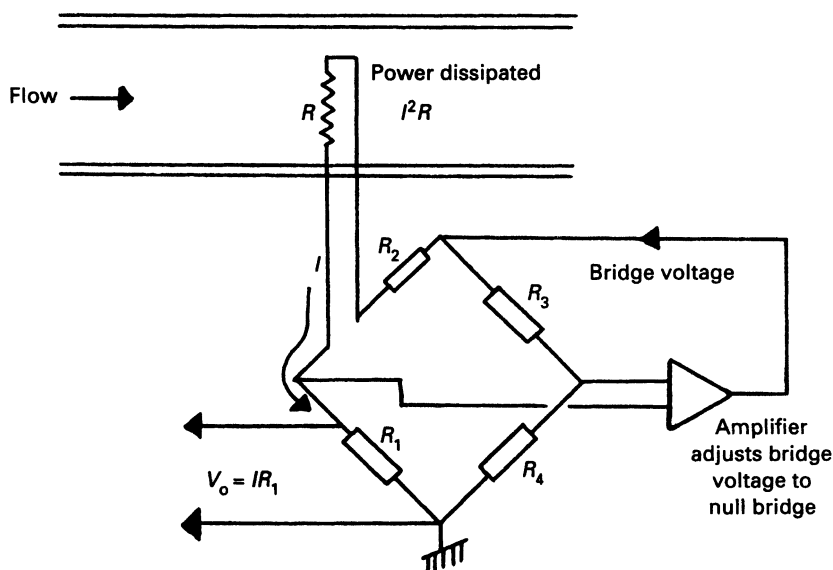

If fluid passes over a hot object, heat is removed. It can be shown that the power loss is:

$$P = A + B\sqrt{v} \quad (12.3)$$

where  $v$  is the flow velocity and  $A$  and  $B$  are constant.  $A$  is related to radiation and  $B$  to conduction.

Figure 12.21 shows a flowmeter based on Equation 12.3. A hot wire is inserted in the flow and maintained at a constant temperature by a self balancing bridge. Changes in the wire temperature result in a resistance change which unbalances the bridge. The bridge voltage is automatically adjusted to restore balance.

The current,  $I$ , though the resistor is monitored. With a constant wire temperature the heat dissipated is equal to the power loss from which:

**Figure 12.21** The hot wire anemometer

$$v = (I^2 R - A)/B^2$$

Obviously the relationship is non linear, and correction will need to be made for the fluid temperature which will affect constants  $A$  and  $B$ .

### 12.3.8 Mass flowmeters

The volume and density of all materials are temperature dependent. Some applications will require true volumetric measurements, some, such as combustion fuels, will really require mass measurement. Previous sections have measured volumetric flow. This section discusses methods of measuring mass flow.

The relationship between volume and mass depends on both pressure and absolute temperature (measured in kelvin). For a gas:

$$\frac{P_1 V_1}{T_1} = \frac{P_2 V_2}{T_2}$$

The relationship for a liquid is more complex, but if the relationship is known and the pressure and temperature are measured along with the delivered volume or volumetric flow the delivered mass or mass flow rate can be easily calculated. Such methods are known as *Inferential* flowmeters.

In Figure 12.22 a fluid is passed over an in-line heater with the resultant temperature rise being measured by two temperature sensors. If the specific heat of the material is constant, the mass flow,  $F_m$ , is given by:

$$F_m = \frac{E}{C_p \theta_s}$$

where  $E$  is the heat input from the heater,  $C_p$  is the specific heat and  $\theta_s$  the temperature rise. The method is only suitable for relatively small flow rates.

Many modern mass flowmeters are based on the Coriolis effect. In Figure 12.23 an object of mass  $m$  is required to move with linear velocity  $v$  from point  $A$  to point  $B$  on a surface which is rotating with angular velocity. If the object

Figure 12.22 Mass flow measurement by noting the temperature rise caused by a constant input power

Figure 12.23 Definition of Coriolis force

moves in a straight line as viewed by a static observer, it will appear to veer to the right when viewed by an observer on the disc.

If the object is to move in a straight line as seen by an observer on the disc a force must be applied to the object as it moves out. This force is known as the *Coriolis force* and is given by

$$F = 2m\omega v$$

where  $m$  is the mass,  $\omega$  is the angular velocity and  $v$  the linear velocity. The existence of this force can be easily experienced by trying to move along a radius of a rotating children's roundabout in a playground.

Coriolis force is not limited to pure angular rotation, but also occurs for sinusoidal motion. This effect is used as the basis of a Coriolis flowmeter shown on Figure 12.24. The flow passes through a 'C' shaped tube which is attached to a leaf spring and vibrated sinusoidally by a magnetic forcer. The Coriolis force arises not, as might be first thought, because of the semi-circle pipe section at the right-hand

Figure 12.24 Simple Coriolis mass flowmeter. A multi-turn coil is often used in place of the 'C' segment

Figure 12.25 Vibrating straight pipe mass flowmeter

side, but from the angular motion induced into the two horizontal pipe sections with respect to the fixed base. If there is no flow, the two pipe sections will oscillate together. If there is flow, the flow in the top pipe is in the opposite direction to the flow in the bottom pipe and the Coriolis force causes a rolling motion to be induced as shown. The resultant angular deflection is proportional to the mass flow rate.

The original meters used optical sensors to measure the angular deflection. More modern meters use a coil rather than a 'C' section and sweep the frequency to determine the resonant frequency. The resonant frequency is then related to the fluid density by:

$$f_c = \sqrt{\frac{K}{\text{density}}}$$

where  $K$  is a constant. The mass flow is determined either by the angular measurement or the phase shift in velocity. Using the resonant frequency maximises the displacement and improves measurement accuracy.

Coriolis measurement is also possible with a straight pipe. In Figure 12.25 the centre of the pipe is being deflected with a sinusoidal displacement, and the velocity of the inlet and outlet pipe sections monitored. The Coriolis effect will cause a phase shift between inlet and outlet velocities. This phase shift is proportional to the mass flow.

## 12.4 Pressure

### 12.4.1 General

There are four types of pressure measurement.

**Differential pressure** is the difference between two pressures applied to the transducer. These are commonly used for flow measurement as described in Section 12.3.2.

**Gauge pressure** is made with respect to atmospheric pressure. It can be considered as a differential pressure measurement with the low pressure leg left open. Gauge pressure is usually denoted by the suffix 'g' (e.g. 37 psig). Most pressure transducers in hydraulic and pneumatic systems indicate gauge pressure.

**Absolute pressure** is made with respect to a vacuum.

$$\begin{aligned} \text{Absolute pressure} &= \text{Gauge pressure} \\ &+ \text{Atmospheric pressure} \end{aligned}$$

Atmospheric pressure is approximately 1 bar, 100 kPa or 14.7 psi.

**Head pressure** is used in liquid level measurement and refers to pressure in terms of the height of a liquid (e.g. inches water gauge). It is effectively a gauge pressure measurement, but if the liquid is held in a vented vessel any changes in atmospheric pressure will affect both legs of the transducer equally giving a reading which is directly related to liquid height.

The head pressure is given by:

$$P = \rho gh \quad (12.4) \Leftarrow$$

where  $P$  is the pressure in pascals,  $\rho$  is the density ( $\text{kgm}^{-3}$ ),  $g$  is acceleration due to gravity ( $9.8 \text{ ms}^{-2}$ ) and  $h$  the column height in metres.

In Imperial units, pounds are a term of weight (i.e. force) not mass so Equation 12.4 becomes

$$P = \rho h$$

where  $P$  is the pressure in pounds per square unit (inch or foot),  $\rho$  is the density in pounds per cubic unit and  $h$  is the height in units.

### 12.4.2 Manometers

Although manometers are not widely used in industry they give a useful insight into the principle of pressure measurement. If a U-tube is part filled with liquid, and differing pressures applied to both legs as Figure 12.26, the liquid will fall on the high pressure side and rise on the low pressure side until the head pressure of liquid matches the pressure difference. If the two levels are separated by a height  $h$  then

$$h = (P_1 - P_2) / \rho g$$

where  $P_1$  and  $P_2$  are the pressures (in pascals),  $\rho$  is the density of the liquid and  $g$  is the acceleration due to gravity.

### 12.4.3 Elastic sensing elements

The Bourdon tube, dating from the mid nineteenth century, is still the commonest pressure indicating device. The tube is manufactured by flattening a circular cross-section tube to the section shown on Figure 12.27 and bending it into a C shape. One end is fixed and connected to the pressure to be measured. The other end is closed and left free.

If pressure is applied to the tube it will try to straighten causing the free end to move up and to the right. This

**Figure 12.26** The U tube manometer. (a) Pressures  $P_1$  and  $P_2$  are equal; (b) Pressure  $P_1$  is greater than  $P_2$  and the distance  $h$  is proportional to  $(P_1 - P_2)$

**Figure 12.27** The Bourdon tube pressure gauge

motion is converted to a circular motion for a pointer with a quadrant and pinion linkage. A Bourdon tube inherently measures gauge pressure.

Bourdon tubes are usable up to about 50 MPa, (about 10 000 psi). Where an electrical output is required the tube can be coupled to a potentiometer or LVDT.

Diaphragms can also be used to convert a pressure differential to a mechanical displacement. Various arrangements are shown on *Figure 12.28*. The displacement can be measured by LVDTs (see Section 12.6.4), strain gauges (see Section 12.8.3). The diaphragm can also be placed between two perforated plates as *Figure 12.29*. The diaphragm and the plates form two capacitors whose value is changed by the diaphragm deflection.

#### 12.4.4 Piezo elements

The piezo electric effect occurs in quartz crystals. An electrical charge appears on the faces when a force is applied.

This charge is directly proportional to the applied force. The force can be related to pressure with suitable diaphragms. The resulting charge is converted to a voltage by the circuit of *Figure 12.30* which is called a *charge amplifier*. The output voltage is given by:

$$V = -q/c$$

Because  $q$  is proportional to the force,  $V$  is proportional to the force applied to the crystal. In practice the charge leaks away, even with FET amplifiers and low leakage capacitors. Piezo-electric transducers are thus unsuitable for measuring static pressures, but they have a fast response and are ideal for measuring fast dynamic pressure changes.

A related effect is the piezo resistive effect which results in a change in resistance with applied force. Piezo resistive devices are connected into a Wheatstone bridge.

#### 12.4.5 Force balance systems

Friction and non-linear spring constants can cause errors in elastic displacement transducers. The force balance system uses closed loop control to balance the force from the pressure with an opposing force which keeps the diaphragm in a fixed position as shown on *Figure 12.31*. As the force from the solenoid is proportional to the current, the current in the coil is directly proportional to the applied pressure. LVDTs are commonly used for the position feedback.

#### 12.4.6 Vacuum measurement

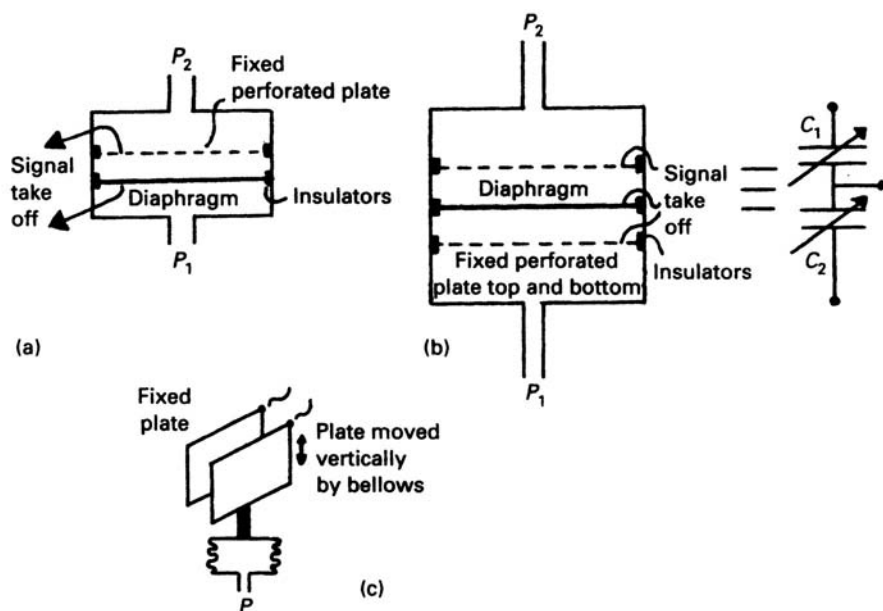

Vacuum measurement is normally expressed in terms of the height of a column of mercury which is supported by the vacuum (e.g. mmHg). Atmospheric pressure (approximately 1 bar) thus corresponds to about 760 mmHg, and an absolute vacuum is 0 mmHg. The term '*torr*' is generally used for 1 mmHg. Atmospheric pressure is thus about 760 torr.

Conventional absolute pressure transducers are usable down to about 20 torr with special diaphragms. At lower pressures other techniques, described below, must be used. At low pressures the range should be considered as logarithmic, i.e. 1 to 0.1 torr is the same 'range' as 0.1 torr to 0.01 torr.

The first method, called the *Pirani gauge*, applies constant energy to heat a thin wire in the vacuum. Heat is lost from a hot body by conduction, convection and radiation. The first two losses are pressure dependent. The heat loss

**Figure 12.28** Various arrangements of elastic pressure sensing elements. (a) Diaphragm; (b) Corrugated diaphragm; (c) Catenary diaphragm; (d) Capsule; (e) Bellows

**Figure 12.29** Variable capacitance pressure sensing elements. (a) Single capacitor variable spacing; (b) Double capacitor variable spacing; (c) Variable area

Figure 12.30 The charge amplifier

decreases as the pressure falls causing the temperature of the wire to rise. The temperature of the wire can be measured from its resistance (see Section 12.2.3) or by a separate thermocouple.

The range of a Pirani gauge is easily changed by altering the energy supplied to the wire. A typical instrument would cover the range 5 torr to  $10^{-5}$  torr in three ranges. Care must be taken not to overheat the wire which will cause a change in the heat loss characteristics.

The second technique, called an *ionisation gauge*, is similar to a thermionic diode. Electrons emitted from the heated cathode cause a current flow which is proportional to the absolute pressure. The current is measured with high sensitivity microammeters. Ionisation gauges can be used over the range  $10^{-3}$  to  $10^{-12}$  torr.

#### 12.4.7 Installation notes

To avoid a response with a very long time constant the pipe run between a plant and a pressure transducer must be kept as short as possible. This effect is particularly important

with gas pressure transducers which can exhibit time constants of several seconds if the installation is poor.

Entrapped air can cause significant errors in liquid pressure measurement, and similarly condensed liquid will cause errors in gas pressure measurement. Ideally the piping should be taken from the top of the pipe and rise to the transducer for gas systems, and be taken from the lower half of the pipe and fall to the transducer for liquid pressure measurement. If this is not possible, vent/drain cocks must be fitted. Care must be taken to avoid sludge build up around the tapping with liquid pressure measurement. Typical installations are shown on Figure 12.32. Under no circumstances should the piping form traps where gas bubbles or liquid sumps can form.

Steam pressure transducers are a special case. Steam can damage the transducer diaphragm, so the piping leg to the transducer is normally arranged to naturally fill with water by taking the tapping of the top of the pipe and mounting the transducer (with unlagged pipes) below the pipe as Figure 12.33(a). If this is not possible, a steam trap is placed in the piping as Figure 12.33(b).

In both cases there will be an offset from the liquid head. A similar effect occurs when a liquid pressure transmitter is situated below the pipe. In both cases the offset pressure can usually be removed in the transducer setup.

Pressure transducers will inevitably need to be changed or maintained on line, so isolation valves should always be fitted. These should include an automatic vent on closure so pressure cannot be locked into the pipe between the transducer and the isolation valve.

Where a low pressure range differential transducer is used with a high static pressure, care must be taken to avoid damage by the static pressure getting 'locked in' to one side. Figure 12.16 (Section 12.3.2) shows a typical manifold for a differential transducer. The bypass valve should always be opened first on removal and closed last on replacement.

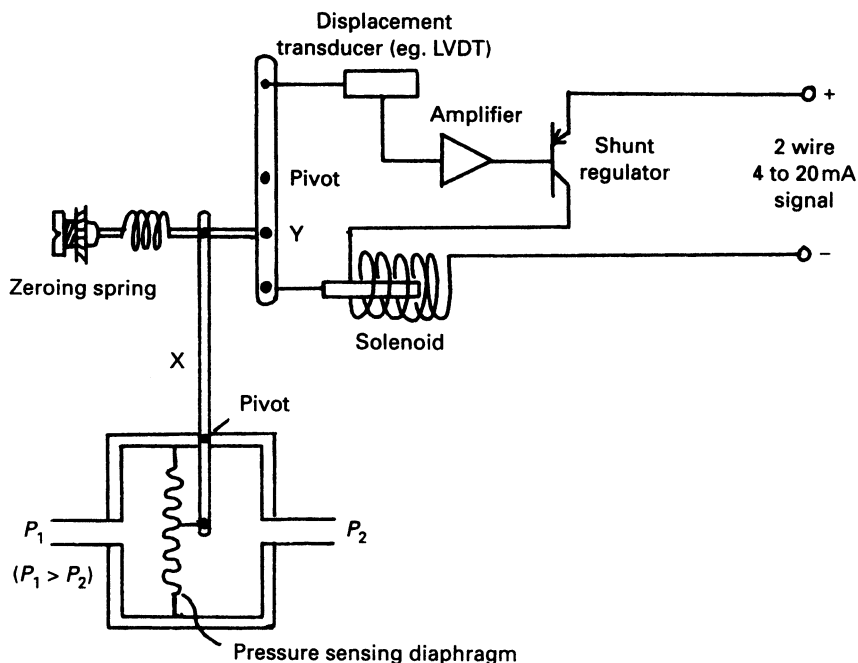

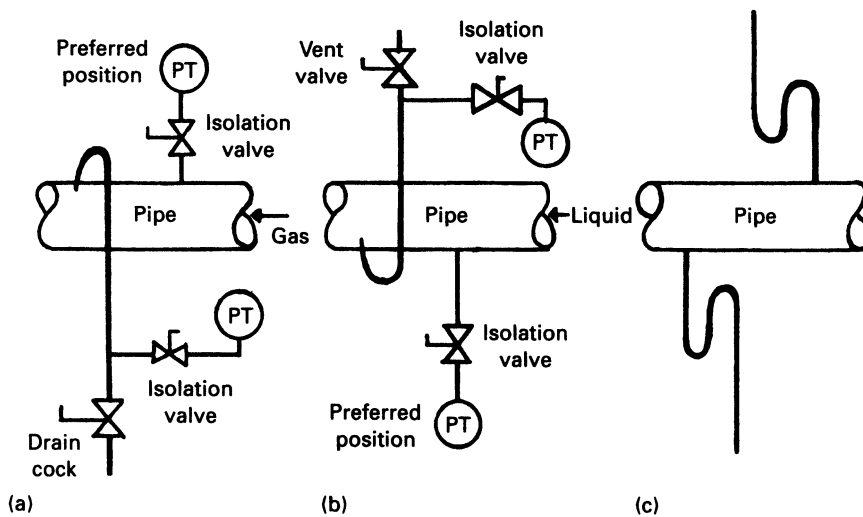

Figure 12.31 A force balance pressure transducer

**Figure 12.32** Installation of pressure transducers. Similar considerations apply to differential pressure transducers used with orifice plates and similar primary flow sensors. (a) Gas pressure transducer; (b) Liquid pressure transducer; (c) Faulty installations with potential traps

**Figure 12.33** Piping arrangements for steam pressure transducers. (a) Preferred arrangement; (b) Alternative arrangement

## 12.5 Level transducers

### 12.5.1 Float based systems

A float is the simplest method of measuring or controlling level. *Figure 12.34* shows a typical method of converting the float position to an electrical signal. The response is non linear, with the liquid level being given by:

$$h = H - l \cdot \sin(\theta) \Leftarrow$$

To minimise errors the float should have a large surface area.

### 12.5.2 Pressure based systems

The absolute pressure at the bottom of a tank has two components and is given by:

$$P = \rho gh + \text{atmospheric pressure}$$

where  $\rho$  is the density,  $g$  is gravitational acceleration and  $h$  the depth of the liquid. The term  $\rho gh$  is called the head pressure. Most pressure transducers measure gauge pressure,

**Figure 12.34** Lever arm float based level measurement system

(see Section 12.4.1), so the indicated pressure will be directly related to the liquid depth. It should be noted that 'h' is the height difference between the liquid surface and the pressure transducer itself. An offset may need to be added, or subtracted, to the reading as shown on *Figure 12.35(a)*.

If the tank is pressurised, a differential pressure transmitter must be used as *Figure 12.35(b)*. This arrangement may also require a correction if the pressure transducer height is not the same as the tank bottom. Problems can also occur if condensate can form in the low pressure leg as the condensate will have its own, unknown, head pressure.

In these circumstances the problems can be overcome by deliberately filling both legs with fluid as *Figure 12.35(c)*. Note that the high pressure leg is now connected to the tank top. The differential pressure is now:

$$\Delta P = (D - h) \cdot g \cdot (\rho_1 - \rho_2) \Leftarrow$$

where  $\rho_1$  is the liquid density and  $\rho_2$  the vapour density (often negligible). Note that the equation is independent of the transducer offset  $H_1$ . This arrangement is often used in boiler applications to measure the level of water in the drum. The filling of the pipes often occurs naturally if they are left unlagged.

**Figure 12.35** Level measurement from hydrostatic pressure. (a) Head error arising from transducer position. This error can be removed by a simple offset; (b) Differential pressure measurement in a pressurised tank; (c) Level measurement with condensable liquid. This method is commonly used for drum level in steam boilers

One problem of all methods described so far is that the pressure transducer must come into contact with the fluid. If the fluid is corrosive or at a high temperature this may cause early failures. The food industries must also avoid stagnant liquids in the measuring legs. One solution is the gas bubbler of Figure 12.36. Here an inert gas (usually argon) is bubbled into the liquid, and the measured gas pressure will be the head pressure  $\rho gh$  at the pipe exit.

### 12.5.3 Electrical probes

Capacitive probes can be used to measure the depth of liquids and solids. A rod, usually coated with PVC or PTFE, is inserted into the tank (Figure 12.37(a)) and the capacitance measured to the tank wall. This capacitance has two components,  $C_1$  above the surface and  $C_2$  below the surface. As the level rises  $C_1$  will decrease and  $C_2$  will increase. These two capacitors are in parallel, but as liquids and solids have a higher di-electric constant than vapour, the net result is that the capacitance rises for increasing level.

**Figure 12.36** Level measurement using a gas bubbler

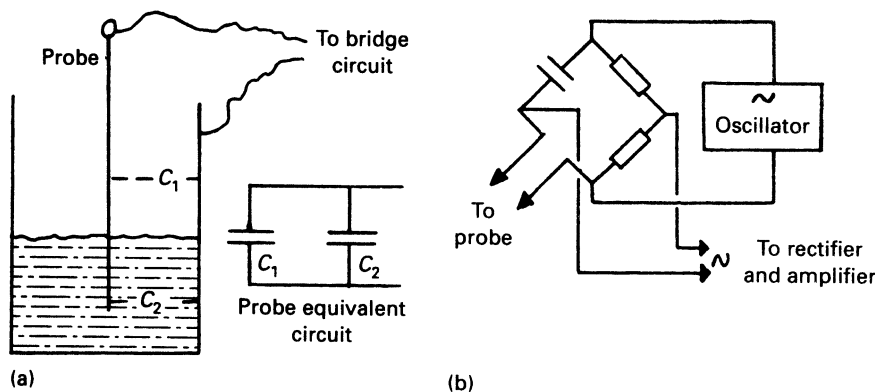

Figure 12.37 Level measurement using a capacitive probe. (a) Physical arrangement; (b) A.c. bridge circuit

The effect is small, however, and the change is best measured with an a.c. bridge circuit driven at about 100 kHz (Figure 12.37(b)). The small capacitance also means that the electronics must be close to the tank to prevent errors from cable capacitance.

The response is directly dependent on the dielectric constant of the material. If this changes, caused, say, by bubbling or frothing, errors will be introduced.

If the resistance of a liquid is reasonably constant, the level can be inferred by reading the resistance between two submerged metal probes. Stainless steel is often used to reduce corrosion. A bridge measuring circuit is again used with an a.c. supply to avoid electrolysis and plating effects. Corrosion can be a problem with many liquids, but the technique works well with water. Cheap probes using this principle are available for stop/start level control applications.

#### 12.5.4 Ultrasonic transducers

Ultrasonic methods use high frequency sound produced by the application of a suitable a.c. voltage to a piezo electric crystal. Frequencies in the range 50 kHz to 1 MHz can be used, although the lower end of the range is more common in industry. The principle is shown on Figure 12.38. An ultrasonic pulse is emitted by a transmitter. It reflects off the surface and is detected by a receiver. The time of flight is given by:

Figure 12.38 Basic arrangement for ultrasonic level measurement

$$t = \frac{2d}{v}$$

where  $v$  is the velocity of sound in the medium above the surface. The velocity of sound in air is about  $3000 \text{ ms}^{-1}$ , so for a tank whose depth can vary from 1 to 10 m, the delay will vary from about 7 ms (full) to 70 ms (empty).

There are two methods used to measure the delay. The simplest, assumed so far and most commonly used in industry, is a narrow pulse. The receiver will see several pulses, one almost immediately through the air, the required surface reflection and spurious reflections from sides, the bottom and rogue objects above the surface (e.g. steps and platforms). The measuring electronics normally provides adjustable filters and upper and lower limits to reject unwanted readings.

Pulse driven systems lose accuracy when the time of flight is small. For a distance below a few millimetres a swept frequency is used where a peak in the response will be observed when the path difference is a multiple of the wavelength, i.e.

$$d = \frac{v}{2f}$$

where  $v$  is the velocity of propagation and  $f$  the frequency at which the peak occurs. Note that this is ambiguous as peaks will also be observed at integer multiples of the wavelength.

Both methods require accurate knowledge of the velocity of propagation. The velocity of sound is  $1440 \text{ ms}^{-1}$  in water,  $3000 \text{ ms}^{-1}$  in air and  $5000 \text{ ms}^{-1}$  in steel. It is also temperature dependent varying in air by 1% for a  $30^\circ\text{C}$  temperature change. Pressure also has an effect. If these changes are likely to be significant they can be measured and correction factors applied.

#### 12.5.5 Nucleonic methods

Radioactive isotopes (such as cobalt 60) spontaneously emit gamma or beta radiation. As this radiation passes through the material it is attenuated according to the relationship:

$$I = I_0 \exp(-\rho d)$$

where  $I_0$  is the initial intensity,  $m$  is a constant for the material,  $\rho$  is the density and  $d$  the thickness of the material. This equation allows a level measurement system to be constructed in one of the ways shown on Figure 12.39. In each case the intensity of the received radiation is dependent on the level, being a maximum when the level is low.

**Figure 12.39** Various methods of level measurement using a radio-active source. (a) Line source, point detector; (b) Point source, line detector; (c) Collimated line source, line detector

The methods are particularly attractive for aggressive materials or extreme temperatures and pressures as all the measuring equipment can be placed outside the vessel.

Sources used in industry are invariably sealed, i.e. contained in a lead or similar container with a shuttered window allowing a narrow beam (typically  $40^\circ \times 42^\circ$ ) to be emitted. The window can usually be closed when the system is not in use and to allow safe transportation. Source strength is determined by the number of disintegrations per second (dps) at the source. There are two units in common use; the curie, (Ci  $3.7 \times 10^{10}$  dps) and the SI derived unit the becquerel (Bq 1 dps). The typical industrial source would be 500 mCi (18.5 GBq) caesium 137 although there are variations by a factor of at least ten dependent on the application.

The strength of a source decays exponentially with time and this decay is described by the *half life* which is the time taken for the strength to decrease by 50%. Cobalt 60, a typical industrial source, for example has a half life of 3.5 years and will hence change by about 1% per month. Sources thus have a built in drift and a system will require regular calibration.

The biological effects of radiation are complex and there is no real safe level; all exposure must be considered harmful and legislation is based around the concept of ALARP; 'as low as reasonably practical'. Exposures should be kept as low as possible, and figures quoted later should not be considered as design targets.

The *adsorbed dose* (AD) is a measure of the energy density adsorbed. Two units are again used; the rad and the SI derived unit the gray. These are more commonly encountered as the millirad (mrad) and the milligray (mGy):

$$1\text{mrad} = 1.6 \times 10^{-4} \text{ MeVg}^{-1}$$

$$1\text{mGy} = 1.6 \times 10^{-6} \text{ MeVg}^{-1}$$

The adsorbed dose is not however directly related to biological damage as it ignores the differing effect of  $\alpha$ ,  $\beta$  and  $\gamma$  radiation. A quality factor  $Q$  is defined which allows a *dose equivalent* (DE) to be calculated from:

$$\text{DE} = Q \times \text{AD}$$

There are, yet again, two units in common use; the rem and SI derived unit the sievert, again these are more commonly encountered as the millirem and millisievert (mSv);

$$\text{mrem} = Q \times \text{mrad}$$

$$\text{mSv} = Q \times \text{mGy}$$

The so called *dose rate* is expressed as DE/time (e.g. mrem/hr). Dose rates fall off as the inverse square of the distance, i.e. doubling the distance from the source gives one quarter of the dose rate.

British legislation recognises three groups of people:

*Classified workers* are trained individuals wearing radiation monitoring devices (usually film badges). They must not be exposed to dose rates of more than 2.5 mrem/hr and their maximum annual exposure (DE) is 5 rem. Medical records and dose history must be kept.

*Supervised workers* operate under the supervision of classified workers. Their maximum dose rate is 0.75 mrem/hr and maximum annual exposure is 1.5 rem.

*Unclassified workers* refers to others and the general public. Here the dose rate must not exceed 0.25 mrem/hr and the annual exposure must be below 0.5 rem.

It must be emphasised that the principle of ALARP applies and these are not design criteria.

Nucleonic level detection also requires detectors. Two types are commonly used, the *Geiger-Muller* (GM) tube and the *scintillation counter*. Both produce a semi-random pulse stream, the number of pulses received in a given time being dependent on the strength of the radiation. This pulse chain must be converted to a d.c. voltage by suitable filtering to give a signal which is dependent on the level of material between the source and the detector.

Conceptually nucleonic level measurement is simple and reliable. Public mistrust and the complex legislation can, however, make it a minefield for the unwary. Professional advice should always be taken before implementing a system.

### 12.5.6 Level switches

Many applications do not require analogue measurement but just a simple material present/absent signal. For liquids the simplest is a float which hangs down when out of a liquid and inverts when floating. The float orientation is sensed by two internal probes and a small mercury pool. Solids can be detected by rotating paddles or vibrating reeds which seize solid when submerged.

Two non-moving detectors are shown on *Figure 12.40*. The first is a heated tube whose heat loss will be higher (and hence the sensed temperature lower) when submerged. The second is a light reflective probe which will experience total internal reflection when submerged.

**Figure 12.40** Non contact level switches. (a) Using heat loss from submerged sensor; (b) Optical level switch based on total internal reflection

## 12.6 Position transducers

### 12.6.1 Introduction

The measurement of position or distance is of fundamental importance in many applications. It also appears as an intermediate variable in other measurement transducers where the measured variable (such as pressure or force) is converted to a displacement.

### 12.6.2 The potentiometer

The simplest position transducer is the humble potentiometer. They can directly measure angular or linear displacements. Figure 12.41 shows a potentiometer with track resistance  $R$ , connected to a supply  $V_i$  and a load  $R_L$ . If the span is  $D$  and the slider at position  $d$ , we can define a fractional displacement  $x = d/D$ . The output voltage is then:

$$V_0 = \frac{x V_i}{1 + (1-x)(R/R_L)}$$

The error is zero at both ends of the travel and maximum at  $x = 2/3$ . If  $R_L$  is significantly larger than  $R$ , the error is

**Figure 12.41** Potentiometer used for position measurement

approximately  $25 \cdot R/R_L\%$  of value or  $15 \cdot R/R_L\%$  of full scale. A 10 K potentiometer connected to a 100 K load will thus have an error of about 1.5% FSD. If  $R_L \gg R$ , then  $V_0 \approx x V_i$ .

Loading errors are further augmented by linearity and resolution errors. Potentiometers have finite resolution from the wire size or grain size of the track. They are also mechanical devices which require a force to move and hence can suffer from stiction, backlash and hysteresis.

The failure mode of a potentiometer also needs consideration. A track break can cause the output signal to be fully high above the failure point and fully low below it. In closed loop position control systems this manifests itself as a high speed dither around the break point.

Potentiometers can be manufactured with track resistance to give a specified non-linear response (e.g. trigonometric, logarithmic, square root etc.).

### 12.6.3 Synchros and resolvers

Figure 12.42(a) shows a transformer whose secondary can be rotated with respect to the primary. At angle  $\theta$  the output voltage will be given by

$$V_0 = K \cdot V_i \cdot \cos \theta$$

where  $K$  is a constant. This relationship is shown on Figure 12.42(b). The output amplitude is dependent on the angle, and the signal can be in phase (from  $\theta = 270^\circ$  to  $90^\circ$ ) or anti-phase (from  $\theta = 90^\circ$  to  $270^\circ$ ). This principle is the basis of synchros and resolvers.

A synchro link in its simplest form consists of a transmitter and receiver connected as Figure 12.43. Although this looks superficially like a three-phase circuit it is fed from a single-phase supply, often at 400 Hz. The voltage applied to the transmitter induces in-phase/anti-phase voltages in the windings as described above and causes currents to flow through the stator windings at the receiver. These currents produce a magnetic field at the receiver which aligns with the angle of the transmitter rotor.

The receiver rotor also produces a magnetic field. If the two receiver fields do not align, torque will be produced on

Figure 12.42 The synchro torque transmitter. (a) Construction; (b) Schematic representation

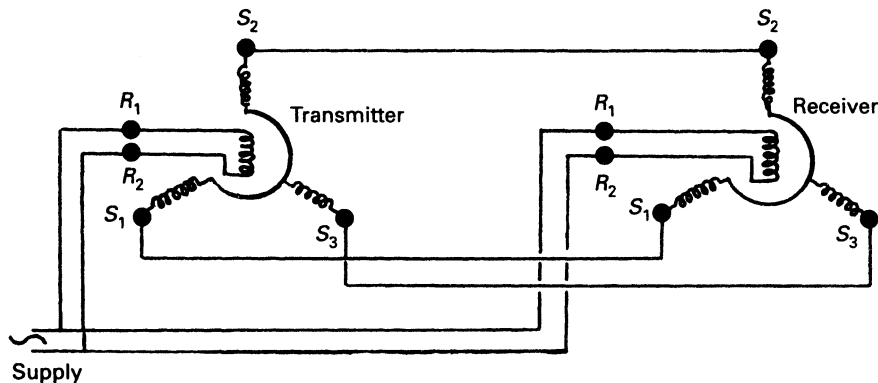

Figure 12.43 A synchro transmitter receiver link

the receiver shaft which causes the rotor to rotate until the rotor and stator fields align, i.e. the receiver rotor is at the same position as the transmitter rotor.

Such a link is called a *torque link* and can be used to remotely position an indicator. A more useful circuit, shown on Figure 12.44 can be used to give an electrical signal which represents the difference in angle of the two shafts. The receiving device is called a *control transformer*.

The transmitter operates as described above and induces a magnetic field in the control transformer. An a.c. voltage will be induced in the control transformer's rotor if it is not perpendicular to the field. The magnitude of this voltage is related to the angle error and the phase to the direction.

The a.c. output signal must be converted to d.c. by a phase sensitive rectifier. The *Cowan rectifier* (Figure 12.45) is commonly used. Another common circuit is the positive/negative amplifier (Figure 12.46) with the electronic polarity switch driven by the reference supply.

Resolvers have two stator coils at right angles and a rotor coil as shown on Figure 12.47. The voltages induced in the two stator coils are simply

$$V_1 = K \cdot \Phi \cos \theta$$

$$V_2 = K \cdot \Phi \sin \theta$$

Resolvers are used for co-ordinate conversion and conversion from rectangular to polar co-ordinates. They are also widely used with solid state digital converters which give a binary output signal (typically 12 bit). One useful feature is that  $(V_1^2 + V_2^2)$  is a constant which makes an open circuit winding easy to detect.

Resolvers can also be used with a.c. applied to the stator windings and the output signal taken from the rotor (Figure 12.48). One stator signal is shifted by  $90^\circ$ . Both signals are usually obtained from a pre-manufactured quadrature oscillator. The output signal is then

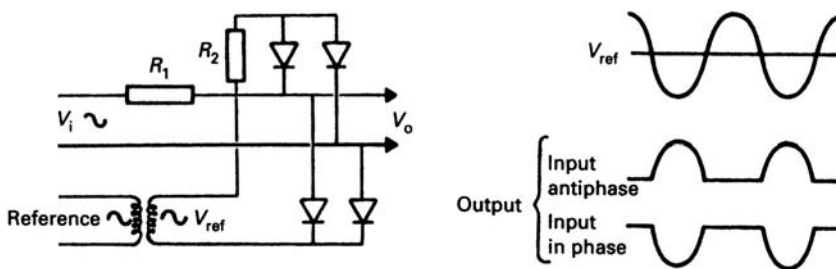

$$V_0 = K \cdot \Phi (\sin \omega t \cdot \cos \theta + \cos \omega t \cdot \sin \theta)$$

which simplifies to

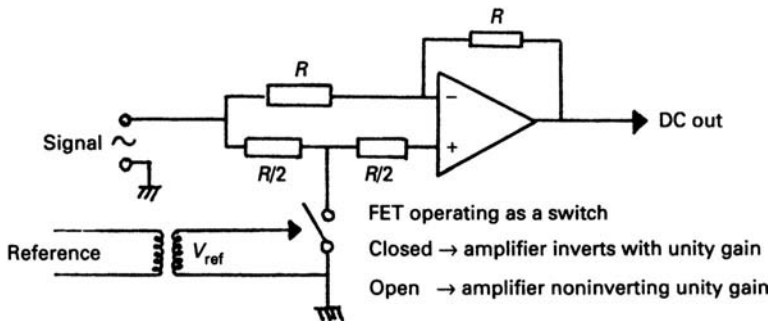

$$V_0 = K \cdot \Phi \sin(\omega t + \theta)$$

**Figure 12.44** Connection of a position control system using a control transformer. The output voltage is zero when the rotor on the control transformer is at  $90^\circ$  to the rotor on the transmitter. Note there are two zero positions  $180^\circ$  apart

**Figure 12.45** The Cowan half wave phase sensitive rectifier

**Figure 12.46** Full wave phase sensitive rectifier based on an operational amplifier. The switch represents a FET driven by a reference signal

**Figure 12.47** The resolver; the reference voltage is applied to the rotor and the output signals read from the two stator windings

**Figure 12.48** Alternative connection for a resolver. Two reference voltages shifted by  $90^\circ$  are applied to the stator windings and the output read from the rotor. The output signal is a constant amplitude sine wave with phase shift determined by the rotor angle

This a.c. signal can be converted to d.c. by a phase sensitive rectifier.

Complete rotary transducers comprising quadrature oscillator, resolver and phase sensitive rectifier can be obtained which give a d.c. output signal proportional to shaft angle. Because there is little friction these are low torque devices.

#### 12.6.4 Linear variable differential transformer (LVDT)

An LVDT is used to measure small displacements, typically less than a few mm. It consists of a transformer with two secondary windings and a movable core as shown on *Figure 12.49(a)*. At the centre position the voltages induced in the secondary windings are equal but of opposite phase giving zero output signal. As the core moves away from the centre one induced voltage will be larger, giving a signal whose amplitude is proportional to the displacement and whose phase shows the direction as *Figure 12.49(b)*. Again a d.c. output signal can be obtained with a phase sensitive rectifier. *Figure 12.49(c)* shows the same idea used to produce a small displacement angular transducer.

#### 12.6.5 Shaft encoders

Shaft encoders give a digital representation of an angular position. They exist in two forms.

An *absolute* encoder gives a parallel output signal, typically 12 bits (one part in 4095) per revolution. Binary coded decimal (BCD) outputs are also available. A simplified four bit encoder would therefore operate as in *Figure 12.50(a)*. Most absolute encoders use a coded wheel similar to *Figure 12.50(b)* moving in front of a set of photocells.

A simple binary coded shaft encoder can give anomalous readings as the outputs change state. Suppose a four bit encoder is going from 0111 to 1000. It is unlikely that all photocells will change together, so the output states could go 0111 > 0000 > 1000 or 0111 > 1111 > 1000 or any other sequence of bits.

There are two solutions to this problem. The first uses an additional track, called an *anti-ambiguity track*, which is used by the encoder's internal logic to inhibit changes around transition points.

The second solution uses a *unit distance code*, such as the *Gray code* described in Section 14.6.4 which has no ambiguity. The conversion logic from Gray to binary is usually contained within the encoder itself.

*Incremental encoders* give a pulse output with each pulse representing a fixed distance. These pulses are counted by an external counter to give indication of position. Simple

encoders can be made by reading the output from a proximity detector in front of a toothed wheel.

A single pulse output train carries no information as to direction. Commercial incremental encoders usually provide two outputs shifted  $90^\circ$  in phase as *Figure 12.51(a)*. For clockwise rotation, A will lead B as *Figure 12.51(b)* and the positive edge of A will occur when B is low. For anti-clockwise rotation B will lead A as *Figure 12.51(c)* and the positive edge of A will occur when B is high. The logic (A and not B) can be used to count up, and (A and B) to count down. The two output incremental encoder can thus be used to follow reversals without cumulative error, but can still lose its datum position after a power failure.

Most PLC systems have dedicated high speed counter cards which can read directly from a two channel incremental encoder.

#### 12.6.6 Variable capacitance transducers

The small deflections obtained in weigh systems or pressure transducers are often converted into an electrical signal by varying the capacitance between two plates. Very small displacements can be detected by these methods.

The capacitance  $C$  of a parallel plate capacitor is given by:

$$C = \frac{\epsilon A}{d}$$

where  $\epsilon$  is the permittivity of the material between the plates,  $A$  the area and  $d$  the separation.

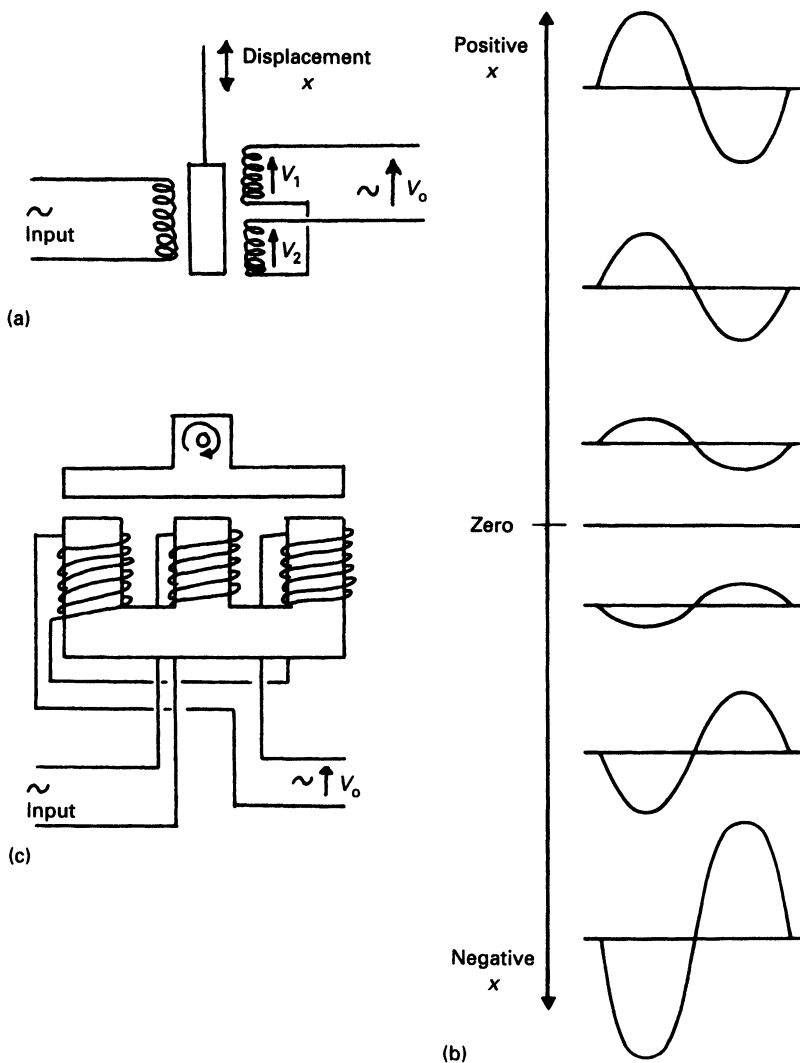

Variation in capacitance can be obtained from varying  $e$  (sliding in a dielectric, or moving the plates horizontally (change  $A$ ) or apart (change  $d$ )). Although the change is linear for  $e$  and  $A$ , the effect is small. A common arrangement uses a movable plate between two fixed plates as *Figure 12.52(a)*. Here two capacitors are formed which can be directly connected into an a.c. bridge as *Figure 12.52(b)*. If the fixed plates are distance  $D$  apart,  $d$  is the null position separation and the centre plate is displaced by  $x$ , the output voltage change can be shown to be:

$$V_0 = \frac{\epsilon x}{2d}$$

#### 12.6.7 Laser distance measurement

Lasers can give very accurate measurement of distance and are often used in surveying. There are two broad classes of laser distance measurement.

In the first, shown on *Figure 12.53* and called a *triangulation laser*, a laser beam is used to produce a very bright

**Figure 12.49** The linear variable displacement transformer (LVDT). (a) Construction; (b) Output signal for various positions; (c) Small displacement angular device

spot on the target object. This is viewed by an imaging device which can be considered as a linear array of tiny photocells. The position of the spot on the image will vary according to the distance as shown, and the distance found by simple triangulation trigonometry.

The second type of distance measurement is used at longer distances and times how long it takes a laser pulse to reach the target and be reflected back. For very long distances, (in surveying for example), a pulse is simply timed. At shorter distances a continuous amplitude modulated laser beam is sent and the phase shift between transmitted and received signals used to calculate the distance. This latter method can give ambiguous results, so often the two techniques are combined to give a coarse measurement from time of flight which is fine tuned by the phase shift.

Lasers can blind, and are classified according to their strength. Class 1 lasers are inherently safe. Class 2 lasers can cause retinal damage with continuous viewing but the natural reaction to blink or look away gives some protection.

Class 3 lasers can cause damage before the natural reaction occurs. Risk assessments, safe working practices and suitable guarding must be provided for Class 2 and 3 lasers. Optical devices such as binoculars must never be used whilst working around lasers.

### 12.6.8 Proximity switches and photocells

Mechanical limit switches are often used to indicate the positional state of mechanical systems. These devices are bulky, expensive and prone to failure where the environment is hostile (e.g. dust, moisture, vibration, heat).

Proximity switches can be considered to be solid state limit switches. The commonest type is constructed around a coil whose inductance changes in the presence of a metal surface. Simple two wire a.c. devices act just like a switch, having low impedance and capable of passing several hundred mA when covered by metal, and a high impedance

**Figure 12.50** Absolute position shaft encoder. (a) Output from a four bit encoder. Real devices use 12 bits and employ unit distance coding such as the Gray code; (b) The wheel on a four bit encoder.

(typical leakage 1 mA) when uncovered. Sensing distances up to 20 mm are feasible, but 5–10 mm is more common.

The leakage in the off state (typically 1 mA) can cause problems with circuits such as high impedance PLC input cards. In these circumstances a dummy load must be provided in parallel with the input.

D.c. powered switches use three wires, two for the supply and one for the output. D.c. sensors use an internal high frequency oscillator to detect the inductance change which gives a much faster response. Operation at several kHz is easily achieved.

A d.c. proximity detector can have an output in either of the two forms of *Figure 12.54*. A PNP output switches a positive supply to a load with a return connected to the negative supply. A PNP output is sometimes called a *current sourcing* output. With an NPN output the load is connected

to the positive supply and the proximity detector connects the load to the negative supply. NPN outputs are therefore sometimes called a *current sinking* output. It is obviously important to match the detector to the load connection.

Inductive detectors only work with metal targets. Capacitive proximity detectors work on the change in capacitance caused by the target and accordingly work with wood, plastic, paper and other common materials. Their one disadvantage is they need adjustable sensitivity to cope with different applications.

Ultrasonic sensors can also be used, operating on the same principle as the level sensor described in Section 12.5.4. Ultrasonic proximity detectors often have adjustable near and far limits so a sensing window can be set.

Photocells (or PECs) are another possible solution. The presence of an object can be detected either by the breaking of a light beam between a light source and a PEC or by bouncing a light beam off the object which is detected by the PEC. In the first approach the PEC sees no light for an object present. In the second approach (called a *retro-reflective* PEC) light is seen for an object present. It is usual to use a modulated light source to avoid erratic operation with changes in ambient light and prevent interaction between adjacent PECs.

## 12.7 Velocity and acceleration

### 12.7.1 Introduction

Velocity is the rate of change of position, and acceleration is the rate of change of velocity. Conversion between them can therefore be easily achieved by the use of integration and differentiation circuits based on d.c. amplifiers. Integration circuits can, though, be prone to long term drift.

### 12.7.2 Velocity

Many applications require the measurement of angular velocity. The commonest method is the tachogenerator which is a simple d.c. generator whose output voltage is proportional to speed. A common standard is 10 volts per 1000 rpm. Speeds up to 10 000 rpm can be measured, the upper limit being centrifugal force on the tacho commutator.

**Figure 12.51** The incremental encoder. (a) Physical arrangements—the two phase shifted outputs give directional information; (b) Clockwise rotation; (c) Anti-clockwise rotation

**Figure 12.52** Capacitive based displacement transducer. (a) Physical arrangement; (b) A.c. bridge

**Figure 12.53** Triangulation laser position measurement

**Figure 12.54** Current sourcing and sinking proximity detectors. (a) PNP current sourcing; (b) NPN current sinking

Pulse tachometers are also becoming common. These are essentially identical to incremental encoders described in Section 12.6.5 and produce a constant amplitude pulse train whose frequency is directly related to rotational speed. This pulse train can be converted into a voltage in three ways.

The first, basically analog, method used fires a fixed width monostable as *Figure 12.55* which gives a mark/space ratio which is speed dependent. The monostable output is then passed through a low pass filter to give an output

**Figure 12.55** Speed measurement using incremental pulse encoder. The pulses from the encoder fire a fixed duration monostable. The resulting pulse train is filtered to give a mean voltage proportional to speed

proportional to speed. The maximum achievable speed is determined by the monostable pulse width.

The second, digital, method counts the number of pulses in a given time. This effectively averages the speed over the count period which is chosen to give a reasonable balance between resolution and speed of response.

Counting over a fixed time is not suitable for slow speeds as adequate resolution can only be obtained with a long duration sample time. At slow speeds, therefore, the period of the pulses is often directly timed giving an average speed per pulse. The time is obviously inversely proportional to speed.

Digital speed control systems often use both of the last two methods and switch between them according to the speed.

Linear velocity can be measured using *Doppler shift*. This occurs when there is relative motion between a source of sound (or electromagnetic radiation) and an object. It is commonly experienced as a change of pitch of a car horn as the vehicle passes.

Suppose an observer is moving with velocity  $v$  towards a source emitting sound with a frequency  $f$ . The observer will see each wavefront arrive early and the perceived frequency will be

$$f_v = (c + v)/\lambda$$

where  $c$  is the velocity of propagation. As the original frequency is  $c/\lambda$ , the frequency shift is

$$\delta f = (f_v - f) = v/\lambda = fv/c \quad (12.5)$$

i.e. proportional to speed.

The Doppler shift thus allows remote measurement of velocity. The principle is shown on *Figure 12.56*. A transmitter, (ultrasonic, radar or light,) emits a constant frequency signal. This is bounced off the target. Two Doppler shifts occur as the object is acting as both moving observer and moving (reflected) source. The frequency shift is thus twice that for the simple case of Equation 12.5.

The transmitted and received frequencies are mixed to give a beat frequency equal to the frequency shift and hence proportional to the target object's speed. The beat frequency can be measured by counting the number of cycles in a given time.

### 12.7.3 Accelerometers and vibration transducers

Both accelerometers and vibration transducers consist of a seismic mass linked to a spring as *Figure 12.57(a)*. The movement will be damped by the dashpot giving a second order response defined by the natural frequency and the damping factor, typically chosen to be 0.7.

If the frame of the transducer is moved sinusoidally, the relationship between the mass displacement and the frequency will be as *Figure 12.57(b)*.

In region A, the device acts as an accelerometer and the mass displacement is proportional to the acceleration. In region C, the mass does not move, and the displacement with respect to the frame is solely dependent on the frame movement (but is shifted by  $180^\circ$ ). In this region the device acts as a vibration transducer. Typically region A extends to about one third of the natural frequency and region C starts at about three times the natural frequency.

In both cases the displacement is converted to an electrical signal by LVDTs or strain gauges.

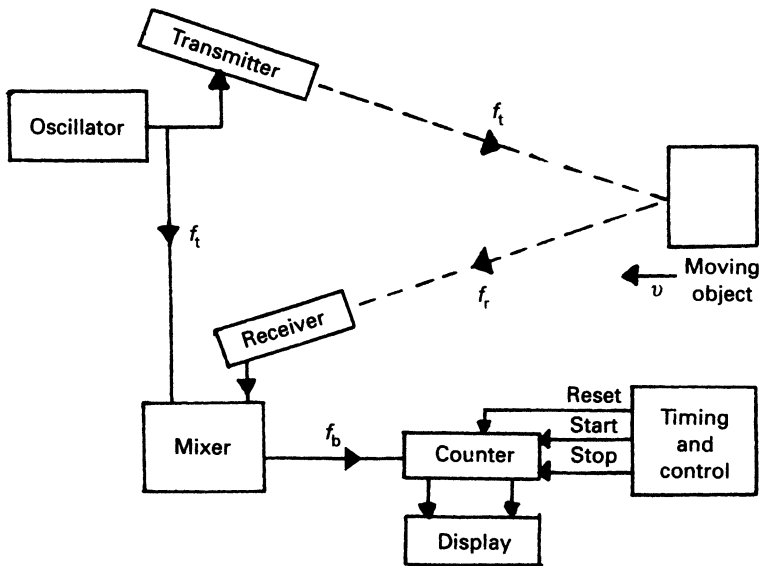

Figure 12.56 Doppler shift velocity measurement

Figure 12.57 Principle of operation of accelerometers and vibration transducers. (a) Schematic diagram; (b) Frequency response. In region A the device acts as an accelerometer. In region C the device acts as a vibration transducer

## 12.8 Strain gauges, loadcells and weighing

### 12.8.1 Introduction

Accurate measurement of weight is required in many industrial processes. There are two basic techniques in use. In the first, shown in Figure 12.58(a) and called a *force balance system*, the weight of the object is opposed by some known force which will equal the weight. Kitchen scales where weights are added to one pan to balance the object in the other pan use the force balance system. Industrial systems use hydraulic or pneumatic pressure to balance the load, the pressure required being directly proportional to the weight.

The second, and commoner, method is called *strain weighing*, and uses the gravitational force from the load to

cause a change in the structure which can be measured. The simplest form is the spring balance of Figure 12.58(b) where the deflection is proportional to the load.

### 12.8.2 Stress and strain

The application of a force to an object will result in deformation of the object. In Figure 12.59 a tensile force  $F$  has been applied to a rod of cross-sectional area  $A$  and length  $L$ . This results in an increase in length  $\Delta L$ . The effect of the force will depend on the force and the area over which it is applied. This is called the *stress*, and is the force per unit area:

$$\text{Stress} = F/A$$

Figure 12.58 The two different weighing principles. (a) Force balance; (b) Strain weighing

Figure 12.59 Tensile strain

Stress has the units of  $\text{N/m}^2$  (i.e. the same as pressure, so pascals are sometimes used).

The resulting deformation is called the *strain*, and is defined as the fractional change in length.

$$\text{Strain} = \Delta L / L$$

Strain is dimensionless. Because the change in length is small, microstrain ( $\mu\text{strain}$  defined as  $\text{strain} \times 10^6$ ) is often used. A 10m rod exhibiting a change in length of 0.0045mm because of an applied force is exhibiting 45  $\mu\text{strain}$ .

The strain will increase as the stress increases as shown on Figure 12.60. Over region AB the object behaves as a spring; the relationship is linear and there is no hysteresis (i.e. the object returns to its original dimension when the force is

Figure 12.60 The relationship between stress and strain

removed. Beyond Point B the object suffers deformation and the change is not reversible. The relationship is now non linear, and with increasing stress the object fractures at point C. The region AB, called the *elastic region*, is used for strain measurement. Point B is called the *elastic limit*. Typically AB will cover a range of 10 000  $\mu\text{strain}$ .

The inverse slope of the line AB is sometimes called the *elastic modulus* (or *modulus of elasticity*). It is more commonly known as *Young's modulus* defined as

$$\text{Young's modulus} = \text{Stress} / \text{Strain} = (F/A) / (\Delta L/L) \Leftarrow$$

Young's modulus has dimensions of  $\text{Nm}^{-2}$ , i.e. the same as pressure. It is commonly given in pascals. Typical values are:

Steel	210 GPa
Copper	120 GPa
Aluminium	70 GPa
Plastics	30 GPa

When an object experiences strain, it displays not only a change in length but also a change in cross-sectional area. This is defined by *Poisson's ratio*, denoted by the Greek letter  $\nu$ . If an object has a length  $L$  and width  $W$  in its unstrained state and experiences changes  $\Delta L$  and  $\Delta W$  when strained, Poisson's ratio is defined as:

$$\nu = (\Delta W / W) / (\Delta L / L) \Leftarrow$$

Typically  $\nu$  is between 0.2 and 0.4. Poisson's ratio can be used to calculate the change in cross-sectional area.

### 12.8.3 Strain gauges

The electrical resistance of a conductor is proportional to the length and inversely proportional to the cross-section. i.e.

$$R = \rho L / A$$

where  $\rho$  is a constant called the *resistivity* of the material.

When a conductor suffers stress, its length and area will both change resulting in a change in resistance. For tensile stress, the length will increase and the cross-sectional area

Figure 12.61 A typical strain gauge (courtesy of Welwyn Strain Measurements)

decrease both resulting in increased resistance. Similarly the resistance will decrease for compressive stress.

Ignoring second order effects the change in resistance is given by:

$$\Delta R/R = G \cdot \Delta L/L \quad (12.6) \Leftarrow$$

where  $G$  is a constant called the *gauge factor*.  $\Delta L/L$  is the strain,  $E$ , so Equation 12.6 can be re-written:

$$\Delta R = G \cdot R \cdot E \quad (12.7) \Leftarrow$$

where  $E$  is the strain experienced by the conductor.

Devices based on the change of resistance with load are called *strain gauges*, and Equation 12.7 is the fundamental strain gauge equation.

Practical strain gauges are not a slab of material as implied so far but consist of a thin small, (typically a few mm), foil similar to Figure 12.61 with a pattern to increase the conductor length and hence the gauge factor. The gauge is attached to some sturdy stressed member with epoxy resin and experiences the same strain as the member. Early gauges were constructed from thin wire but modern gauges are photo-etched from metallised film deposited onto a polyester or plastic backing. Normal gauges can experience up to 10 000  $\mu$ strain without damage. Typically the design will aim for 2000  $\mu$ strain under maximum load.

A typical strain gauge will have a gauge factor of 2, a resistance of 120  $\Omega$  and experience 1000  $\mu$ strain. From Equation 12.7 this will result in a resistance change of 0.24  $\Omega$ .

Strain gauges must ignore strains in unwanted directions. A gauge has two axis, an active axis along which the strain is applied and a passive axis (usually at 90°) along which the

gauge is least sensitive. The relationship between these is defined by the *cross-sensitivity*:

$$\text{cross-sensitivity} = \frac{\text{sensitivity along passive axis}}{\text{sensitivity along active axis}}$$

Cross-sensitivity is typically about 0.002.

#### 12.8.4 Bridge circuits

The small change in resistance is superimposed on the large unstrained resistance. Typically the change will be 1 part in 5000. In Figure 12.62 the strain gauge  $R_g$  is connected into a classical Wheatstone bridge. In the normal laboratory method,  $R_a$  and  $R_b$  are made equal and calibrated resistance box  $R_c$  adjusted until  $V_0$  (measured by a sensitive millivoltmeter,) is zero. Resistance  $R_c$  then equals  $R_g$ .

With a strain gauge, however, we are not interested in the actual resistance, but the change caused by the applied load. Suppose  $R_b$  and  $R_c$  are made equal, and  $R_a$  is made equal to the unloaded resistance of the strain gauge. Voltages  $V_1$  and  $V_2$  will both be half the supply voltage and  $V_0$  will be zero. If a load is applied to the strain gauge such that its resistance changes by fractional change  $x$  (i.e.  $x = \Delta R/R$ ) it can be shown that

$$V_0 = \frac{V_s}{2} \cdot \frac{x}{2(2+x)} \quad (12.8) \Leftarrow$$

In a normal circuit  $x$  will be very small compared with 2. For the earlier example  $x$  has the value 0.24/120 = 0.002, so Equation 12.8 can be simplified to:

$$V_0 = \frac{V_s}{4} \cdot \frac{\Delta R}{R} \cdot \frac{1}{2}$$

**Figure 12.62** Simple measurement of strain with a Wheatstone bridge

But  $\Delta R = E \cdot G \cdot \epsilon$  where  $E$  is the strain and  $G$  the gauge factor giving

$$V_o = E \cdot G \cdot \epsilon_s / 4 \quad (12.9) \Leftarrow$$

For small values of  $x$ , the output voltage is thus linearly related to the strain.

It is instructive to put typical values into Equation 12.9. For a 24 V supply, 1000  $\mu$ strain and gauge factor 2 we get 12 mV. This output voltage must be amplified before it can be used. Care must be taken to avoid common mode noise so the differential amplifier circuit of *Figure 12.63* is commonly used.

The effect of temperature on resistance was described in Section 12.2.3, and resistance changes from temperature variation are of a similar magnitude to resistance changes from strain. The simplest way of preventing this is to use two gauges arranged as *Figure 12.64(a)*. One gauge has its active axis and the other gauge the passive axis aligned with the load. If these are connected into a bridge circuit as shown on *Figure 12.64(b)* both gauges will exhibit the same resistance change from temperature and these will cancel leaving the output voltage purely dependent on the strain.

Temperature errors can also occur from dimensional changes in the member to which the strain gauges are attached. Gauges are often temperature compensated by having coefficients of linear expansion identical to the material to which they are attached.

Many applications use gauges in all four arms of the bridge as shown on *Figure 12.64(c)* with two active gauges

and two passive gauges. This provides temperature compensation and doubles the output voltage giving

$$V_o = E \cdot G \cdot \epsilon_s / 2$$

In the arrangement of *Figure 12.64(d)* four gauges are used with two gauges experiencing compressive strain and two experiencing tensile strain. Here all four gauges are active, giving

$$V_o = E \cdot G \cdot \epsilon_s \quad (12.10) \Leftarrow$$

Again temperature compensation occurs because all gauges are at the same temperature.

Gauges are manufactured to a tolerance of about 0.5%, i.e. about  $\pm 0.6 \Omega$  for a typical 120  $\Omega$  gauge. As this is larger than the resistance change from strain some form of zeroing will be required. Three methods of achieving this are shown on *Figure 12.65*. Arrangement b and c are preferred if the zeroing is remote from the bridge.

Equation 12.10 shows that the output voltage is directly related to the supply voltage. This implies that a large voltage should be used to increase the sensitivity. Unfortunately a high voltage supply cannot be used or  $I^2 R$  heating in the gauges will cause errors and ultimately failure. Bridge voltages of 15–30 V and currents of 20–100 mA are typically used.

Equation 12.10 also implies that the supply voltage must be stable. If the bridge is remote from the supply and electronics, as is usually the case, voltage drops down the cabling can introduce significant errors. *Figure 12.66* shows a typical cabling scheme used to give remote zeroing and compensation for cabling resistance. The supply is provided on cores 2 and 6 and monitored on cores 1 and 7 to keep constant voltage at the bridge itself.

## 12.8.5 Load cells

A loadcell converts a force (usually the gravitational force from an object being weighed) to a strain which can then be converted to an electrical signal by strain gauges. A load cell will typically have the local circuit of *Figure 12.67* with four gauges, two in compression and two in tension, and six external connections. The span and zero adjust on test (AOT) are factory set to ensure the bridge is within limits that can be further adjusted on site. The temperature compensation resistors compensate for changes in Young's

**Figure 12.63** Differential amplifier. The output voltage is determined by the difference between the two input voltages

modulus with temperature, not changes of the gauges themselves which the bridge inherently ignores.

Coupling of the load requires care, a typical arrangement being shown on *Figure 12.68*. A pressure plate applies the load to the proof-ring via a knuckle and avoids error from slight misalignment. A flexible diaphragm seals against dust and weather. A small gap ensures that shock overloads will make the loadcell bottom out without damage to the proof-ring or gauges. Maintenance must ensure that dust does not close this gap and cause the proof-ring to carry only part of the load. Bridging and binding are common causes of load-cells reading below the load weight.

Multi-cell weighing systems can be used, with the readings from each cell being summed electronically. Three cell systems inherently spread the load across all cells. With four cell systems the support structure must ensure that all cells are in contact with the load at all times.

Usually the load cells are the only route to ground from the weigh platform. It is advisable to provide a flexible earth strap, not only for electrical safety but also to provide a route for any welding current which might arise from repairs or later modification.

### 12.8.6 Weighing systems

A weigh system is usually more than a collection of load-cells and a display. *Figure 12.69* is a taring weigh system used when a 'recipe' of several materials is to be collected in a hopper. The gross weight is the weight from the load cells, i.e. the materials and the hopper itself. Each time the tare command is given, the gross weight is stored and this stored value subtracted from the gross weight to give the net weight display. In this way the weight of each new material can be clearly seen. This type of weigh system can obviously be linked into a supervisory PLC or computer control network.

*Figure 12.70* is a batch feeder system where material is fed from a vibrating feeder into a weigh hopper. The system is first tared, then a two speed system used with a changeover from fast to dribble feed a pre-set weight before the target weight. The feeder turns off just before the correct weight to allow for the material in flight from the feeder. This is known as '*in flight compensation*', '*anticipation*' or '*preact*'. To reduce the weigh time the fast feed should be set as fast as possible without causing avalanching in the feed hopper and the changeover to slow feed made as late as possible. The accuracy of the system is mainly dependent on the repeatability of the preact weight, so the slow speed should be set as low as possible.

Material is often carried on conveyor belts and *Figure 12.71* shows a method of providing feed rate in weight per unit time (e.g. kg per min).

The conveyor passes over a load cell of known length and the linear speed is obtained from the drive motor, probably from a tachogenerator. If the weigh platform has length  $L$  m, and is indicating weight  $W$  kg at speed  $V$  ms<sup>-1</sup>, the feed rate is simply  $W \cdot V / L$  kgs<sup>-1</sup>.

## 12.9 Fieldbus systems

A Fieldbus, discussed in more detail in Chapter 16, Section 16.5 is a way of interconnecting several devices (e.g. transducers, controllers, actuators etc.) via a simple and cheap serial cable. Devices on the network are identified by addresses which allows messages to be passed between them.

**Figure 12.64** Use of multiple strain gauges. (a) Two gauges used to give temperature compensation; (b) Two gauges connected into bridge. Temperature effects will affect both gauges equally and have no effect; (c) Four gauge bridge gives increased sensitivity and temperature compensation; (d) Arrangement for four gauges. Two will be in compression and two in tension for load changes. Temperature affects all gauges equally

Figure 12.68 Construction of a typical commercial loadcell

Figure 12.69 Taring weighing system

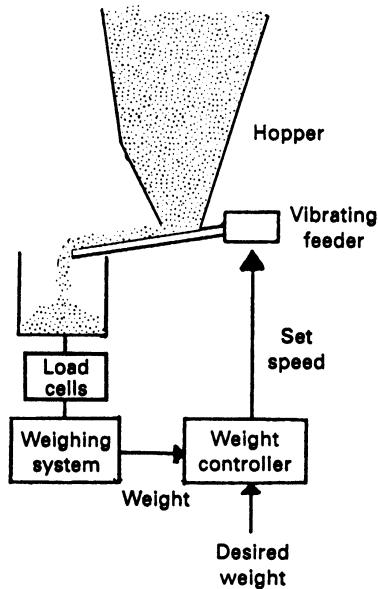

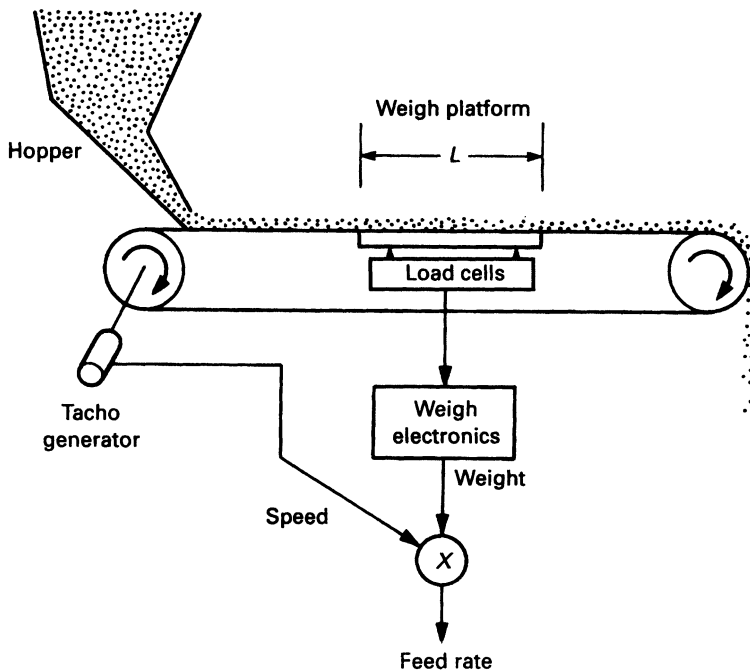

Figure 12.70 A batch weighing system

Of particular interest in instrumentation is the HART protocol. HART (for Highway Addressable Remote Transducer) was originally introduced by Rosemount as a closed standard for their own devices. Generously, Rosemount have passed the rights to the Hart Communication Foundation and HART is now an open protocol which can be used by anyone. It is a very simple master/slave system; devices only speak when requested and the

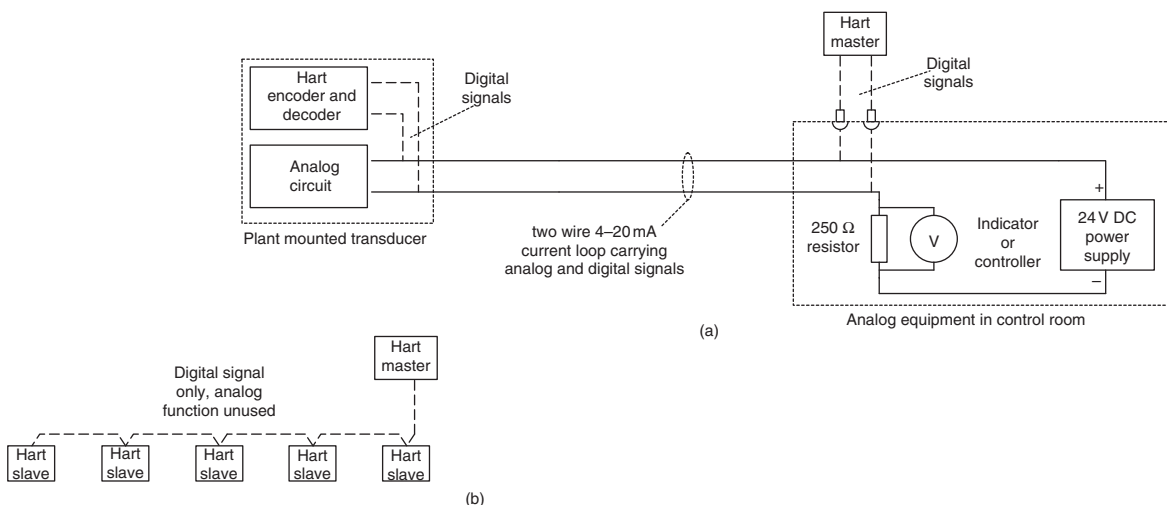

**Figure 12.71** Continuous belt weighing system

operation is always master request, slave replies. Up to fifteen slaves can be connected to each master.

HART can work in two ways. In its simplest, and probably commonest, form of point to point it superimposes the serial communication data on to a standard 4–20 mA loop signal as shown in *Figure 12.72(a)*. Frequency shift keying (FSK) is used with frequencies of 1200 Hz for a '1' and 2200 Hz for a '0'. These frequencies are far too high to affect the analogue instrumentation so the analog signal is

still used in the normal manner. The system operates with one master (usually a computer, PLC or hand held programming terminal) and one slave (a transducer or actuator). The attraction of this approach is that it allows HART to be retro-fitted onto existing cabling and instrumentation schemes. The disadvantage is that the full cabling benefits of a fieldbus system are not realised.

The serial data, though, allows much more information to be conveyed in addition to the basic analog signal. HART

**Figure 12.72** The Hart communication system. (a) Hart digital data superimposed onto a two wire 4–20 mA analog loop to give additional data. A Hart master (e.g. a PLC or hand held terminal) is used to read the digital data. The transducer can also be configured by the master; (b) A Hart based fieldbus system. All data transfer is done via digital communications. Hart is not as efficient in this mode of operation as normal Fieldbus systems

devices can all be remotely configured and monitored allowing very simple diagnostics and quick replacement after a failure. In addition much more plant data can be passed from the transducer. A flow transducer giving flow as the 4–20 mA analogue signal can also give temperature and pressure via the HART link along with diagnostic information about the transducer status. With a HART programming terminal connected to the line, the transducer can also be made to send fixed currents to aid loop checks and fault diagnosis.

The second method of using HART is in a normal Fieldbus multidrop system as *Figure 12.72(b)*. Here each device has an identifying address and sends data to the master on request. Usually devices (and their relevant parameters) are polled on a regular cyclic scan. The multidrop brings all the cost savings from simple cabling and makes the system easy to modify and expand. By comparison with other fieldbus systems, however, HART is rather slow, and this slow response time can cause difficulties in some applications. The speed is generally adequate for simple monitoring systems where the process variables cannot change quickly.

## 12.10 Installation notes

Analogue systems are generally based on low voltages and are consequently vulnerable to electrical noise. In most plants, a PLC may be controlling 415 V high power motors at 100 A, and reading thermocouple signals of a few mV. Great care must be taken to avoid interference from the high voltage signals.

The first precaution is to adopt a sensible earthing layout. A badly laid out system, as *Figure 12.73*, will have common return paths, and currents from the high powered load returning through the common impedance  $Z_e$  will induce error

**Figure 12.73** A poorly installed earthing system which leads to interaction between signals

**Figure 12.74** An earth loop formed by connecting both ends of a screened cable to the local earth. Screens should be earthed at one point only

voltages into the low level analog circuit. It should be realised that there are at least three distinct 'earths' in a system.

- A safety earth (used for doors, frames etc.)
- A dirty earth (used for high voltage/high current signals)
- A clean earth (for low voltage analog signals)

These should meet at one point and one point only (which implies all analog signals should return, and hence be referenced to, the same point).

Screened cable is needed for all analog signals, with foil screening to be used in preference to braided screen. The screen should NOT be earthed at both ends as any difference in earth potential between the two points will cause current to flow in the screen as *Figure 12.74*, and induce noise onto the signal lines. A screen must be earthed at one point only, ideally the receiving end. When a screened cable goes through intermediate junction boxes, screen continuity must be maintained, AND the screen must be sleeved to prevent it touching the frame of the junction boxes. Earthing faults in screened cables can cause very elusive faults.

High voltage and low voltage cables should be well separated, most manufacturers suggest at least one metre between 415 V and low voltage cables but this can be difficult to achieve in practice. In any case, separation can only be achieved until some other person, not knowing the system well, straps a 415 V cable to the same cable tray as a multicore thermocouple cable. It is therefore good practice to use trunking or conduit for low voltage signals as a way of identifying low voltage cables for future installers. The same result can also be achieved by using cables with different coloured PVC sleeves. Inevitably high voltage and low voltage cables will have to cross at some points. If spacing can not be achieved the crossings should always be at 90°.

In an ideal world, separate cubicles should be provided for 110 V/high current devices, and low voltage signals, but this is often not cost effective. Where both types of signals have to share a cubicle the cables should take separate, well separated routes, and high and low voltage devices separated as far as possible.

## 13.1 Introduction

Examples of the conscious application of feedback control ideas have appeared in technology since very early times: certainly the float-regulator schemes of ancient Greece were notable examples of such ideas. Much later came the automatic direction-setting of windmills, the Watt governor, its derivatives, and so forth. The first third of the 1900s witnessed applications in areas such as automatic ship steering and process control in the chemical industry. Some of these later applications attracted considerable analytical effort aimed at attempting to account for the seemingly capricious dynamic behaviour that was sometimes found in practice.

However, it was not until during, and immediately after, World War II that the fundamentals of the above somewhat disjointed control studies were subsumed into a coherent body of knowledge which became recognised as a new engineering discipline. The great thrust in achieving this had its main antecedents in work done in the engineering electronics industry in the 1930s. Great theoretical strides were made and the concept of feedback was, for the first time, recognised as being all pervasive. The practical and theoretical developments emanating from this activity, constitute the classical approach to control which are explored in some detail in this chapter.

Since the late 1940s, tremendous efforts have been made to expand the boundaries of control engineering theory. For example, ideas from classical mechanics and the calculus of variations have been adapted and extended from a control-theoretic viewpoint. This work is based largely on the state-space description of systems (this description is briefly described in Section 13.11). However, it must be admitted that the practical uses and advantages of many of these developments have yet to be demonstrated. Most control system design work is still based on the classical work mentioned previously. Moreover, nowadays these applications rely, very heavily, on the use of computer techniques; indeed, computers are commonly used as elements in control loops.

Techniques from the 'classical' period of control engineering development is easily understood, wide-ranging in application and, perhaps most importantly, capable of coping with deficiencies in detailed knowledge about the system to be controlled.

These techniques are easily adapted for use in the computer-aided design of control systems, and have proved themselves capable of extension into the difficult area of multi-variable system control; however, this latter topic is beyond the scope of this chapter. So with the above comments in mind, a conventional basic approach to control theory is presented, with a short discussion of the state-space approach and a more extensive forage into sampled-data systems. These latter systems have become important owing to the incorporation of digital computers, particularly micro-computers, into the control loop. Fortunately, an elementary theory for sampled data can be established which nicely parallels the development of basic continuous control theory.

The topics covered in this introduction, and extensions of them, have stood practitioners in good stead for several decades now, and can be confidently expected to go on delivering good service for some decades to come.

## 13.2 Laplace transforms and the transfer function

In most engineering analysis it is usual to produce mathematical models (of varying precision) to predict the behaviour of

physical systems. Often such models are manifested by a differential equation description. This appears to fit in with the causal behaviour of idealised components, e.g. Newton's law relating the second derivative of displacement to the applied force. It is possible to model such behaviour in other ways (for example, using integral equations), although these are much less familiar to most engineers. All real systems are non-linear; however, it is fortuitous that most systems behave approximately like linear ones, with the implication that superposition holds true to some extent. We further restrict the coverage here in that we shall be concerned particularly with systems whose component values are not functions of time—at least over the time-scale of interest to us.

In mathematical terms this latter point implies that the resulting differential equations are not only linear, but also have constant coefficients, e.g. many systems behave approximately according to the equation

$$\frac{d^2x}{dt^2} + 2\zeta\omega_n \frac{dx}{dt} + \omega_n^2 x = \omega_n^2 f(t) \quad (13.1)$$

where  $x$  is the dependent variable (displacement, voltage, etc.),  $f(t)$  is a forcing function (force, voltage source, etc.), and  $\omega_n^2$  and  $\zeta$  are constants the values of which depend on the size and interconnections of the individual physical components making up the system (spring-stiffness constant, inductance values, etc.).

Equations having the form of Equation (13.1) are called 'linear constant coefficient ordinary differential equations' (LCCDE) and may, of course, be of any order. There are several techniques available for solving such equations but the one of particular interest here is the method based on the Laplace transformation. This is treated in detail elsewhere, but it is useful to outline the specific properties of particular interest here.

### 13.2.1 Laplace transformation

Given a function  $f(t)$ , then its Laplace transformation  $F(s)$  is defined as

$$L[f(t)] = \mathcal{F}(s) = \int_0^{\infty} f(t) \exp(-st) dt$$

where, in general,  $s$  is a complex variable and of such a magnitude that the above integral converges to a definite functional value.

A list of Laplace transformation pairs is given in *Table 13.1*.

The essential usefulness of the Laplace transformation technique in control engineering studies is that it transforms LCCDE and integral equations into algebraic ones and, hence, makes for easier and standard manipulation.

### 13.2.2 The transfer function

This is a central notion in control work and is, by definition, the Laplace transformation of the output of a system divided by the Laplace transformation of the input, with the tacit assumption that all initial conditions are at zero.

Thus, in *Figure 13.1*, where  $y(t)$  is the output of the system and  $u(t)$  is the input, then the transfer function  $G(s)$  is  $L[y(t)]/L[u(t)] = Y(s)/U(s) = \mathcal{G}(s)$

Supposing that  $y(t)$  and  $u(t)$  are related by the general LCCDE

$$a_n \frac{d^n y}{dt^n} + a_{n-1} \frac{d^{n-1} y}{dt^{n-1}} + \dots = a_0 y$$

**Table 13.1** Laplace transforms and z transforms

$f(t)$	$F(s)$	$F(z)$
0	0	0
$f(t - nT)$	$\exp(-nsT)F(s)$	$z^{-n}F(z)$

$\delta(t) + \alpha\exp(\alpha t)$	$s(s - \alpha)^{-1}$	—
$t \exp(\alpha t)$	$(s - \alpha)^{-2}$	$TZ \exp(\alpha T)[z - \exp(\alpha T)]^{-2}$
$t^n \exp(\alpha t)$	$n!(s - \alpha)^{-(n+1)}$	—
$\sin \omega t$	$\frac{\omega}{s^2 + \omega^2}$	$\frac{z \sin \omega T}{z^2 - 2z \cos \omega T + 1}$
$\cos \omega t$	$\frac{s}{s^2 + \omega^2}$	$\frac{z(z - \cos \omega T)}{z^2 - 2z \cos \omega T + 1}$
$\frac{t}{2\omega} \sin \omega t$	$\frac{s}{(s^2 + \omega^2)}$	—
$\frac{1}{2\omega} (\sin \omega t - t \cos \omega t)$	$\frac{\omega^2}{(s^2 + \omega^2)^2}$	—
$\frac{1}{\cos \delta_\zeta} \sin(\omega t + \delta_\zeta)$	$\frac{A}{s^2 + \omega^2} \left( s + \frac{\omega}{A} \right)$ (where $\tan \delta_\zeta = \frac{\omega}{A}$ )	—
$\frac{1}{\cos \delta_\zeta} \cos(\omega t + \delta_\zeta)$	$\frac{1}{s^2 + \omega^2} (s - \frac{\omega}{A})$	—
$\exp(\alpha t) \sin \omega t$	$\frac{\omega}{(s - \alpha)^2 + \omega^2} = \frac{\omega}{(s - \alpha + j\omega)(s - \alpha - j\omega)}$	$\frac{z \exp(\alpha T) \sin \omega T}{z^2 - 2z \exp(\alpha T) \cos \omega T + \exp(2\alpha T)}$
$\exp(\alpha t) \cos \omega t$	$\frac{s - \alpha}{(s - \alpha)^2 + \omega^2}$	$\frac{z[z - \exp(\alpha T) \cos \omega T]}{z^2 - 2z \exp(\alpha T) \cos \omega T + \exp(2\alpha T)}$
$\frac{t}{2\omega} \exp(\alpha t) \sin \omega t$	$\frac{s - \alpha}{[(s - \alpha)^2 + \omega^2]^2}$	—
$\frac{1}{2\omega} \exp(\alpha t) (\sin \omega t - \cos \omega t)$	$\frac{\omega^2}{[(s - \alpha)^2 + \omega^2]^2}$	—
$\frac{1}{\cos \delta_\zeta} \exp(\alpha t) \sin(\omega t + \delta_\zeta)$	$\frac{A}{(s - \alpha)^2 + \omega^2} \left( s - \frac{\omega}{A} + \frac{\omega}{A} \right)$ (where $\tan \delta_\zeta = \frac{\omega}{A}$ )	—
$\frac{1}{\cos \delta_\zeta} \exp(\alpha t) \cos(\omega t + \delta_\zeta)$	$\frac{1}{(s - \alpha)^2 + \omega^2} (s - \frac{\omega}{A} - \frac{\omega}{A})$	—
$\sinh \omega t$	$\omega(s^2 - \omega^2)^{-1}$	—
$\cosh \omega t$	$s(s^2 - \omega^2)^{-1}$	—

cont'd

**Table 13.1** (continued)

$f'(t)$	$sF(s) - f(0-)$	—
$f''(t)$	$s^2F(s) - sf(0-) - f'(0-)$	—
$f^n(t)$	$s^nF(s) - s^{n-1}f(0-) - s^{n-2}f'(0-) \dots - f^{n-1}(0-)$	—
$f^{-1}(t)$	$\frac{F(s)}{s} + \frac{f^{-1}(0-)}{s}$	—
$f(t)$	$sF(s)$	$F(z)$
$t \rightarrow 0$	$s \rightarrow \infty \Leftarrow$	$z \rightarrow \infty \Leftarrow$
$f(t)$	$sF(s)$	$(z-1)z^{-1}F(z)$
$t \rightarrow \infty \Leftarrow$	$s \rightarrow 0$	$z \rightarrow 1$

$\delta(t)$ , The unit impulse function.

$h(t)$ , The unit step function.

$u_T(t)$ , The unit step function followed by a unit negative step at  $t = T$ , where  $T$  is the sampling period.

**Figure 13.1** Input–output representation

$$= b_m \frac{d^m u}{dt^m} + b_{m-1} \frac{d^{m-1} u}{dt^{m-1}} + \dots + b_0 u \quad (13.2)$$

then, on Laplace transforming and ignoring initial conditions, we have (see later for properties of Laplace transformation)

$$(a_n s^n + a_{n-1} s^{n-1} + \dots + a_0) Y(s) \Leftarrow \\ = (b_m s^m + b_{m-1} s^{m-1} + \dots + b_0) U(s) \Leftarrow$$

whence

$$\frac{Y(s)}{U(s)} \Leftarrow G(s) = \frac{\sum_{i=0}^m b_i s^i}{\sum_{i=0}^n a_i s^i}$$

There are a number of features to note about  $G(s)$ .

- (1) Invariably  $n > m$  for physical systems.
- (2) It is a ratio of two polynomials which may be written

$$G(s) = \frac{b_m(s - z_1) \dots (s - z_m) \Leftarrow}{a_n(s - p_1) \dots (s - p_n) \Leftarrow}$$

$z_1, \dots, z_m$  are called the *zeros* and  $p_1, \dots, p_n$  are called the *poles* of the transfer function.

- (3) It is not an explicit function of input or output, but depends entirely upon the nature of the system.
- (4) The block diagram representation shown in *Figure 13.1* may be extended so that the interaction of composite systems can be studied (provided that they do not load each other); see below.
- (5) If  $u(t)$  is a delta function  $\delta(t)$ , then  $U(s) = 1$ , whence  $Y(s) = G(s)$  and  $y(t) = g(t)$ , where  $g(t)$  is the *impulse response* (or *weighting function*) of the system.
- (6) Although a particular system produces a particular transfer function, a particular transfer function does not imply a particular system, i.e. the transfer function specifies merely the input–output relationship between two variables and, in general, this relationship may be realised in an infinite number of ways.
- (7) Although we might expect that all transfer functions will be ratios of finite polynomials, an important and

common element which is an exception to this is the pure-delay element. An example of this is a loss-free transmission line in which any disturbance to the input of the line will appear at the output of the line without distortion, a finite time (say  $\tau$ ) later. Thus, if  $u(t)$  is the input, then the output  $y(t) = u(t - \tau)$  and the transfer function  $Y(s)/U(s) = \exp(-s\tau)$ . Hence, the occurrence of this term within a transfer function expression implies the presence of a pure delay; such terms are common in chemical plant and other fluid-flow processes.

Having performed any manipulations in the Laplace transformation domain, it is necessary for us to transform back to the time domain if the time behaviour is required. Since we are dealing normally with the ratio of polynomials, then by partial fraction techniques we can arrange  $Y(s)$  to be written in the following sequences:

$$Y(s) = \frac{K(s - z_1)(s - z_2) \dots (s - z_m) \Leftarrow}{(s - p_1)(s - p_2) \dots (s - p_n) \Leftarrow}$$

$$Y(s) = K \left[ \frac{A_1}{s - p_1} + \frac{A_2}{s - p_2} + \dots + \frac{A_n}{s - p_n} \right] \left($$

and by so arranging  $Y(s)$  in this form the conversion to  $y(t)$  can be made by looking up these elemental forms in *Table 13.1*.

**Example** Suppose that

$$Y(s) = \frac{5(s^2 + 4s + 3) \Leftarrow}{s^3 + 6s^2 + 8s} = \frac{5(s^2 + 4s + 3) \Leftarrow}{s(s + 2)(s + 4) \Leftarrow} \\ = 5 \left[ \frac{3}{8s} + \frac{1}{4(s + 2) \Leftarrow} + \frac{3}{8(s + 4) \Leftarrow} \right] \left($$

Then

$$y(t) = \frac{5}{4} \left[ \frac{3}{2} \{1 + \exp(-4t)\} + \exp(-2t) \right] \Leftarrow$$

### 13.2.3 Certain theorems

A number of useful transform theorems are quoted below, without proof.

#### (1) Differentiation

If  $F(s)$  is the Laplace transformation of  $f(t)$ , then

$$L[dn f(t)/dt^n] = s^n F(s) - s^{n-1} f(0) = s^{n-2} f'(0) - \dots - f^{n-1}(0) \Leftarrow$$

For example, if  $f(t) = \exp(-bt)$ , then

$$L\left[\frac{d^3}{dt^3}\exp(-bt)\right] \left( \leftarrow \frac{s^3}{s+b} - s^2 + bs - b^2 \right)$$

(2) *Integration*

If  $L[f(t)] = F(s)$ , then

$$L\left[\int_0^1 f(t)dt\right] \left( \leftarrow \frac{F(s)}{s} + f(0) \leftarrow \right)$$

Repeated integration follows in a similar fashion.

(3) *Final-value theorem*

If  $f(t)$  and  $f'(t)$  are Laplace transformable and if  $L[f(t)] = F(s)$ , then if the limit of  $f(t)$  exists as  $t$  goes towards infinity, then

$$\lim_{s \rightarrow 0} sF(s) = \lim_{t \rightarrow \infty} f(t) \leftarrow$$

For example,

$$F(s) = \frac{b-a}{s(s+a)(s+b)} \leftarrow$$

then

$$\lim_{s \rightarrow 0} \frac{s(b-a)}{s(s+a)(s+b)} = \frac{b-a}{ab} = \lim_{t \rightarrow \infty} f(t) \leftarrow$$

(4) *Initial-value theorem*

If  $f(t)$  and  $f'(t)$  are Laplace transformable and if  $L[f(t)] = F(s)$ , then

$$\lim_{s \rightarrow \infty} sF(s) = \lim_{t \rightarrow 0} f(t) \leftarrow$$

(5) *Convolution*

If  $L[f_1(t)] = F_1(s)$  and  $L[f_2(t)] = F_2(s)$ , then

$$F_1(s) \cdot F_2(s) = L\left[\int_0^{\infty} f_1(t-\tau) \cdot f_2(\tau) d\tau\right] \left( \leftarrow \right)$$

### 13.3 Block diagrams

It is conventional to represent individual transfer functions by boxes with an input and output (see note (4) in Section 13.2.2). Provided that the components represented by the transfer function do not load those represented by the transfer function in a connecting box, then simple manipulation of the transfer functions can be carried out. For example, suppose that there are two transfer functions in cascade (see Figure 13.2): then we may write  $X(s)/U(s) = G_1(s)$  and  $Y(s)/X(s) = G_2(s)$ . Eliminating  $X(s)$  by multiplication, we have  $Y(s)/U(s) = G_1(s)G_2(s) \leftarrow$

which may be represented by a single block. This can obviously be generalised to any number of blocks in cascade.

Another important example of block representation is the prototype feedback arrangement shown in Figure 13.3. We see that  $Y(s) = G(s)E(s)$  and  $E(s) = U(s) - H(s)Y(s)$ . Eliminating  $E(s)$  from these two equations results in

Figure 13.2 Systems in cascade

Figure 13.3 Block diagram of a prototype feedback system

Figure 13.4 Reduction of the diagram shown in Figure 13.3 to a single block

$$\frac{Y(s)}{U(s)} \leftarrow \frac{G(s)}{1 + H(s)G(s)} = W(s) \leftarrow$$

In block diagram form we have Figure 13.4. If we eliminate  $Y(s)$  from the above equations, we obtain

$$\frac{E(s)}{U(s)} \leftarrow \frac{1}{1 + (H(s)G(s))} \leftarrow$$

### 13.4 Feedback

The last example is the basic feedback conceptual arrangement, and it is pertinent to investigate it further, as much effort in dealing with control systems is devoted to designing such feedback loops. The term 'feedback' is used to describe situations in which a portion of the output (and/or processed parts of it) are fed back to the input of the system. The appropriate application may be used, for example, to improve bandwidth, improve stability, improve accuracy, reduce effects of unwanted disturbances, compensate for uncertainty and reduce the sensitivity of the system to component value variation.

As a concrete example consider the system shown in Figure 13.5, which displays the arrangements for an angular position control system in which a desired position  $\theta_d$  is indicated by tapping a voltage on a potentiometer. The actual position of the load being driven by the motor (usually via a gearbox) is monitored by  $\theta_o$ , indicated, again electrically, by a potentiometer tapping. If we assume identical potentiometers energised from the same voltage supply, then the misalignment between the desired output and the actual output is indicated by the difference between the respective potentiometer voltages. This difference (proportional to error) is fed to an amplifier whose output, in turn,

**Figure 13.5** Schematic diagram of a simple position and control system

drives the motor. Thus, the arrangement seeks to drive the system until the output  $\theta_o$  and input  $\theta_r$  are coincident (i.e. the error is zero).

In the more general block diagram form, the above schematic will be transformed to that shown in *Figure 13.6*, where  $\theta_r(s)$ ,  $\theta_o(s)$  are the Laplace transforms of the input, output position:  $K_1(s)$  and  $K_2(s)$  are the potentiometer transfer functions (normally taken as straight gains);  $V_r(s)$  is the Laplace transform of the reference voltage;  $V_o(s)$  is the Laplace transform of the output voltage;  $G_m(s)$  is the motor transfer function;  $G_l(s)$  is the load transfer function; and  $A(s)$  is the amplifier transfer function.

Let us refer now to *Figure 13.3* in which  $U(s)$  is identified as the transformed input (reference or demand) signal,  $Y(s)$  is the output signal and  $E(s)$  is the error (or actuating) signal.  $G(s)$  represents the *forward transfer function* and is the product of all the transfer functions in the forward loop, i.e.  $G(s) = A(s)G_m(s)G_l(s)$  in the above example.

$H(s)$  represents the *feedback transfer function* and is the product of all transfer functions in the feedback part of the loop.

We saw in Section 13.3 that we may write

$$\frac{Y(s)}{U(s)} = \frac{G(s)}{1 + H(s)G(s)}$$

and

$$\frac{E(s)}{U(s)} = \frac{1}{1 + H(s)G(s)}$$

i.e. we have related output to input and the error to the input.

The product  $H(s)G(s)$  is called the *open-loop transfer function* and  $G(s)/[1 + H(s)G(s)]$  the *closed-loop transfer function*. The open-loop transfer function is most useful in studying the behaviour of the system, since it relates the error to the demand. Obviously it would seem desirable for this error to be zero at all times, but since we are normally considering systems containing energy storage components, total elimination of error at all times is impossible.

### 13.5 Generally desirable and acceptable behaviour

Although specific requirements will normally be drawn up for a particular control system, there are important general requirements applicable to the majority of systems. Usually an engineering system will be assembled from readily available components to perform some function, and the choice of these components will be restricted. An example of this would be a diesel engine–alternator set for delivering electrical power, in which normally the most convenient diesel engine–alternator combination will be chosen from those already manufactured.

Even if such a system were assembled from customer-designed components, it would be fortuitous if it performed in a satisfactory self-regulatory way without further consideration of its control dynamics. Hence, it is the control engineer's task to take such a system and devise economical ways of making the overall system behave in a satisfactory manner under the expected operational conditions.

For example, a system may oscillate, i.e. it is unstable; or, although stable, it might tend to settle after a change in input demand to a value unacceptably far from this new demand, i.e. it lacks static accuracy. Again, it might settle to a satisfactory new steady state, but only after an unsatisfactory transient response. Alternatively, normal operational load disturbances on the system may cause unacceptably wide variation of the output variable, e.g. voltage and frequency of the engine–alternator system.

All these factors will normally be quantified in an actual design specification, and fortunately a range of techniques is available for improving the behaviour. But the application of a particular technique to improve the performance of one aspect of behaviour often has a deleterious effect on another, e.g. improved stability with improved static accuracy tends to be incompatible. Thus, a compromise is sought which gives the 'best' acceptable all-round performance. We now discuss

**Figure 13.6** Block diagram of the system shown in *Figure 13.5*

some of these concepts and introduce certain techniques useful in examining and designing systems.

### 13.6 Stability

This is a fairly easy concept to appreciate for the types of system under consideration here. Equation (13.2) with the right-hand side made equal to zero governs the free (or unforced, or characteristic) behaviour of the system, and because of the nature of the governing LCCDE it is well known that the solution will be a linear combination of exponential terms, *viz.*

$$y(t) = \sum_{i=1}^n A_i \exp(\alpha_i t) \Leftarrow$$

where the  $\alpha_i$  values are the roots of the so-called 'characteristic equation'.

It will be noted that should any  $\alpha_i$  have a positive real part (in general, the roots will be complex), then any disturbance will grow in time. Thus, for stability, no roots must lie in the right-hand half of the complex plane or  $s$  plane. In a transfer function context this obviously translates to 'the roots of the denominator must not lie in the right-hand half of the complex plane'.

For example, if  $W(s) = G(s)/[1 + H(s)G(s)]$ , then the roots referred to are those of the equation

$$1 + H(s)G(s) = 0$$

In general, the determination of these roots is a non-trivial task and, as at this stage we are interested only in whether the system is stable or not, we can use certain results from the theory of polynomials to achieve this without the necessity for evaluating the roots.

A preliminary examination of the location of the roots may be made using the *Descartes rule of signs*, which states: if  $f(x)$  is a polynomial, the number of positive roots of the equation  $f(x) = 0$  cannot exceed the number of changes of sign of the numerical coefficients of  $f(x)$ , and the number of negative roots cannot exceed the number of changes of sign of the numerical coefficients of  $f(-x)$ . 'A change of sign' occurs when a term with a positive coefficient is immediately followed by one with a negative coefficient, and vice versa.

**Example** Suppose that  $f(x) = x^3 + 3x - 2 = 0$ ; then there can be at most one positive root. Since  $f(-x) = -x^3 - 3x - 2$ , the equation has no negative roots. Further, the equation is cubic and must have at least one real root (complex roots occur in conjugate pairs); therefore the equation has one positive-real root.

Although Descartes' result is easily applied, it is often indefinite in establishing whether or not there is stability, and a more discriminating test is that due to Routh, which we give without proof.

Suppose that we have the polynomial

$$a_0 s^n + a_1 s^{n-1} + \dots + a_{n-1} s + a_n = 0$$

where all coefficients are positive, which is a necessary (but not sufficient) condition for the system to be stable, and we construct the following so-called 'Routh array':

$$\begin{array}{lllll} s^n & : & a_0 & a_2 & a_4 & a_6 & \dots \\ s^{n-1} & : & a_1 & a_3 & a_5 & a_7 & \dots \\ s^{n-2} & : & b_1 & b_2 & b_3 & \dots \\ s^{n-3} & : & c_1 & c_2 & c_3 & \dots \\ s^{n-4} & : & d_1 & d_2 & \dots \end{array}$$

where

$$\begin{aligned} b_1 &= \frac{a_1 a_2 - a_0 a_3}{a_1}, \quad {}_s b_2 = \frac{a_1 a_4 - a_0 a_5}{a_1}, \quad {}_s b_3 = \frac{a_1 a_6 - a_0 a_7}{a_1}, \dots \\ c_1 &= \frac{b_1 a_3 - a_1 b_2}{b_1}, \quad {}_s c_2 = \frac{b_1 a_5 - a_1 b_3}{b_1}, \dots \% \\ d_1 &= \frac{c_1 b_2 - b_1 c_2}{c_1}, \dots \end{aligned}$$

This array will have  $n + 1$  rows.

If the array is complete and *none* of the elements in the first column vanishes, then a sufficient condition for the system to be stable (i.e. the characteristic equation has all its roots with negative-real parts) is for all these elements to be positive. Further, if these elements are not all positive, then the number of changes of sign in this first column indicates the number of roots with positive-real parts.

**Example** Determine whether the polynomial  $s^4 + 2s^3 + 6s^2 + 7s + 4 = 0$  has any roots with positive-real parts. Construct the Routh array:

$$\begin{array}{llll} s^4 & : & 1 & 6 & 4 \\ s^3 & : & 2 & 7 & \\ s^2 & : & \frac{(2)(6) - (1)(7)}{2} = 2.5 & \frac{(2)(4) - (1)(0)}{2} = 4 & \\ s & : & \frac{(2.5)(7) - (2)(4)}{2.5} = 3.8 & & \\ s^0 & : & 4 & & \end{array}$$

There are five rows with the first-column elements all positive, and so a system with this polynomial as its characteristic would be stable.

There are cases that arise which need a more delicate treatment.

- (1) Zeros occur in the first column, while other elements in the row containing a zero in the first column are non-zero.

In this case the zero is replaced by a small positive number,  $\varepsilon$ , which is allowed to approach zero once the array is complete.

For example, consider the polynomial equation

$$s^5 + 2s^4 + 2s^3 + 4s^2 + 11s + 8 = 0:$$

$$\begin{array}{llll} s^5 & : & 1 & 2 & 11 \\ s^4 & : & 2 & 4 & 8 \\ s^3 & : & \varepsilon & 5 & 0 \\ s^2 & : & \alpha_1 & 8 & \\ s^1 & : & \alpha_2 & 0 & \\ s^0 & : & 8 & & \end{array}$$

where

$$\alpha_1 = \frac{4\varepsilon - 10}{\varepsilon} \simeq -\frac{10}{\varepsilon} \quad \text{and} \quad \alpha_2 = \frac{5\alpha_1 - 8\varepsilon}{\alpha_1} \simeq \varepsilon$$

Thus,  $\alpha_1$  is a large negative number and we see that there are effectively two changes of sign and, hence, the equation has two roots which lie in the right-hand half of this plane.

- (2) Zeros occur in the first column and other elements of the row containing the zero are also zero.

This situation occurs when the polynomial has roots that are symmetrically located about the origin of the  $s$  plane, i.e. it contains terms such as  $(s + j\omega)(s - j\omega)$  or  $(s + v)(s - v)$ .

This difficulty is overcome by making use of the auxiliary equation which occurs in the row immediately before the zero entry in the array. Instead of the

all-zero row the equation formed from the preceding row is differentiated and the resulting coefficients are used in place of the all-zero row.

For example, consider the polynomial  $s^3 + 3s^2 + 6s + 6 = 0$ .

$$\begin{array}{l} s^3 : 1 \quad 2 \\ s^2 : 3 \quad 6 \quad (\text{auxiliary equation } 3s^2 + 6 = 0) \\ s^1 : 0 \quad 0 \end{array}$$

Differentiate the auxiliary equation giving  $6s = 0$ , and compile a new array using the coefficients from this last equation, viz.

$$\begin{array}{l} s^3 : 1 \quad 2 \\ s^2 : 3 \quad 6 \\ s^1 : 6 \quad 0 \\ s^0 : 1 \end{array}$$

Since there are no changes of sign, the system will not have roots in the right-hand half of the  $s$  plane.

Although the Routh method allows a straightforward algorithmic approach to determining the stability, it gives very little clue as to what might be done if stability conditions are unsatisfactory. This consideration is taken up later.

## 13.7 Classification of system and static accuracy

### 13.7.1 Classification

The discussion in this section is restricted to unity-feedback systems (i.e.  $H(s) = 1$ ) without seriously affecting generalities. We know that the open-loop system has a transfer function  $KG(s)$ , where  $K$  is a constant and we may write

$$KG(s) = \frac{K(s - z_1)(s - z_2) \dots (s - z_m)}{s^l(s + p_1)(s + p_2) \dots (s + p_n)} = \frac{K \sum_{k=0}^m b_k s^k}{s^l \sum_{k=0}^{n-1} a_k s^k}$$

and for physical systems  $n \geq m + 1$ .

The *order* of the system is defined as the degree of the polynomial in  $s$  appearing in the denominator, i.e.  $n$ .

The *rank* of the system is defined as the difference in the degree of the denominator polynomial and the degree of the numerator polynomial, i.e.  $n - m \geq 1$ .

The *class* (or *type*) is the degree of the  $s$  term appearing in the denominator (i.e.  $l$ ), and is equal to the number of integrators in the system.

*Example*

$$(1) \quad G(s) = \frac{s + 1}{s^4 + 6s^3 + 9s^2 + 3s}$$

implies order 4, rank 3 and type 1.

$$(2) \quad G(s) = \frac{s^2 + 4s + 1}{(s + 1)(s^2 + 2s + 4)}$$

implies order 3, rank 1 and type 0.

### 13.7.2 Static accuracy

When a demand has been made on the system, then it is generally desirable that after the transient conditions have

decayed the output should be equal to the input. Whether or not this is so will depend both on the characteristics of the system and on the input demand. Any difference between the input and output will be indicated by the error term  $e(t)$  and we know that for the system under consideration

$$E(s) = \frac{U(s)}{1 + KG(s)}$$

Let  $e_{ss} = \lim_{t \rightarrow \infty} e(t)$  (if it exists), and so  $e_{ss}$  will be the steady-state error. Now from the final-value theorem we have

$$e_{ss} = \lim_{t \rightarrow \infty} e(t) = \lim_{s \rightarrow 0} [sE(s)]$$

Thus,

$$e_{ss} = \lim_{s \rightarrow 0} \left[ \frac{sU(s)}{1 + KG(s)} \right]$$

#### 13.7.2.1 Position-error coefficient $K_p$

Suppose that the input is a unit step, i.e.  $R(s) = 1/s$ ; then

$$e_{ss} = \lim_{s \rightarrow 0} \left[ \frac{1}{1 + KG(s)} \right] = \frac{1}{1 + \lim_{s \rightarrow 0} [KG(s)]} = \frac{1}{1 + K_p}$$

where  $K_p = \lim_{s \rightarrow 0} [KG(s)]$  and this is called the *position-error coefficient*.

*Example* For a type-0 system

$$KG(s) = \frac{K \sum_{k=0}^m b_k s^k}{\sum_{k=0}^{n-1} a_k s^k}$$

Therefore  $K_p = K(b_0/a_0)$  and  $e_{ss} = 1/(1 + K_p)$ .

It will be noted that, after the application of a step, there will always be a finite steady-state error between the input and the output, but this will decrease as the gain  $K$  of the system is increased.

*Example* For a type-1 system

$$KG(s) = \frac{K \sum_{k=0}^m b_k s^k}{s \left( \sum_{k=0}^{n-1} a_k s^k \right)}$$

and

$$K_p = \lim_{s \rightarrow 0} \left[ K \sum_{k=0}^m b_k s^k \right] / \left[ s \left( \sum_{k=0}^{n-1} a_k s^k \right) \right] \rightarrow \infty$$

Thus,

$$e_{ss} = \frac{1}{1 + \infty} = 0$$

i.e. there is no steady-state error in this case and we see that this is due to the presence of the integrator term  $1/s$ . This is an important practical result, since it implies that steady-state errors can be eliminated by use of integral terms.

#### 13.7.2.2 Velocity-error coefficient, $K_v$

Let us suppose that the input demand is a unit ramp, i.e.  $u(t) = t$ , so  $U(s) = 1/s^2$ . Then

$$e_{ss} = \lim_{s \rightarrow 0} [sE(s)] = \lim_{s \rightarrow 0} \left[ \frac{1}{s + sKG(s)} \right] = \frac{1}{\lim_{s \rightarrow 0} [sKG(s)]} = \frac{1}{K_v}$$

where  $K_v = \lim_{s \rightarrow 0} [sKG(s)]$  is called the *velocity-error coefficient*.

**Examples** For a type-0 system  $K_v = 0$ , whence  $e_{ss} \rightarrow \infty$ .

For a type-1 system  $K_v = K(b_0/a_0)$  and so this system can follow but with a finite error.

For a type-2 system

$$K_v = \lim_{s \rightarrow 0} \left[ \frac{K b_0}{s a_0} \right] \rightarrow \infty \Leftarrow$$

whence  $e_{ss} \rightarrow 0$  and so the system can follow in the steady state without error.

### 13.7.2.3 Acceleration-error coefficient $K_a$

In this case we assume that  $u(t) = t^2/2$ , so  $U(s) = 1/s^3$  and so

$$e_{ss} = \lim_{s \rightarrow 0} [sE(s)] = \lim_{s \rightarrow 0} \left[ \frac{1}{s^2 + s^2 KG(s)} \right] \Leftarrow$$

$$= \frac{1}{\lim_{s \rightarrow 0} [s^2 KG(s)]} \Leftarrow \frac{1}{K_a}$$

where  $K_a = \lim_{s \rightarrow 0} [s^2 KG(s)]$  is called the *acceleration-error coefficient* and similar analyses to the above may be performed.

These error-coefficient terms are often used in design specifications of equipment and indicate the minimum order of the system that one must aim to design.

### 13.7.3 Steady-state errors due to disturbances

The prototype unity-feedback closed-loop system is shown in Figure 13.7 modified by the intrusion of a disturbance  $D(s)$

Figure 13.7 Schematic diagram of a disturbance entering the loop

Figure 13.8 First-order lag response to a unit step (time constant = 1, 2, 3, units)

being allowed to affect the loop. For example, the loop might represent a speed-control system and  $D(s)$  might represent the effect of changing the load. Now, since linear systems are under discussion, in order to evaluate the effects of this disturbance on  $Y(s)$  (denoted by  $Y_D(s)$ ), we may tacitly assume  $U(s) = 0$  (i.e. invoke the superposition principle)

$$Y_D(s) = D(s) - KG(s)Y_D(s) \Leftarrow$$

$$Y_D(s) = D(s)/[1 + KG(s)] \Leftarrow$$

Now  $E_D(s) = -Y_D(s) = -D(s)/[1 + KG(s)]$ , and so the steady-state error,  $e_{ssD}$  due to the application of the disturbance, may be evaluated by use of the final-value theorem as

$$e_{ssD} = -\lim_{s \rightarrow 0} \left[ \frac{sD(s)}{1 + KG(s)} \right] \Leftarrow$$

Obviously the disturbance may enter the loop at other places but its effect may be established by similar analysis.

## 13.8 Transient behaviour

Having developed a means of assessing stability and steady-state behaviour, we turn our attention to the transient behaviour of the system.

### 13.8.1 First-order system

It is instructive to examine first the behaviour of a first-order system (a first-order lag with a time constant  $T$ ) to a unit-step input (Figure 13.8).

Now

$$\frac{Y(s)}{U(s)} \Leftarrow G(s) = \frac{1}{1 + sT}$$

**Figure 13.9** First-order lag incorporated in a feedback loop

where  $U(s) = 1/s$

$$Y(s) = \frac{1}{s(1+sT)} = \frac{1}{Ts} - \frac{1}{1+sT}$$

or  $y(t) = 1 - \exp(-t/T)$ ;

note also that  $dy/dt = (1/T) \exp(-t/T)$ .

Figure 13.8 shows this time response for different values of  $T$  where it will be noted that the corresponding trajectories have slopes of  $1/T$  at time  $t=0$  and reach approximately 63% of their final values after  $T$ .

Suppose now that such a system is included in a unity-feedback arrangement together with an amplifier of gain  $K$  (Figure 13.9); therefore

$$\frac{Y(s)}{U(s)} = \frac{K/(1+sT)}{1 + K/(1+sT)} = \frac{K}{(1+K) \left(1 + s \frac{T}{1+K}\right)}$$

For a unit-step input the time response will be

$$y(t) = \frac{K}{1+K} [1 - \exp\{-(1+K)(t/T)\}]$$

This expression has the same form as that obtained for the open loop but the effective time constant is modified by the gain and so is the steady-state condition (Figure 13.10). Such an arrangement provides the ability to control the effective time constant by altering the gain of an amplifier, the original physical system being left unchanged.

### 13.8.2 Second-order system

The behaviour characteristics of second-order systems are probably the most important of all, since many systems of seemingly greater complexity may often be approximated by a second-order system because certain poles of their transfer function dominate the observed behaviour. This has led to

system specifications often being expressed in terms of second-order system behavioural characteristics.

In Section 13.2 the importance of the second-order behaviour of a generator was mentioned, and this subject is now taken further by considering the system shown in Figure 13.11.

The closed-loop transfer function for this system is given by

$$W(s) = \frac{KG(s)}{1 + KG(s)} = \frac{K}{s^2 + as + K}$$

and this may be rewritten in general second-order terms in the form

$$W(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$$

where  $K = \omega_n^2$  and  $\zeta = a/(2\sqrt{K})$ . The unit-step response is given by

$$y(t) = 1 - \exp(-\zeta\omega_n t) [\cos(\gamma\omega_n t) - (\zeta/\gamma) \sin(\gamma\omega_n t)]$$

where  $\gamma = \sqrt{1 - \zeta^2}$ . This assumes, of course, that  $\zeta < 1$ , so giving an oscillating response decaying with time.

The rise time  $t_r$  will be defined as the time to reach the first overshoot (note that other definitions are used and it is important to establish which particular definition is being used in a particular specification):

$$t_r = \pi/(\gamma\omega_n) = \pi/\sqrt{K - (a/2)^2}$$

i.e. the rise time decreases as the gain  $K$  is increased.

The percentage overshoot is defined as:

$$\text{Percentage overshoot} = \frac{100(\text{Max. value of } y(t) - \text{Steady-state value})}{\text{Steady-state value}}$$

$$= 100 \exp(-\zeta\pi/\gamma) = 100 \exp[-\alpha\pi/\sqrt{(4K - a^2)}]$$

i.e. the percentage overshoot increases as the gain  $K$  increases.

**Figure 13.10** Response of first-order lag: (a) open-loop condition ( $T=1$ ); (b) closed-loop condition ( $T=1$ ,  $K=2$ )

Figure 13.11 Second-order system

The frequency of oscillation  $\omega_r$  is immediately seen to be

$$\omega_r = \omega_n \gamma = \sqrt{[K - (a/2)^2]} \leftarrow$$

i.e. the frequency of oscillation increases as the gain  $K$  increases.

The *predominant time constant* is the time constant associated with the envelope of the response (Figure 13.12) which is given by  $\exp(-\zeta\omega_n t)$  and thus the predominant time constant is  $1/\zeta\omega_n$ :

$$\frac{1}{\zeta\omega_n} = \frac{1}{(a/2\sqrt{K})\sqrt{K}} = \frac{2}{a}$$

Note that this time constant is unaffected by the gain  $K$  and is associated with the 'plant parameter  $a$ ', which will normally be unalterable, and so other means must be found to alter the predominant time constant should this prove necessary.

The *settling time*  $t_s$  is variously defined as the time taken for the system to reach 2–5% (depending on specification) of its final steady state and is approximately equal to four times the predominant time constant.

Figure 13.12 Step response of the system shown in Figure 13.11. The rise time  $t_r$  is the time taken to reach maximum overshoot. The predominant time constant is indicated by the tangents to the envelope curve

Figure 13.13 Schematic diagram showing the incorporation of velocity feedback

It should be obvious from the above that characteristics desired in plant dynamical behaviour may be conflicting (e.g. fast rise time with small overshoot) and it is up to the skill of the designer to achieve the best compromise. Overspecification can be expensive.

A number of the above items can be directly affected by the gain  $K$  and it may be that a suitable gain setting can be found to satisfy the design with no further attention. Unfortunately, the design is unlikely to be as simple as this, in view of the fact that the predominant time constant cannot be influenced by  $K$ . A particularly important method for influencing this term is the incorporation of so-called *velocity feedback*.

### 13.8.3 Velocity feedback

Given the prototype system shown in Figure 13.11, suppose that this is augmented by measuring the output  $y(t)$ , differentiating to form  $\dot{y}(t)$ , and feeding back in parallel with the normal feedback a signal proportional to  $\dot{y}(t)$ : say  $T\dot{y}(t)$ . The schematic of this arrangement is shown in Figure 13.13. Then, by simple manipulation, the modified transfer function becomes

$$W'(\bar{s}) = \frac{K}{s^2 + (a + KT)s + K}$$

whence the modified predominant time constant is given by  $2/(a + TK)$ . The designer effectively has another string to his bow in that manipulation of  $K$  and  $T$  is normally very much in his command.

A similar effect may be obtained by the incorporation of a *derivative* term to act on the error signal (Figure 13.14) and in this case the transfer function becomes

$$W'(\bar{s}) = \frac{K(1 + Ts)}{s^2 + (a + KT)s + K}$$

It may be demonstrated that this derivative term when correctly adjusted can both stabilise the system and increase the speed of response. The control shown in Figure 13.14 is referred to as *proportional-plus-derivative* control and is very important.

### 13.8.4 Incorporation of integral control

Mention has previously been made of the effect of using integrators within the loop to reduce steady-state errors; a particular study with reference to input/output effects was given. In this section consideration is given to the effects of disturbances injected into the loop, and we consider again

Figure 13.14 Schematic diagram of the proportional-plus-derivative control system

the simple second-order system shown in Figure 13.11 but with a disturbance occurring between the amplifier and the plant dynamics. Appealing to superposition we can, without loss of generality, put  $U(s) = 0$  and the transfer function between the output and the disturbance is then given by

$$\frac{Y(s)}{D(s)} = \frac{1}{s(s+a) + K}$$

Assuming that  $d(t)$  is a unit step,  $D(s) = 1/s$ , and using the final-value theorem,  $\lim_{t \rightarrow \infty} y(t)$  is obtained from

$$\lim_{t \rightarrow \infty} y(t) = \lim_{s \rightarrow 0} s \left[ \frac{1}{s(s+a) + K} \right] = \frac{1}{K}$$

and so the effect of this disturbance will always be present. By incorporating an integral control as shown in Figure 13.15, the output will, in the steady state, be unaffected by the disturbance, viz.

$$Y(s) = \frac{Ts}{Ts^2(s+a) + K(1+Ts)} D(s)$$

and so

$$y_{ss} \rightarrow 0$$

This controller is called a *proportional-plus-integral* controller.

An unfortunate side-effect of incorporating integral control is that it tends to destabilise the system, but this can be minimised by careful choice of  $T$ . In a particular case it might be that *proportional-plus-integral-plus-derivative (PID) control* may be called for, the amount of each particular control type being carefully proportioned.

In the foregoing discussions we have seen, albeit by using specific simple examples, how the behaviour of a plant might be modified by use of certain techniques. It is hoped that this will leave the reader with some sort of feeling for what might be done before embarking on more general tools, which tend to appear rather rarefied and isolated unless a basic physical feeling for system behaviour is present.

### 13.9 Root-locus method

The root locus is merely a graphical display of the *variation of the poles of the closed-loop system* when some parameter, often the gain, is varied. The method is useful since the loci may be obtained, at least approximately, by straightforward application of simple rules, and possible modification to reshape the locus can be assessed.

Considering once again the unity-feedback system with the open-loop transfer function  $KG(s) = Kb(s)/a(s)$ , where  $b(s)$  and  $a(s)$  represent  $m$ th- and  $n$ th-order polynomials, respectively, and  $n > m$ , then the closed-loop transfer function may be written as

$$W(s) = \frac{KG(s)}{1 + KG(s)} = \frac{Kb(s)}{a(s) + Kb(s)}$$

Note that the system is  $n$ th order and the zeros of the closed loop and the open loop are identical for unity feedback. The characteristic behaviour is determined by the roots of  $1 + KG(s) = 0$  or  $a(s) + Kb(s) = 0$ . Thus,  $G(s) = -(1/K)$  or  $b(s)/a(s) = -(1/K)$ .

Let  $s_r$  be a root of this equation; then

$$\text{mod} \left[ \frac{b(s_r)}{a(s_r)} \right] = \frac{1}{K}$$

and

$$\text{phase} \left[ \frac{b(s_r)}{a(s_r)} \right] = 180^\circ + n360^\circ$$

where  $n$  may take any integer value, including  $n=0$ . Let  $z_1, \dots, z_m$  be the roots of the polynomial  $b(s)=0$ , and  $p_1, \dots, p_n$  be the roots of the polynomial  $a(s)=0$ . Then

$$b(s) = \prod_{i=1}^m (s - z_i)$$

Figure 13.15 Schematic diagram of the proportional-plus-integral control system

and

$$a(s) = \prod_{i=1}^n (s - p_i) \Leftarrow$$

Therefore

$$\frac{\prod_{i=1}^m |s_r - z_i|}{\prod_{i=1}^n |s_r - p_i|} = \frac{1}{K}, \text{ the magnitude condition}$$

and

$$\sum_{i=1}^m \left( \text{phase}(s_r - z_i) \right) - \sum_{i=1}^n \left( \text{phase}(s_r - p_i) \right) = 180^\circ + n360^\circ, \text{ the angle or phase condition}$$

Now, given a complex number  $p_j$ , the determination of the complex number  $(s - p_j)$ , where  $s$  is some point in the complex plane, is illustrated in Figure 13.16, where the  $\text{mod}(s - p_j)$  and  $\text{phase}(s - p_j)$  are also illustrated. The determination of the magnitudes and phase angles for all the factors in the transfer function, for any  $s$ , can therefore be done graphically.

The complete set of all values of  $s$ , constituting the root locus may be constructed using the angle condition alone; once found, the gain  $K$  giving particular values of  $s_r$  may be easily determined from the magnitude condition.

**Example** Suppose that  $G(s) = K/[(s + a)(s + b)]$ , then it is fairly quickly established that the only sets of points satisfying the angle condition

$$-\text{phase}(s_r + a) - \text{phase}(s_r + b) = 180 + n360^\circ \Leftarrow$$

are on the line joining  $-a$  to  $-b$  and the perpendicular bisector of this line (Figure 13.17).

### 13.9.1 Rules for construction of the root locus

- (1) The angle condition must be obeyed.
- (2) The magnitude condition enables calibration of the locus to be carried out.
- (3) The root locus on the real axis must be in sections to the left of an odd number of poles and zeros. This follows immediately from the angle condition.

**Figure 13.16** Representation of  $(s - p_j)$  on the  $s$  plane ( $l = |s - p_j|$ ;  $\beta = \angle(s - p_j)$ )

**Figure 13.17** Root-locus diagram for  $KG(s) = K/[(s + a)(s + b)]$

- (4) The root locus must be symmetrical with respect to the horizontal real axis. This follows because complex roots must appear as complex conjugate pairs.
- (5) Root loci always emanate from the poles of the open-loop transfer function where  $K = 0$ . Consider  $a(s) + Kb(s) = 0$ ; then  $a(s) = 0$  when  $K = 0$  and the roots of this polynomial are the poles of the open-loop transfer function. Note that this implies that there will be  $n$  branches of the root locus.
- (6)  $m$  of the branches will terminate at the zeros for  $K \rightarrow \infty$ . Consider  $a(s) + Kb(s) = 0$ , or  $(1/K)a(s) + b(s) = 0$ , whence as  $K \rightarrow \infty$ ,  $b(s) \rightarrow 0$  and, since this polynomial has  $m$  roots, these are where  $m$  of the branches terminate. The remaining  $n - m$  branches terminate at infinity (in general, complex infinity).
- (7) These  $n - m$  branches go to infinity along asymptotes inclined at angles  $\phi_i$  to the real axis, where

$$\phi_i = \frac{(2i + 1)}{n - m} 180^\circ, \quad i = 0, 1, \dots, (n - m - 1) \Leftarrow$$

Consider a root  $s_r$  approaching infinity,  $(s_r - a) \rightarrow s_r$  for all finite values of  $a$ . Thus, if  $\phi_i$  is the phase  $s_r$ , then each pole and each zero term of the transfer function term will contribute approximately  $\phi_i$  and  $-\phi_i$ , respectively. Thus,

$$\phi_i(n - m) = 180^\circ + i360^\circ$$

$$\phi_i = \frac{(2i + 1)}{n - m} 180^\circ, \quad i = 0, 1, \dots, (n - m - 1) \Leftarrow$$

- (8) The centre of these asymptotes is called the 'asymptote centre' and is (with good accuracy) given by

$$\sigma_A = \frac{\left( \sum_{i=1}^n p_i - \sum_{j=1}^m z_j \right)}{(n - m)} \Leftarrow$$

This can be shown by the following argument. For very large values of  $s$  we can consider that all the poles and zeros are situated at the point  $\sigma_A$  on the real axis. Then the characteristic equation (for large values of  $s$ ) may be written as

$$1 + \frac{K}{(s + \sigma_A)^{n-m}} = 0$$

or approximately, by using the binomial theorem,

$$1 + \frac{K}{s^{n-m} + (n - m)s^{n-m-1}\sigma_A} = 0$$

Also, the characteristic equation may be written as

$$1 + \frac{K \prod_{i=1}^m (s + z_i)}{\prod_{i=1}^n (s + p_i)} = 0$$

Expanding this for the first two terms results in

$$1 + \frac{K}{s^{n-m} + (a_{n-1} - b_{m-1})s^{n-m-1}} = 0$$

where

$$b_{m-1} = \sum_{i=1}^m z_i \quad \text{and} \quad a_{n-1} = \sum_{i=1}^n p_i$$

whence

$$(a_{n-1} - b_{m-1}) = (n - m)\sigma_A$$

$$\sigma_A = \frac{a_{n-1} - b_{m-1}}{n - m}$$

as required.

- (9) When a locus breaks away from the real axis, it does so at the point where  $K$  is a local maximum. Consider the characteristic equation  $1 + K[b(s)/a(s)] = 0$ ; then we can write  $K = p(s)$ , where  $p(s) = -[a(s)/b(s)]$ . Now, where two poles approach each other along the real axis they will both be real and become equal when  $K$  has the maximum value that will enable them both to be real and, of course, coincident. Thus, an evaluation of  $K$  around the breakaway point will rapidly reveal the breakaway point itself.

**Example** Draw the root locus for

$$KG(s) = \frac{K(s+1)}{s(s+2)(s+3)}$$

Procedure (Figure 13.18):

- (1) Plot the poles of the open-loop system (i.e. at  $s=0$ ,  $s=-2$ ,  $s=-3$ ).
- (2) Plot the zeros of the system (i.e. at  $z=-1$ ).
- (3) Determine the sections on the real axis at which closed-loop poles can exist. Obviously these are between 0 and  $-1$  (this root travels along the real axis between these values as  $K$  goes from  $0 \rightarrow \infty$ ), and between  $-2$  and  $-3$  (two roots are moving towards each other as  $K$  increases and, of course, will break away).
- (4) Angle of asymptotes

$$\phi_1 = \frac{1}{2} + 180^\circ = 90^\circ$$

$$\phi_2 = \frac{3}{2} \times 180^\circ = 270^\circ$$

- (5) Centroid  $\sigma_A$  is located at

$$\sigma_A = \frac{-2 - 3 + 1}{2} = -2$$

- (6) Breakaway point,  $\sigma_B$

$\sigma_B$	-2.45	-2.465	-2.48
$K$	0.418	0.4185	0.418

- (7) Modulus. For a typical root situated at, for example, point A, the gain is given by  $K = l_2 l_3 l_4 / l_1$ .

**Figure 13.18** Root-locus construction for  $KG(s) = [K(s+1)]/[s(s+2)(s+3)]$

After a little practice the root locus can be drawn very rapidly and compensators can be designed by pole-zero placement in strategic positions. A careful study of the examples given in the table will reveal the trends obtainable for various pole-zero placements.

## 13.10 Frequency-response methods

Frequency-response characterisation of systems has led to some of the most fruitful analysis and design methods in

the whole of control system studies. Consider the situation of a linear, autonomous, stable system, having a transfer function  $G(s)$ , and being subjected to a unit-magnitude sinusoidal input signal of the form  $\exp(j\omega t)$ , starting at  $t=0$ . The Laplace transformation of the resulting output of the system is

$$C(s) = G(s)/(s - j\omega)$$

and the time domain solution will be

$$c(t) = G(j\omega) \exp(j\omega t) + \left( \begin{array}{l} \text{Terms whose exponential terms} \\ \text{correspond to the roots} \\ \text{of the denominator of } G(s) \end{array} \right)$$

Since a stable system has been assumed, then the effects of the terms in the parentheses will decay away with time and so, after a sufficient lapse of time, the steady-state solution will be given by

$$c_{ss}(t) = G(j\omega) \exp(j\omega t)$$

The term  $G(j\omega)$ , obtained by merely substituting  $j\omega$  for  $s$  in the transfer function form, is termed the *frequency-response function*, and may be written

$$G(j\omega) = |G(j\omega)| \angle G(j\omega)$$

where  $|G(j\omega)| = \text{mod } G(j\omega)$  and  $\angle G(j\omega) = \text{phase } G(j\omega)$ . This implies that the output of the system is also sinusoidal in magnitude  $|G(j\omega)|$  with a phase-shift of  $\angle G(j\omega)$  with reference to the input signal.

**Example** Consider the equation of motion

$$m\ddot{y} + bz + ky = f(t)$$

$$\frac{Y(s)}{F(s)} = G(s) = \frac{1}{ms^2 + bs + k}$$

If  $f(t) = F_0 \exp(j\omega t)$ , then

$$y_{ss}(t) = \frac{F_0 \exp(j\omega t)}{(k - \omega^2 m) + j\omega b}$$

whence

$$y_{ss}(t) = \frac{F_0 \exp[j(\omega t - \phi)]}{\sqrt{(k - \omega^2 m)^2 + (b\omega)^2}}$$

where  $\phi = \arctan b\omega/(k - m\omega^2)$ .

Within the area of frequency-response characterisation of systems three graphical techniques have been found to be particularly useful for examining systems and are easily seen to be related to each other. These techniques are based upon:

- (1) The *Nyquist plot*, which is the locus of the frequency-response function plotted in the complex plane using  $\omega$  as a parameter. It enables stability, in the closed-loop condition, to be assessed and also gives an indication of how the locus might be altered to improve the behaviour of the system.
- (2) The *Bode diagram*, which comprises two plots, one showing the amplitude of the output frequency response (plotted in decibels) against the frequency  $\omega$  (plotted logarithmically) and the other of phase angle  $\theta_\omega$  of the output frequency response plotted against the same abscissa.
- (3) The *Nichols chart*, a direct plot of amplitude of the frequency response (again in decibels) against the phase

angle, with frequency  $\omega$  as a parameter, but further enables the closed-loop frequency response to be read directly from the chart.

In each of these cases it is the *open-loop* steady-state frequency response, i.e.  $G(j\omega)$ , which is plotted on the diagrams.

### 13.10.1 Nyquist plot

The closed-loop transfer function is given by

$$\frac{C(s)}{R(s)} = \frac{G(s)}{1 + H(s)G(s)}$$

and the stability is determined by the location of the roots of  $1 + H(s)G(s) = 0$ , i.e. for stability no roots must have positive-real parts and so must not lie on the positive-real half of the complex plane. Assume that the open-loop transfer function  $H(s)G(s)$  is stable and consider the contour  $C$ , the so-called 'Nyquist contour' shown in Figure 13.19, which consists of the imaginary axis plus a semicircle of large enough radius in the right half of the  $s$  plane such that any zeros of  $1 + H(s)G(s)$  will be contained within this contour. This contour  $C_n$  is mapped via  $1 + H(s)G(s)$  into another curve  $\gamma_n$  into the complex plane  $s'$ . It follows immediately from complex variable theory that the closed loop will be stable if the curve  $\gamma_n$  does not encircle the origin in the  $s'$  plane and unstable if it encircles the origin or passes through the origin. This result is the basis of the celebrated Nyquist stability criterion. It is rather more usual to map not  $1 + H(s)G(s)$  but  $H(s)G(s)$ ; in effect this is merely a change of origin from  $(0, 0)$  to  $(-1, 0)$ , i.e. we consider curve  $\gamma'_n$ .

The statement of the stability criterion is that the closed-loop system will be stable if the mapping of the contour  $C_n$  by the open-loop frequency-response function  $H(j\omega)G(j\omega)$  does not enclose the so-called critical point  $(-1, 0)$ . Actually further simplification is normally possible, for:

- (1)  $|H(s)G(s)| \rightarrow 0$  as  $|s| \rightarrow \infty$ , so that the very large semicircular boundary maps to the origin in the  $s'$  plane.
- (2)  $H(-j\omega)G(-j\omega)$  is the complex conjugate of  $H(j\omega)G(j\omega)$  and so the mapping of  $H(-j\omega)G(-j\omega)$  is merely the mirror image of  $H(j\omega)G(j\omega)$  in the real axis.
- (3) Note:  $H(j\omega)G(j\omega)$  is merely the frequency-response function of the open loop and may even be directly measurable from experiments. Normally we are mostly interested in how this behaves in the vicinity of the  $(-1, 0)$  point and, therefore, only a limited frequency range is required for assessment of stability.

The mathematical mapping ideas stated above are perhaps better appreciated practically by the so-called *left-hand rule* for an open-loop stable system, which reads as follows: if the open-loop sinusoidal response is traced out going from low frequencies towards higher frequencies, the closed loop will be stable if the critical point  $(-1, 0)$  lies on the left of all points on  $H(j\omega)G(j\omega)$ . If this plot passes through the critical point, or if the critical point lies on the right-hand side of  $H(j\omega)G(j\omega)$ , the closed loop will be unstable.

If the open loop has poles that actually lie on the imaginary axis, e.g. integrator  $1/s$ , then the contour is indented as shown in Figure 13.20 and the above rule still applies to this modification.

#### 13.10.1.1 Relative stability criteria

Obviously the closer the  $H(j\omega)G(j\omega)$  locus approaches the critical point, the more critical is the consideration of stability, i.e. we have an indication of relative stability,

**Figure 13.19** Illustration of Nyquist mapping: (a) mapping contour on the  $s$  plane; (b) resulting mapping of  $1 + H(s)G(s) = 0$  and the shift of the origin

**Figure 13.20** Modification of the mapping contour to account for poles appearing at the origin

given a measure by the gain and phase margins of the system.

If the modulus of  $H(j\omega)G(j\omega) = X$  with a phase shift of  $180^\circ$ , then the *gain margin* is defined as

$$\text{Gain margin} = 1/X$$

The gain margin is usually specified in decibels, where we have

$$\text{Gain margin (dB)} = 20 \log(1/X) = -20 \log X$$

The *phase margin* is the angle which the line joining the origin to the point on the open-loop response locus corresponding to unit modulus of gain makes with the negative-real axis. These margins are probably best appreciated diagrammatically (Figure 13.21). They are useful, since a

**Figure 13.21** Illustration of the gain and phase margins. Gain margin  $= 1/X$ ; phase margin  $= 0$

rough working rule for reasonable system damping and stability is to shape the locus so that a gain margin of at least 6 dB is achieved and a phase margin of about  $40^\circ$ .

Examples of the Nyquist plot are shown in Figure 13.22. Although from such plots the modifications necessary to achieve more satisfactory performance can be easily appreciated, precise compensation arrangements are not easily determined, since complex multiplication is involved and an appeal to the Bode diagram can be more valuable.

### 13.10.2 Bode diagram

As mentioned above, the Bode diagram is a logarithmic presentation of the frequency response and has the advantage

Figure 13.22 Transfer function plots for typical transfer functions

over the Nyquist diagram that individual factor terms may be added rather than multiplied, the diagram can usually be quickly sketched using asymptotic approximations and several decades of frequency may be easily considered.

Now suppose that

$$H(s)G(s) = H(s)G_1(s)G_2(s)G_3(s) \dots$$

i.e. the composite transfer function may be thought of as being composed of a number of simpler transfer functions multiplied together, so

$$\begin{aligned} |H(j\omega)G(j\omega)| &= |H(j\omega)||G_1(j\omega)||G_2(j\omega)||G_3(j\omega)| \dots \\ 20 \log |H(j\omega)G(j\omega)| &= 20 \log |H(j\omega)| + 20 \log |G_1(j\omega)| + \dots \\ &+ 20 \log |G_2(j\omega)| + 20 \log |G_3(j\omega)| + \dots \end{aligned}$$

This is merely each individual factor (in decibels) being added algebraically to a grand total. Further,

$$\begin{aligned} \angle H(j\omega)G(j\omega) &= \angle H(j\omega) + \angle G_1(j\omega) + \angle G_2(j\omega) + \dots \\ &+ \angle G_3(j\omega) + \dots \end{aligned}$$

i.e. the individual phase shift at a particular frequency may be added algebraically to give the total phase shift.

It is possible to construct Bode diagrams from elemental terms including gain ( $K$ ), differentiators and integrators ( $s$  and  $1/s$ ), lead and lag terms ( $(as+1)$  and  $(1+as)^{-1}$ ), quadratic lead and lag terms ( $(bs^2+cs+1)$  and  $(bs^2+cs+1)^{-1}$ ), and we consider the individual effects of their presence in a transfer function on the shape of the Bode diagram.

- (a) *Gain term,  $K$*  The gain in decibels is simply  $20 \log K$  and is frequency independent; it merely raises (or lowers) the combined curve  $20 \log K$  dB.
- (b) *Integrating term,  $1/s$*  Now  $|G(j\omega)| = 1/\omega$  and  $\angle G(j\omega) = -90^\circ$  (a constant) and so the gain in decibels is given by  $20 \log(1/\omega) = -20 \log \omega$ . On the Bode diagram this corresponds to a straight line with slope  $-20$  dB/decade (or  $-6$  dB/octave) of frequency and passes through  $0$  dB at  $\omega = 1$  (see plot 4 in Figure 13.22).
- (c) *Differentiating term,  $s$*  Now  $|G(j\omega)| = \omega$  and  $\angle G(j\omega) = 90^\circ$  (a constant) and so the gain in decibels is given by  $20 \log \omega$ . On the Bode diagram this corresponds to a straight line with slope  $20$  dB/decade of frequency and passes through  $0$  dB at  $\omega = 1$ .
- (d) *First-order lag term,  $(1+s\tau)^{-1}$*  The gain in decibels is given by

$$20 \log \left( \frac{1}{1 + \omega^2 \tau^2} \right)^{1/2} = -10 \log(1 + \omega^2 \tau^2)$$

and the phase angle is given by  $\angle G(j\omega) = -\tan^{-1} \omega\tau$ . When  $\omega^2 \tau^2$  is small compared with unity, the gain will be approximately  $0$  dB, and when  $\omega^2 \tau^2$  is large compared with unity, the gain will be  $-20 \log \omega\tau$ . With logarithmic plotting this specifies a straight line having a slope of  $-20$  dB/decade of frequency ( $6$  dB/octave) intersecting the  $0$  dB line at  $\omega = 1/\tau$ . The actual gain at  $\omega = 1/\tau$  is  $-3$  dB and so the plot has the form shown in plot 1 of Figure 13.22. The frequency at which  $\omega = 1/\tau$  is called the *corner* or *break frequency*. The two straight lines, i.e. those with  $0$  dB and  $-20$  dB/decade, are called the 'asymptotic approximations' to the Bode plot. These approximations are often good enough for not too demanding design purposes.

The phase plot will lag a few degrees at low frequencies and fall to  $-90^\circ$  at high frequency, passing through  $-45^\circ$  at the break frequency.

- (e) *First-order lead term,  $1 + \omega\tau$*  The lead term properties may be argued in a similar way to the above, but the gain, instead of falling, rises at high frequencies at  $20$  dB/decade and the phase, instead of lagging, leads by nearly  $90^\circ$  at high frequencies.
- (f) *Quadratic-lag term,  $1/(1 + 2\tau\zeta s + \tau^2 s^2)$*  The gain for the quadratic lag is given by

$$-10 \log \left[ 1 - \left( \frac{\omega}{\omega_n} \right)^2 + \left( \frac{\omega}{\omega_n} \right)^2 \right] \left( \frac{\omega}{\omega_n} \right)^2$$

and the phase angle by

$$\angle G(j\omega) = -\arctan \left[ \frac{2\zeta(\omega/\omega_n)}{1 - (\omega/\omega_n)^2} \right]$$

where  $\tau = 1/\omega_n$ . At low frequencies the gain is approximately  $0$  dB and at high frequencies falls at  $-40$  dB/decade. At the break frequency  $\omega = 1/\tau$  the actual gain is  $20 \log(1/2\zeta)$ . For low damping (say  $\zeta < 0.5$ ) an asymptotic plot can be in considerable error around the break frequency and more careful evaluation may be required around this frequency. The phase goes from minus a few degrees at low frequencies towards  $-180^\circ$  at high frequencies, being  $-90^\circ$  at  $\omega = 1/\tau$ .

- (g) *Quadratic lead term,  $1 + 2\tau\zeta s + \tau^2 s^2$*  This is argued in a similar way to the lag term with the gain curves inscribed and the phase going from plus a few degrees to  $180^\circ$  in this case.

*Example* Plot the Bode diagram of the open-loop frequency-response function

$$G(j\omega) = \frac{10(1+j\omega)}{j\omega(j\omega+2)(j\omega+3)}$$

and determine the gain and phase margins (see Figure 13.23). Note: Figure 13.22 shows a large number of examples and also illustrates the gain and phase margins.

### 13.10.3 Nichols chart

This is a graph with the open-loop gain in decibels as co-ordinate and the phase as abscissa. The open-loop frequency response is for a particular system and is plotted with frequency  $\omega$  as parameter. Now the closed-loop frequency response is given by

$$W(j\omega) = \frac{G(j\omega)}{1 + G(j\omega)}$$

and corresponding lines of constant magnitude and constant phase of  $W(j\omega)$  are plotted on the Nichols chart as shown in Figure 13.24.

When the open-loop frequency response of a system has been plotted on such a chart, the closed-loop frequency response may be immediately deduced from the contours of  $W(j\omega)$ .

## 13.11 State-space description

Usually in engineering, when analysing time-varying physical systems, the resulting mathematical models are in differential equation form. Indeed, the introduction of the Laplace transformation, and similar techniques, leading to the whole edifice of transfer-function-type analysis and design methods are, essentially, techniques for solving, or manipulating to

**Figure 13.23** (a) Gain and phase curves for individual factors (see Figure 13.18); (b) Composite gain and phase curves. Note that the phase margin is about 60°, and the gain margin is infinite because the phase tends asymptotically to -180°.

advantage, differential equation models. In the state-space description of systems, which is the concern of this section, the models are left in the differential equation form, but rearranged into the form of a set of first-order simultaneous differential equations. There is nothing unique to systems analysis in doing this, since this is precisely the required form that differential equations are placed in if they are to be integrated by means of many common numerical techniques, e.g. the Runge-Kutta methods. Most of the interest in the state-space form of studying control systems stems from the 1950s, and intensive research work in this area has continued since then; however, much of it is of a highly theoretical nature. It is arguable that these methods have yet to fulfill the

hopes and aspirations of the research workers who developed them. The early expectation was that they would quickly supersede classical techniques. This has been very far from true, but they do have a part to play, particularly if there are good mathematical models of the plant available and the real plant is well instrumented.

Consider a system governed by the  $n$ th order linear constant-coefficient differential equation

$$\frac{d^n y}{dt^n} + \dots + a_1 \frac{dy}{dt} + a_0 y = \epsilon u(t)$$

where  $y$  is the dependent variable and  $u(t)$  is a time-variable forcing function.

**Figure 13.24** Nichols chart and plot of the system shown in Figure 13.23. Orthogonal families of curves represent constant  $|W(j\omega)|$  and constant  $\angle W(j\omega)$

Let  $y = x_1$ , then

$$\frac{dy}{dt} = \frac{dx_1}{dt} = \dot{x}_2$$

say, and

$$\frac{d^2y}{dt^2} = \frac{dx_2}{dt} = x_3$$

$$\frac{d^{n-1}y}{dt^{n-1}} = \frac{dx_{n-1}}{dt} = \dot{x}_n$$

From the governing differential equation we can write

$$\frac{d^n y}{dt^n} = \frac{dx_n}{dt} = -a_0 x_1 - a_1 x_2 - \dots - a_{n-1} x_n + k u(t)$$

i.e. the  $n$ th order differential equation has been transformed into  $n$  first-order equations. These can be arranged into matrix form:

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \vdots \\ \dot{x}_{n-1} \\ \dot{x}_n \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & \dots & 0 \\ 0 & 0 & 1 & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 1 & 0 & 0 \\ -a_0 & -a_1 & \dots & -a_{n-1} & 0 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_{n-1} \\ x_n \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ k \end{bmatrix} u(t) \quad (13.3)$$

which may be written in matrix notation as

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{b}u(t)$$

where  $\mathbf{x} = [x_1, \dots, x_n]^T$  and is called the 'state vector',  $\mathbf{b} = [0, 0, \dots, k]^T$  and  $\mathbf{A}$  is the  $n \times n$  matrix pre-multiplying  $\mathbf{x}$  on the right-hand side of Equation (13.3).

It can be shown that the eigenvalues of  $\mathbf{A}$  are equal to the characteristic roots of the governing differential equation which are also equal to the poles of the transfer function  $Y(s)/U(s)$ . Thus the time behaviour of the matrix model is essentially governed by the position of the eigenvalues of the  $\mathbf{A}$  matrix (in the complex plane) in precisely the same manner as the poles govern the transfer function behaviour. Hence, if these eigenvalues do not lie in acceptable positions in this plane, the design process is to somehow modify the  $\mathbf{A}$  matrix so that the corresponding eigenvalues do have acceptable positions (cf. the placement of closed-loop poles in the  $s$  plane).

**Example** Consider a system governed by the general second-order linear differential equation

$$\frac{d^2y}{dt^2} + 2\zeta\omega_n \frac{dy}{dt} + \omega_n^2 y = u$$

Let  $y = x_1$ , then

$$\frac{dy}{dt} = \frac{dx_1}{dt} = x_2$$

and so

$$\frac{dx_2}{dt} = -\omega_n^2 x_1 - 2\zeta\omega_n x_2 + \omega_n^2 u$$

or

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\omega_n^2 & -2\zeta\omega_n \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ \omega_n^2 \end{bmatrix} u \quad (13.4)$$

The eigenvalues of the  $\mathbf{A}$  matrix are given by the solution to the equation  $\lambda^2 + 2\zeta\omega_n\lambda + \omega_n^2 = 0$ , i.e.

$$\lambda_{1,2} = -\zeta\omega_n \pm \omega_n\sqrt{\zeta^2 - 1}$$

Now let  $u = r - k_1 x_1 - k_2 x_2$  where  $r$  is an arbitrary, or reference, value or input, and  $k_1$  and  $k_2$  are constants. Note this is a feedback arrangement, since  $u$  has become a linear function of the state variables which, in a dynamic system, might be position and velocity. Substituting for  $u$  in equation (13.3), gives

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\omega_n^2(1+k_1) & -\omega_n(2\zeta + \omega_n k_2) \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ \omega_n^2 \end{bmatrix} r$$

The eigenvalues of the  $\mathbf{A}$  matrix are given by the roots of  $\lambda^2 + (2\zeta\omega_n + \omega_n^2 k_2)\lambda + \omega_n^2(1+k_1) = 0$  and, by choosing suitable values for  $k_1$  and  $k_2$  (the feedback factors), the eigenvalues can be made to lie in acceptable positions in the complex plane. Note that, in this case,  $k_1$  alters the effective undamped natural frequency, and  $k_2$  alters the effective damping of the second-order system.

If the governing differential equation has derivatives on the right-hand side, then the derivation of the first-order set involves a complication. Overcoming this is easily illustrated by an example. Suppose that

$$\frac{d^2 y}{dt^2} + a_1 \frac{dy}{dt} + a_2 y = b_0 u + b_1 \frac{du}{dt}$$

Let  $y = x_1$ , and

$$\frac{dy}{dt} = \frac{dx_1}{dt} = x_2 + b_1 u$$

then

$$\begin{aligned} \frac{d^2 y}{dt^2} &= \frac{dx_2}{dt} + b_1 \frac{du}{dt} = -a_1(x_2 + b_1 u) - a_0 x_1 + b_0 u + b_1 \frac{du}{dt} \\ \begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} &= \begin{bmatrix} 0 & 1 \\ -a_0 & -a_1 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} b_1 \\ b_0 - a_1 b_1 \end{bmatrix} u \end{aligned}$$

Note that care may be necessary in interpreting the  $x$  derivatives in a physical sense.

The state-space description is also a convenient way of dealing with multi-input/multi-output systems. A simple example is shown in *Figure 13.25*, where  $U_1(s)$  and  $U_2(s)$  are the inputs and  $Y_1(s)$  and  $Y_2(s)$  are the corresponding outputs, and so

$$Y_1(s) = \frac{k_1}{s+a_1} U_1(s) + \frac{k_3}{s+a_3} U_2(s)$$

and

$$Y_2(s) = \frac{k_2}{s+a_1} U_1(s) + \frac{k_4}{s+a_4} U_2(s)$$

The first of these two equations may be written as

$$[s^2 + s(a_1 + a_2) + a_1 a_3] Y_1(s) = k_1 U_1(s) + k_3 U_2(s)$$

or

$$\frac{d^2 y_1}{dt^2} + (a_1 + a_2) \frac{dy_1}{dt} + a_1 a_3 y_1 = k_1 u_1 + k_2 u_2$$

let  $y_1 = x_1$ , then

$$\frac{dy_1}{dt} = \frac{dx_1}{dt} = x_2$$

**Figure 13.25** Block diagram of a two-input/two-output multi-variable system

and

$$\frac{d^2 y_1}{dt^2} = \frac{dx_2}{dt} = -(a_1 + a_2)x_2 - a_3 x_1 + u_1 + u_2$$

Similarly, for the second of the two equations, writing

$$y_2 = x_3 \text{ and } \frac{dy_2}{dt} = \frac{dx_3}{dt} = a_4 x_3 + u_1 + u_2$$

leads to

$$\frac{d^2 y_2}{dt^2} = \frac{dx_4}{dt} = -(a_2 + a_4)x_4 - a_4 x_3 + u_1 + u_2$$

Whence the entire set may be written as

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \\ \dot{x}_4 \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ a_1 a_3 & -(a_1 + a_3) & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -a_2 a_4 & -(a_2 + a_4) \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} + \begin{bmatrix} 0 \\ k_3 \\ 0 \\ k_4 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$$

The problem is now how to specify  $u_1$  and  $u_2$  (e.g. a linear combination of state variables similar to the simple second-order system above), so as to make the plant behave in an acceptable manner. It must be pointed out that the theory of linear matrix-differential equations is an extremely well developed mathematical topic and has been extensively plundered in the development of state-space methods. Thus a vast literature exists, and this is not confined to linear systems. Such work has, among other things, discovered a number of fundamental properties of systems (for example, controllability and observability); these are well beyond the scope of the present treatment. The treatment given here is a very short introduction to the fundamental ideas of the state-space description.

### 13.12 Sampled-data systems

Sampled-data systems are ones in which signals within the control-loop are sampled at one or more places. Some sort of sampling action may be inherent in the very mode of operation of some of the very components comprising the plant, e.g. thyristor systems, pulsed-radar systems and reciprocating internal combustion engines. Moreover, sampling is inevitable if a digital computer is used to implement the control laws, and/or used in condition monitoring

operations. Nowadays, digital computers are routinely used in control-system operation for reasons of cheapness and versatility, e.g. they may be used not only to implement the control laws, which can be changed by software alterations alone, but also for sequencing control and interlocking in, say, the start up and safe operation of complex plant. Whatever the cause, sampling complicates the mathematical analysis and design of systems.

Normally most of the components, comprising the system to be controlled, will act in a continuous (analogue) manner, and hence their associated signals will be continuous. With the introduction of a digital computer it is necessary to digitise the signal, by an analogue-to-digital converter before the signal enters the computer. The computer processes this digital sequence, and then outputs another digital sequence which, in turn, passes to a digital-to-analogue converter. This process is shown schematically in Figure 13.26.

In this diagram the sampling process is represented by the periodic switch (period  $T$ ), which at each sampling instant is closed for what is regarded as an infinitesimal time. The digital-to-analogue process is represented by the hold block. Thus the complete system is a hybrid one, made up of an interconnection of continuous and discrete devices. The most obvious way of representing the system mathematically is by a mixed difference-differential equation set. However, this makes a detailed analysis of the complete system difficult.

Fortunately, provided the investigator or system designer is prepared to accept knowledge of the system's behaviour at the instants of sampling only, a comparatively simple approach having great similarity to that employed for wholly continuous systems is available. At least for early stages of the analysis or design proposal, the added complications involved in this process are fairly minor. Further, the seemingly severe restriction of knowing the system's behaviour at the instants of sampling only is normally quite acceptable; for example, the time constants associated with the plant will generally be much longer than the periodic sampling time, so the plant effectively does not change its state significantly in the periodic time. The sampling time period is a parameter which often can be chosen by the designer, who will want sampling to be fast enough to avoid aliasing problems; however, the shorter the sampling period the less time the computer has available for other loops. Suffice it to say that the selection of the sampling period is normally an important matter.

If we take a continuous signal  $y(t)$ , say, and by the periodic sampling process convert it into a sequence of values  $y(n)$ , where  $n$  represents the  $n$ th sampling period, then the sequence  $y(n)$  becomes the mathematical entity we manipulate, and the values of  $y(t)$  between these samples will not be known. However, if at an early stage it is essential to know the inter-sample behaviour of the system with some accuracy, then advance techniques are available for this purpose.<sup>1</sup> In addition, it is now fairly routine to simulate control system behaviour before implementation, and a

Figure 13.26 General arrangement of a sampled-data system

good simulation package should be capable of illustrating the inter-sample behaviour.

We need techniques for mathematically manipulating sequences, and these are discussed in the following section.

### 13.13 Some necessary mathematical preliminaries

#### 13.13.1 The $z$ transformation

This transformation plays the equivalent role in sampled-data system studies as the Laplace transformation does in the case of continuous systems; indeed, these two transformations are mathematically related to each other. It is demonstrated below that the behaviour of sampled-data systems at the sampling instant is governed mathematically by difference equations, e.g. a linear system might be governed by the equation

$$y(n) + a_1 y(n-1) + a_2 y(n-2) = b_1 x(n) + b_2 x(n-1)$$

where, in the case of  $y(n)$ , the value of a variable at instant  $n$  is in fact dependent on a linear combination of its previous two values and the current and previous values of an independent (forcing variable)  $x(n)$ . In a similar way to using the Laplace transformation to convert linear differential equations to transfer-function form, the  $z$  transformation is used to convert linear difference equations into the so-called 'pulse transfer-function form'. The definition of the  $z$  transformation of a sequence  $y(n)$ ,  $n = 0, 1, 2, \dots$ , is

$$Z[y(n)] = Y(z) = \sum_{n=0}^{\infty} y(n)z^{-n}$$

The  $z$  transformations of commonly occurring sequences are listed in Table 13.1, and a simple example will illustrate how such transformations may be found.

Suppose  $y(n) = nT$  ( $n = 0, 1, 2, \dots$ ) such a sequence would be obtained by sampling the continuous ramp function  $y(t) = t$ , at intervals of time  $T$ . Then, by definition,

$$\begin{aligned} Z[y(n)] &= Y(z) = 0 + Tz^{-1} + 2Tz^{-2} + \dots \Leftarrow \\ &= T(z^{-1} + 2z^{-2} + \dots) \Leftarrow \\ &= \frac{Tz}{(z-1)^2} \end{aligned}$$

It can also be shown that

$$Z[y(n-1)] = z^{-1}Z[y(n)] = z^{-1}Y(z) \Leftarrow$$

and

$$Z[y(n-2)] = z^{-2}Z[y(n)] = z^{-2}Y(z) \Leftarrow$$

Then, applying this to the difference equation above, we have

$$Y(z) = -(a_1 z^{-1} + a_2 z^{-2})Y(z) + (b_0 + b_1 z^{-1})X(z) \Leftarrow$$

or

$$Y(z) = \frac{(b_0 + b_1 z^{-1})X(z)}{(1 + a_1 z^{-1} + a_2 z^{-2})} \Leftarrow$$

So that, if  $x(n)$  or  $X(z)$  is given,  $Y(z)$  can be rearranged into partial fraction form, and  $y(n)$  determined from the table. For example, suppose that

$$Y(z) = \frac{z(z-0.25)}{(z-1)(z-0.5)} \Leftarrow$$

then

$$\frac{Y(z)}{z} = \frac{1.5}{z-1} - \frac{0.5}{z-0.5}$$

or

$$Y(z) = \frac{1.5z}{z-1} - \frac{0.5z}{z-0.5}$$

Whence, from the tables we see that

$$y(n) = 1.5 - 0.5 \exp(-0.60n) \Leftarrow$$

The process of dividing  $Y(z)$  by  $z$  before taking partial fractions is important, as most tabulated values of the transformation have  $z$  as a factor in the numerator, and the partial function expansion process needs the order of the denominator to exceed that of the numerator.

An alternative method of approaching the  $z$  transform is to assume that the sequence to be transformed is a direct consequence of sampling a continuous signal using an impulse modulator. Thus a given signal  $y(t)$  is sampled with periodic time  $T$ , to give the assumed signal  $y^*(t)$ , where

$$y^*(t) = y(0)\delta(t) + y(T)\delta(t-T) + y(2T)\delta(t-2T) + \dots \Leftarrow$$

where  $\delta(t)$  is the delta function.

Taking the Laplace transformation of  $y^*(t)$  gives the series

$$\mathcal{L}[y^*(t)] = y(0) + y(T)e^{-sT} + y(2T)e^{-2sT} + \dots \Leftarrow$$

On making the substitution  $e^{sT} = z$ , then the resulting series is identical to that obtained by taking the  $z$  transformation of the sequence  $y(n)$ . For convenience, we often write  $Y(z) = Z[y^*(t)]$ .

$z = e^{sT}$  may be regarded as constituting a transformation of points in an  $s$  plane to those in a  $z$  plane, and this has exceedingly important consequences. If, for example, we map lines representing constant damping  $\zeta$ , and constant natural frequency  $\omega_n$ , for a system represented in an  $s$  plane onto a  $z$  plane, we obtain Figure 13.27.

There are important results to be noted from this diagram.

- (1) The stability boundary in the  $s$  plane (i.e. the imaginary axis) transforms into the unit circle  $|z| = 1$  in the  $z$  plane.
- (2) Points in the  $z$  plane indicate responses relative to the periodic sampling time  $T$ .
- (3) The negative real axis of the  $z$  plane always represents half the sampling frequency  $\omega_s$ , where  $\omega_s = 2\pi/T$ .
- (4) Vertical lines (i.e. those with constant real parts) in the left-half plane of the  $s$  plane map into circles *within* the unit circle in the  $z$  plane.
- (5) Horizontal lines (i.e. lines of constant frequency) in the  $s$  plane map into radial lines in the  $z$  planes.
- (6) The mapping is not one-to-one; and frequencies greater than  $\omega_s/2$  will coincide on the  $z$  plane with corresponding points below this frequency. Effectively this is a consequence of the Nyquist sampling theorem which states, essentially, that faithful reconstruction of a sampled signal cannot be achieved if the original continuous signal contained frequencies greater than one-half the sampling frequency.

A vitally important point to note is that *all the roots* of the denominator of a pulse transfer function of a system must fall *within* the unit circle, on the  $z$  plane, if the system is to be stable; this follows from (1) above.

#### 13.14 Sampler and zero-order hold

The sampler produces a series of discrete values at the sampling instant. Although in theory these samples exist for

**Figure 13.27** Natural frequency and damping loci in the  $z$  plane. The lower half is the mirror image of the half shown. (Reproduced from Franklin *et al.*,<sup>2</sup> courtesy of Addison-Wesley)

zero time, in practice they can be taken into the digital computer and processed. The output from the digital computer will be a sequence of samples with, again in theory, each sample existing for zero time. However, it is necessary to have a continuous signal constructed from this output, and this is normally done using a *zero-order hold*. This device has the property that, as each sample (which may be regarded as a delta function) is presented to its input, it presents the strength of the delta function at its output until the next sample arrives, and then changes its output to correspond to this latest value, and so on.

This is illustrated diagrammatically in *Figure 13.28*. Thus a unit delta function  $\delta(t)$  arriving produces a positive unit-value step at the output at time  $t$ . At time  $t = T$ , we may regard a negative unity-value step being superimposed on the output. Since the transfer function of a system may be

regarded as the Laplace transformation of the response of that system to a delta function, the zero-order hold has the transfer function

$$\frac{1}{s} [1 - e^{-sT}]$$

### 13.15 Block diagrams

In a similar way to their use in continuous-control-system studies, block diagrams are used in sampled-data-system studies. It is convenient to represent individual pulse transfer functions in individual boxes. The boxes are joined together by lines representing their  $z$  transformed input/output sequences to form the complete block diagrams. The manipulation of

**Figure 13.28** Diagrammatic representation of input/output for zero-order hold

**Figure 13.29** Cascade transfer functions with sampling between connections

the block diagrams may be conducted in a similar fashion to that adopted for continuous systems. Again, it must be stressed that such manipulation breaks down if the boxes load one another.

Consider the arrangement shown in *Figure 13.29*. Here we have a number of continuous systems, represented by their transfer functions, in cascade. However, a sampler has been placed in each signal line, and so for each box we may write

$$C_1(s) = G_1(s)R^*(s) \rightarrow C_1^*(s) = G_1^*(s)R^*(s) \Leftarrow$$

$$C_2(s) = G_2(s)C_1^*(s) \rightarrow C_2^*(s) = G_2^*(s)C_1^*(s) \Leftarrow$$

$$C(s) = G_3(s)C_2^*(s) \rightarrow C^*(s) = G_3^*(s)C_2^*(s) \Leftarrow$$

Thus

$$C^*(s) = G_1^*(s)G_2^*(s)G_3^*(s)R^*(s) \Leftarrow$$

i.e.

$$\frac{C(z)}{R(z)} \Leftarrow G_1(z)G_2(z)G_3(z) \Leftarrow$$

This, of course, generalises for  $n$  similar pulse transfer functions in series to give

$$\frac{C(z)}{R(z)} \Leftarrow \prod_{i=1}^n G_i(z) \Leftarrow$$

It is necessary to realise that this result does not apply if there is no sampler between two or more boxes. As an illustration, *Figure 13.30(a)* shows the arrangement for which the above result applies. We have

$$G_1(s) = \frac{1}{s}$$

whence (see *Table 13.1*)

$$G_1(z) = \frac{z}{z-1}$$

and

$$G_2(s) = \frac{1}{s+1}$$

whence (see *Table 13.1*)

$$G_2(z) = \frac{z}{z-e^{-T}}$$

Therefore,

$$\frac{C(z)}{R(z)} \Leftarrow G_1(z)G_2(z) = \frac{z^2}{(z-1)(z-e^{-T})} \Leftarrow$$

*Figure 13.30(b)* shows the arrangement *without* a sampler between  $G_1(s)$  and  $G_2(s)$ , and so

$$\frac{C(z)}{R(z)} \Leftarrow Z \left[ \frac{1}{s(s+1)} \right] \left( = \frac{z(1-e^{-T})}{(z-1)(z-e^{-T})} \right)$$

Note that  $Z[G_1(s)G_2(s)]$  is often written  $G_1G_2(z)$ , and thus, in general,  $G_1(z)G_2(z) \neq G_1G_2(z)$ .

### 13.16 Closed-loop systems

*Figure 13.31* shows the sampler in the error channel of an otherwise continuous system. We may write

$$C(s) = G(s)E^*(s) \Leftarrow$$

and

$$E(s) = R(s) - H(s)C(s) \Leftarrow$$

or

$$E(s) = R(s) - H(s)G(s)E^*(s) \Leftarrow$$

and

$$E^*(s) = R^*(s) - HG^*(s)E^*(s) \Leftarrow$$

and so

$$E^*(s) = \frac{R^*(s)}{1 + HG^*(s)} \Leftarrow$$

Thus

$$\frac{C^*(s)}{R^*(s)} \Leftarrow \frac{G^*(s)}{1 + HG^*(s)} \Leftarrow$$

or

$$\frac{C(z)}{R(z)} \Leftarrow \frac{G(z)}{1 + HG(z)} \Leftarrow$$

(a)

(b)

**Figure 13.30** Two transfer functions with (a) sampler interconnection and (b) with continuous signal connecting transfer functions

**Figure 13.31** Prototype sampled system with a sampler in the error channel

**Figure 13.32** Prototype sampled system with a sampler in the feedback channel

If the sampler is in the feedback loop, as shown in *Figure 13.32*, a similar analysis would show that

$$C(z) = \frac{GR(z)}{1 + HG(z)}$$

Note that, in this case, it is not possible to take the ratio  $C(z)/R(z)$ . We may conclude that the position of the sampler(s) within the loop has a vitally important effect on the behaviour of the system.

**Example** Consider the arrangement shown in *Figure 13.33*. To calculate the pulse transfer function it is necessary to determine

$$L\left[\frac{1}{s} \cdot \frac{1}{s} (1 - e^{-sT})\right] \quad \left(\text{Consider (from Table 13.1)}$$

$$Z\left[\frac{1}{s^2}\right] = \frac{Tz}{(z-1)^2}$$

and, therefore,

$$Z\left[e^{-sT} \frac{1}{s^2}\right] = z^{-1} Z\left[\frac{1}{s^2}\right] = \frac{T}{(z-1)^2}$$

**Figure 13.33** Arrangement used in the example in Section 13.16

Thus

$$Z\left[\frac{1}{s^2} (1 - e^{-Ts})\right] = \frac{T}{(z-1)} = G(z)$$

and

$$\frac{C(z)}{R(z)} = \frac{G(z)}{1 + G(z)} = \frac{T}{z + (T-1)}$$

## 13.17 Stability

It should be appreciated from the above that, in general,  $C(z)/R(z)$  results in a ratio of polynomials in  $z$  in a similar way as, for continuous systems,  $C(s)/R(s)$  results in a ratio of polynomials in  $s$ . Thus, just as the equation  $1 + G(s)H(s) = 0$  is called the 'characteristic equation' for the continuous system,  $1 + GH(z) = 0$  is the characteristic equation for the sampled-data system. Both of these characteristic equations are polynomials in their respective variables, and the positions of the roots of these equations determine the characteristic behaviour of the corresponding closed-loop systems. Mathematically, the process of determining the roots is identical in the two cases. The difference between the two characteristic equations arises because of the need to interpret the effects of the location of the roots, when they are plotted in their respective  $s$  and  $z$  planes, on the two plants. For continuous systems, if any of these poles are located in the right-half  $s$  plane, then the system is unstable. Similarly, since the whole of the left-hand  $s$  plane maps into the unit-circle of the  $z$  plane under the transformation  $z = e^{sT}$ , then in the sample-data case, for stability *all* of the roots of  $1 + GH(z) = 0$  must lie within the unit circle.

Much of the design process of control systems is to arrange for the roots of the characteristic equation to locate at desired positions in either the  $s$  or  $z$  plane. It will be recalled, from continuous theory, that the locus of these roots, as a particular parameter is varied, may be determined by using the root-locus technique. Thus, since the characteristic equation of the sample-data system has a similar form (i.e. a polynomial), the root-locus technique may be applied to  $1 + GH(z) = 0$  in exactly the same way. Only once the root-locus has been determined is there a difference in interpreting the effects of pole positions between the two cases.

## 13.18 Example

Consider the system shown in *Figure 13.34*, and suppose that the requirement is to draw the root-locus diagrams for, say, sampling periods of 1 and 0.5 secs.

The first requirement is to determine the pulse-transfer function for the open loop, i.e.  $G(z)$ :

Figure 13.34 Arrangement used in the example in Section 13.18

$$G(z) = Z \left[ \frac{K(1 - e^{-Ts})}{s^2(s+1)} \right] = K(1 - z^{-1}) Z \left[ \frac{1}{s^2(s+1)} \right]$$

Consider

$$Z \left[ \frac{1}{s^2(s+1)} \right] = Z \left[ \frac{1}{2} - \frac{1}{s} + \frac{1}{s+1} \right]$$

where, from Table 13.2, we have

$$Z \left[ \frac{1}{s^2(s+1)} \right] = \frac{Tz}{(z-1)^2} - \frac{z}{z-1} + \frac{z}{z-e^{-T}} = z \left[ \frac{z(T + e^{-T} - 1) + 1 - e^{-T}(1+T)}{(z-1)^2(z-e^{-T})} \right]$$

and so

$$G(z) = \frac{K[z(T + e^{-T} - 1) + 1 - e^{-T}(1+T)]}{(z-1)(z-e^{-T})}$$

Thus, when  $T = 1$  sec,

$$G_1(z) = \frac{0.368K(z + 0.718)}{(z-1)(z-0.368)}$$

and when  $T = 0.5$  sec

$$G_2(z) = \frac{0.107K(z + 0.841)}{(z-1)(z-0.606)}$$

Both of these equations have two real poles and one zero pole, and the root loci are as shown in Figures 13.35 and 13.36. It can be seen that the difference in the two sampling times  $T$  causes fairly dramatic changes; when  $T = 1$  sec the system becomes unstable at  $K = 1.9$ , and when  $T = 0.5$  sec the system becomes unstable at  $K = 3.9$ . The process of drawing the root locus for either a continuous plant or a sampled-data plant is identical. It is the interpretation of the positions of the roots that is different, although in both cases the design is to place the roots in acceptable locations in the two planes. It is possible to use Bode diagrams in sampled-data design work and this is explained in many of the references given in the Bibliography at the end of this chapter.

Figure 13.35 Root locus plot:  $G(z) = [0.368K(z + 0.718)] / [(z-1)(z-0.368)]$

Figure 13.36 Root-locus plot:  $G(z) = [0.107K(z + 0.841)]/[(z - 1)(z - 0.606)]$

### 13.19 Dead-beat response

Consider the system shown above where  $T=1$  secs and  $K=1$ ; suppose that compensation of the form

$$D(z) = \frac{1.582(z - 0.368)}{(z + 0.418)}$$

is inserted immediately after the sampler. Then it is easy to show that

$$\frac{C(z)}{R(z)} = \frac{0.582(z + 0.71)}{z^2}$$

If

$$R(z) = \frac{z}{z - 1}$$

i.e.  $r(t)$  is a unit step function, then

$$\begin{aligned} C(z) &= \frac{0.582(z + 0.718)}{z(z - 1)} \\ &= \frac{1}{z} \left[ \frac{0.582z + 0.418}{z - 1} \right] \left( \right. \\ &= \frac{1}{z} \left[ 0.582 + \frac{1}{z} + \frac{1}{z^2} + \dots \right] \left( \right. \end{aligned}$$

i.e.  $c(0)=0$ ,  $c(1)=0.582$  and  $c(n)=1$ , for  $n=2, 3, \dots$

The implication is that  $c(t)$  has reached its target position after two sample periods. If an  $n$ th order system reaches its target position in, at most,  $n$ th sampling instants, then this

is called a 'dead-beat response'; a controller that achieves this, such as  $D(z)$  above, is called a 'dead-beat controller' for this system. This is an interesting response, for it is not possible to achieve this with a continuous control system.

At least two dangers are inherent in dead-beat controllers:

- (1) the demanded controller outputs during the process may be excessive; and
- (2) there may be an oscillation set up which is not detected without further analysis.

In fact, the system is only 'dead beat' at the sampling instants. Indeed, in the above example, there is an oscillation between sampling instants of about 10% of the step value. However, theoretically it is possible for a sampled-data system to complete a transient of the above nature in finite time.

### 13.20 Simulation

#### 13.20.1 System models

Regardless of the simulation language to be used, a necessary prerequisite is a description of the system of interest by a mathematical model. Some physical systems can be described in terms of models that are of the state transition type. If such a model exists, then given a value of the system variable of interest, e.g. voltage, charge position, displacement, etc., at time  $t$ , then the value of the variable (state) at some future time  $t + \Delta t$  can be predicted. The prediction of the variable of interest (state variable)  $x(t)$  at time  $t + \Delta t$ , given a state transition model  $S$ , can be expressed by the state equation:

$$x(t + \Delta t) = S[x(t), t, \Delta t] \quad (13.5)$$

Equation (13.5) shows that the future state is a function of the current state  $x(t)$  at the current time  $t$  and the time increment  $\Delta t$ . Thus, once the model is known, from either empirical or theoretical considerations, Equation (13.5), given an initial condition (value), allows for the recursive computation of  $x(t)$  for any number of future steps in time. For an initial value of the state variable  $\bar{x} = x(t_1)$  at time  $t_1$ , then

$$x(t_1 + \Delta t) = S[\bar{x}, t_1, \Delta t] \Leftarrow$$

then letting  $t_2 = t_1 + \Delta t$ , Equation (13.5) for the next time step  $\Delta t$ , becomes

$$x(t_2 + \Delta t) = S[x(t_2), t_2, \Delta t] \Leftarrow$$

Obviously, this operation is continued until the calculation of the state variable has been performed for the total time period of interest.

Systems of interest will clearly not be characterised only by a single state variable but by several state variables. Figure 13.37 is a schematic representation of a multi-variable system that has  $r$  inputs,  $n$  states and  $m$  outputs.

In general, the simulation will involve calculation of all of the state variables, even though the response of only a selected number of output variables is of interest. For many systems, the output variables may well exhibit a simple one-to-one correspondence to the state variables. As shown by the representation in Figure 13.37, the values of the state variables depend on the inputs to the system. For a single interval, between the  $k$  and  $k+1$  time instants, the state equations for the  $n$  state variable system for a change in the  $j$ th input ( $j \leq r$ )  $u_j(t)$  is written as

$$\begin{aligned} x_1(t_k + \Delta t) &= S_1[x_1(t_k), u_j(t_k), t_k, \Delta t] \Leftarrow \\ x_2(t_k + \Delta t) &= S_2[x_2(t_k), u_j(t_k), t_k, \Delta t] \Leftarrow \\ &\vdots \\ x_n(t_k + \Delta t) &= S_n[x_n(t_k), u_j(t_k), t_k, \Delta t] \Leftarrow \end{aligned} \quad (13.6)$$

The above system of equations, a collection of difference equations, would be used to predict the state variables  $x_1, x_2, \dots, x_n$  at time intervals of  $\Delta t$  from the initial time  $t_0$  until the total time duration of interest  $T = t_0 + K \Delta t$ . For engineering systems, the dependent variable will generally be a continuous variable. In this case the system description will be in terms of a differential equation of the form

$$dx/dt = g(x, t) \quad (13.7) \Leftarrow$$

Recalling basic calculus for a small time increment, the left-hand side of Equation (13.7) can be expressed as

Figure 13.37 Schematic representation of a multi-variable system

$$\lim_{\Delta t \rightarrow 0} \frac{x(t + \Delta t) - x(t)}{\Delta t} \Leftarrow$$

so, for a small time increment  $\Delta t$ , Equation (13.7) can be written as

$$\begin{aligned} x(t + \Delta t) &= x(t) + [g(x, t)]\Delta t \\ \text{or} \\ x(t + \Delta t) &= G[x(t), t, \Delta t] \Leftarrow \end{aligned} \quad (13.8)$$

Equation (13.8) is a form of Equation (13.5), so for a small time increment, a first-order ordinary differential equation can be approximated by a state transition representation.

It thus follows from the preceding discussion that, in digital continuous system simulation, the principal numerical task is the approximate integration of Equation (13.7). For a small time increment  $DT$ , the integration step size, the computation involves the evaluation of the difference equation

$$x(t + DT) = x(t) + [g(x(t))]DT \quad (13.9a) \Leftarrow$$

which can be written explicitly as

$$x(t_{k+1}) = x(t_k) + \int_{t_k}^{t_{k+1}} g[x(t_k), t_k]DT \quad (13.9b) \Leftarrow$$

where  $DT = t_{k+1} - t_k$ . The calculation starts with a known value of the initial state  $x(0)$  at time  $t_0$  and proceeds successively to evaluate  $x(t_1)$ ,  $x(t_2)$ , etc. The computation involves successive computation of  $x(t_{k+1})$  by alternating calculation of the derivative  $g[x(t_k), t_k]$  followed by integration to compute  $x(t_{k+1})$  at time  $t_{k+1} = t_k + DT$ .

Obviously, most physical systems will be described by second or higher order ordinary differential equations so the higher order equation must be re-expressed in terms of a group of first-order ordinary differential equations by introducing state variables. For an  $n$ th order equation,

$$\frac{d^n z}{dt^n} = f\left[z, \frac{dz}{dt}, \frac{d^2 z}{dt^2}, \dots, \frac{d^{n-1} z}{dt^{n-1}}; t\right] \quad (13.10) \Leftarrow$$

the approach involves the introduction of new variables as state variables to yield the following first-order differential equations

$$\begin{aligned} \frac{dx_1}{dt} &= x_2 \\ \frac{dx_2}{dt} &= x_3 \\ \frac{dx_3}{dt} &= x_4 \\ &\vdots \\ \frac{dx_{n-1}}{dt} &= x_n \\ \frac{dx_n}{dt} &= f(x_1, x_2, x_3, \dots, x_n; t) \Leftarrow \end{aligned} \quad (13.11)$$

$$\frac{dx_n}{dt} = f(x_1, x_2, x_3, \dots, x_n; t) \Leftarrow$$

It should be noted that this equation can be expressed in shorthand notation as a vector-matrix differential equation. In an analogous manner, Equation (13.6) can be expressed as a vector differential equation. There is no unique approach to the selection of state variables for system representation, but for many systems the choice of state variables will be obvious. In electric circuit problems, capacitor voltages and inductor currents would be logical choices, as would position, velocity and acceleration for mechanical systems.

### 13.20.2 Integration schemes

The simple integration step, embodied by the first-order Euler form in Equation (13.9a) only provides a satisfactory approximation of the solution of the differential equation, within specified error limits, for a very small integration step size  $DT$ . Since the small integration interval leads to substantial computing effort and to round-off error accumulation, all digital simulation languages use improved integration schemes. Despite the wide variety of different integration schemes that are available in the many different simulation languages, the calculational approach can be categorised into two groups. The types of algorithm are:

- (1) **Multi-step formulae** In such algorithms, the value of  $x(t+DT)$  is not calculated by the simple linear extrapolation of Equation (13.9a). Rather than use only  $x(t)$  and one derivative value, the algorithms use a polynomial approximation based on past values of  $x(t)$  and  $g[x(t),t]$ , that is at times  $t-DT$ ,  $t-2DT$ , etc.
- (2) **Runge-Kutta formulae** In Runge-Kutta type algorithms, the derivative value used for the calculation of  $x(t+DT)$  is not the point value at time  $t$ . Instead, two or more approximate derivative values in the interval  $t$ ,  $t+DT$  are calculated and then a weighted average of these derivative values is used instead of a single value of the derivative to compute  $x(t+DT)$ .

### 13.20.3 Organisation of problem input

Most simulation language input is structured into three separate sections, although in some programs the statement can be used with limited sectioning of the program. A typical structure and the type of statements, functions or parts of the simulation program that appear are as follows.

- (1) **Initialisation**  
 Problem documentation (e.g. name, date, etc.).  
 Initial conditions for state variables.  
 Parameter values (problem variables that may not be constant, problem time, integration order, integration step size, etc.).  
 Problem constants.
- (2) **Dynamic**  
 Derivative statements.  
 Integration statements (including any control parameters not given in the initialisation section).
- (3) **Terminal**  
 Conditional statements (e.g. total time, variable(s), value(s), etc.).  
 Multiple run parameters.  
 Output (print/plot/display) option(s).  
 Output format (e.g. designation of independent variable; increment for independent variable; dependent variable(s) to be output; maximum and minimum values of variable(s); or automatic scaling; total number of points for the independent variable or total length of time).

It should be understood that the specific form of the statements within each section is not exactly the same for all digital simulation languages. However, from the continuous system modelling package (CSMP) simulation programs presented in the next section, with the aid of the appropriate language manual, there should be no difficulty in formulating a simulation program using any continuous system simulation language (CSSL)-type digital simulation program.

### 13.20.4 Illustrative example

Simulation programs are presented, using the CSMP language, that would be suitable for investigating system dynamic behaviour. The system model, although relatively simple in nature, is typical of those used for system representation.

#### 13.20.4.1 Example

Frequently, it will be found that system dynamic behaviour can be described by a differential equation of the form

$$y^n + a_1 y^{n-1} + a_2 y^{n-2} + \dots + a_{n-1} y^1 + a_n y = b_0 r^m + b_1 r^{m-1} + \dots + b_{m-1} r^1 + b_m r \quad (13.12) \Leftarrow$$

where

$$y^n = \frac{d^n y}{dt^n} \text{ and } r^m = \frac{d^m r}{dt^m}$$

Use of CSMP for studying the dynamic behaviour of a system described by a high-order differential equation is illustrated here using a simulation program for the differential equation

$$y^3 + 2.5y^2 + 3.4y^1 + 0.8y = 7.3r \quad (13.13) \Leftarrow$$

with the initial conditions

$$y^2(0) = 0; y^1(0) = -4.2; y^0 = 2.5$$

Development of the simulation program follows logically by rewriting Equation (13.13) as

$$\frac{d^3 y}{dt^3} = -2.5 \frac{d^2 y}{dt^2} - 3.4 \frac{dy}{dt} - 0.8y + 7.3r \quad (13.14) \Leftarrow$$

$$\left. \frac{d^2 y}{dt^2} \right|_{t=0} = 0; \quad \left. \frac{dy}{dt} \right|_{t=0} = -4.2; \quad y|_{t=0} = 2.5$$

A block diagram showing the successive integrations to be solved for the dependent variable  $y$  is given in Figure 13.38. As can be seen from the labelling on the diagram, the output of the integration blocks is successive derivative values and

**Figure 13.39** Simulation program for studying the dynamic behaviour of a system described by a third-order differential equation

the dependent variable. In fact, the output of each integration block is a state variable. This becomes obvious by introducing new variables,  $x_1, x_2, x_3$  defined as:

$$x_1 = y$$

$$\frac{dx_1}{dt} = x_2$$

$$\frac{dx_2}{dt} = x_3$$

which allows Equation (13.14) to be expressed as

$$\frac{dx_1}{dt} = x_2 \quad (13.15) \Leftarrow$$

$$\frac{dx_2}{dt} = x_3$$

$$\frac{dx_3}{dt} = -2.5x_3 - 3.4x_2 - 0.8x_1 + 7.3r$$

with the initial conditions

$$x_3(0) = 0; \quad x_2(0) = -4.2; \quad x_1(0) = 2.5$$

A program for solving equation (13.15) is given in *Figure 13.39*. Examination of the program shows that the value of the forcing function  $r$  is not constant but varies with time. The variation is provided using the quadratic interpolation function, NLFGEN. Total simulation time is set for 6 min with the interval for tabular output specified as 0.2 min. The time unit is determined by the problem parameters. It is to be noted that the program does not include any specification for the method of integration. The CSMP language does not require that a method of integration be given, but a particular method may be specified. If a method is not given, then by default the variable step size fourth-order Runge-Kutta method is used for calculation. The initial step size, by default, is taken as 1/16 of the PRDEL (or OUTDEL) value. Minimum step size can be limited by

giving a value for DELMIN as part of the TIMER statement. If a DELMIN value is not given then, by default, the minimum step size is  $FINTIM \times 10^{-7}$ .

## 13.21 Multivariable control

Classical process control analysis is concerned with single loops having a single setpoint, single actuator and a single controlled variable. Unfortunately, in practice, plant variables often interact, leading to interaction between control loops. A typical interaction is shown on *Figure 13.40*, where a single combustion air fan feeds several burners in a multi-zone furnace. An increase in air flow, via  $V_1$  say to raise the temperature in zone 1, will lead to a reduction in the duct air pressure  $P_d$ , and a fall in air flow to the other zones. This will lead to a small fall in temperature in the other zones which will cause their temperature controllers to call for increased air flow which affects the duct air pressure again. The temperature control loops interact via the air valves and the duct air pressure.

Where interaction between variables is encountered an attempt should always be made to remove the source of the interaction, as this leads to a simpler, more robust, system. In *Figure 13.40*, for example, the interaction could be reduced significantly by adding a pressure control loop which maintains duct pressure by using a VF to set the speed of the combustion airfan. Often, however, the interaction is inherent and cannot be removed.

*Figure 13.41* is a general representation of two interacting control loops. The blocks  $C_1$  and  $C_2$  represent the controllers comparing setpoint  $R$  with process variable  $V$  to give a controller output  $U$ . The blocks  $K_{ab}$  represent the transfer function relating variable  $a$  to controller output  $b$ . Blocks  $K_{11}$  and  $K_{12}$  are the normal forward control path, with blocks  $K_{21}$  and  $K_{22}$  representing the interaction between the loops.

The process gain of process 1 can be defined as  $\Delta V_1 / \Delta U_2$  where  $\Delta$  denotes small change. This process gain can be measured with loop 2 in open loop (i.e.  $U_2$  fixed) or loop 2 in closed loop control (i.e.  $V_2$  fixed) we can thus observe two gains

$$K_{2OL} = \frac{\Delta V_1}{\Delta U_1} \text{ for loop 2 open loop}$$

and

$$K_{2CL} = \frac{\Delta V_1}{\Delta U_1} \text{ for loop 2 closed loop}$$

The gains will, of course vary with frequency and have magnitude and phase shift components. We can now define a relative gain  $\lambda$  for loop 1

$$\lambda = \frac{K_{2OL}}{K_{2CL}}$$

**Figure 13.40** A typical example of interaction between variables in multi-variable control. The air flows interact via changes in the duct air pressure

**Figure 13.41** General representation of interacting loops

If  $\lambda$  is unity, changing from manual to auto in loop 2 does not affect loop 1, and there is no interaction between the loops.

If  $\lambda < 1$ , the interaction will apparently increase process 1 gain when loop 2 is switched to automatic. If  $\lambda > 1$ , process 1 gain will apparently be decreased when loop 2 is in automatic.

This apparent change in gain can be seen with loop 2 in manual,  $U_2$  is fixed, so  $K_{2OL}$  is simply  $K_{11}$ . To find  $K_{2CL}$  we must consider what happens when loop 2 effectively shunts  $K_{11}$ . We have

$$V_1 = K_{11}U_1 + K_{12}U_2 \quad (13.16) \Leftarrow$$

and

$$V_2 = K_{22}U_2 + K_{21}U_1 \quad (13.17) \Leftarrow$$

Re-arranging Equation 13.17 gives

$$U_2 = \frac{V_2 - K_{21}U_1}{K_{22}}$$

which can be substituted in Equation 13.16 giving

$$V_1 = K_{11}U_1 + \frac{K_{12}}{K_{22}}(V_2 - K_{21}U_1) \Leftarrow$$

The process 1 gain with loop 2 in auto is

$$\begin{aligned} K_{2CL} &= \frac{dV_1}{dU_1} \\ &= \frac{K_{11}K_{22} - K_{12}K_{21}}{K_{22}} \end{aligned}$$

The relative gain,  $\lambda$ , is

$$\begin{aligned} \lambda &= \frac{K_{2OL}}{K_{2CL}} \\ &= \frac{1}{1 - K_{12}K_{21}/K_{11}K_{22}} \end{aligned}$$

It should be remembered that the gains  $K_{ab}$  are dynamic functions, so  $\lambda$  will vary with frequency.

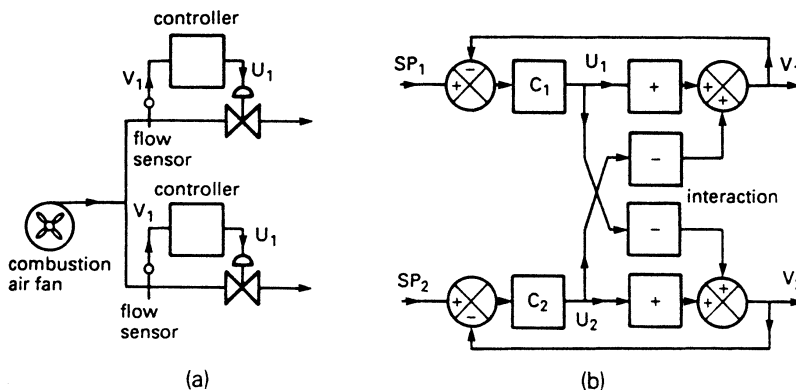

The term  $(K_{12}K_{21}/K_{11}K_{22})$  is the ratio between the interaction and forward gains. This should be in the range 0 to 1. If the term is greater than unity, the interactions have more effect than the supposed process, and the process variables are being manipulated by the wrong actuators!

It is possible to determine the range of  $\lambda$  from the relationship  $(K_{12}K_{21}/K_{11}K_{22})$ . If this is positive,  $\lambda$  will be greater than unity, and loop 1 process gain will decrease when loop 2 is switched to auto. This will occur if there is an even number of  $K_{ab}$  blocks with negative sign (0, 2 or 4). If the relationship is negative,  $\lambda$  will be less than unity and loop 1 process gain will increase when loop 2 is closed. This occurs if there is an odd number of blocks with negative sign (1 or 3).

The combustion air flow system of Figure 13.40 is redrawn on Figure 13.42(a). Increasing  $U_1$  obviously decreases  $V_2$ , and increasing  $U_2$  similarly decreases  $V_1$ . The interaction block diagram thus has the signs of Figure 13.42(b). There are two negative blocks, so  $\lambda_{\zeta}$  is greater than unity.

If  $\lambda_{\zeta}$  is greater than unity, the interaction can be considered benign as the reduced process gain will tend to increase the loop stability (albeit at the expense of response time). The loops can be tuned individually in the knowledge that they will remain stable with all loops in automatic control.

If  $\lambda$  is in the range  $0 < \lambda < 1$ , care must be taken as it is possible for loops to be individually stable but collectively unstable requiring a reduction in controller gains to maintain stability. The closer  $\lambda$  gets to zero, the greater the interaction and the more de-gaining will be required.

**Figure 13.42** The combustion air system redrawn to show interactions: (a) block diagram; (b) interaction diagram, with two negative blocks the interaction decreases the apparent process gain and the interaction is benign

The calculation of dynamic interaction is difficult, even for the two variable case. With more interacting variables, the analysis becomes exceedingly complex and computer solutions are best used. Ideally, though, interactions once identified, should be removed wherever possible.

## 13.22 Dealing with non-linear elements

### 13.22.1 Introduction

All systems are non linear to some degree. Valves have non linear transfer functions, actuators often have a limited velocity of travel and saturation is possible in every component. A controller output is limited to the range 4–20 mA, say, and a transducer has only a restricted measurement range.

One of the beneficial effects of closed loop control is the reduced effect of non linearities. The majority of non linearities are therefore simply lived with, and their effect on system performance is negligible. Occasionally, however, a non linear element can dominate a system and in these cases its effect must be studied.

Some non linear elements can be linearised with a suitable compensation circuit. Differential pressure flow meters have an output which is proportional to the square of flow. Following a non linear differential pressure flow transducer with a non linear square root extractor gives a linear flow measurement system.

Cascade control can also be used around a non linear element to linearise its performance as seen by the outer loop. Butterfly valves are notoriously non linear. They have an S shaped flow/position characteristic, suffer from backlash in the linkages and are often severely velocity limited. Enclosing a butterfly valve within a cascade flow loop, for example, will make the severely non linear flow control valve appear as a simple linear first order lag to the rest of the system.

There are two basic methods of analysing the behaviour of systems with non linear elements. It is also possible, of course, to write computer simulation programs and often this is the only practical way of analysing complex non linearities.

### 13.22.2 The describing function

If a non linear element is driven by a sine wave, its output will probably not be sinusoidal, but it will be periodic with the same frequency as the input, but of differing shape and possibly shifted in phase as shown on *Figure 13.43*. Often the shape and phase shift are related to the amplitude of the driving signal.

Fourier analysis is a technique that allows the frequency spectrum of any periodic waveform to be calculated. A simple pulse can be considered to be composed of an infinite number of sine waves.

The non linear output signals of *Figure 13.43* could therefore be represented as a frequency spectrum, obtained from Fourier analysis. This is, however, unnecessarily complicated. Process control is generally concerned with only dominant effects, and as such it is only necessary to consider the fundamental of the spectrum. We can therefore represent a non linear function by its gain and phase shift at the fundamental frequency. This is known as the *describing function*, and will probably be frequency and amplitude dependant.

*Figure 13.44* shows a very crude bang/bang servo system used to control level in a header tank. The level is sensed by

a capacitive probe which energises a relay when a nominal depth of probe is submerged. The relay energises a solenoid which applies pneumatic pressure to open a flow valve. This system is represented by *Figure 13.45*.

The level sensor can be considered to be a level transducer giving a 0–10 V signal over a 0.3 m range. The signal is filtered with a 2 sec time constant to overcome noise from splashing, ripples etc. The level transducer output is compared with the voltage from a setpoint control and the error signal energises or de-energises the relay. We shall assume no hysteresis for simplicity although this obviously would be desirable in a real system.

The relay drives a solenoid assumed to have a small delay in operation which applies 15 psi to an instrument air pipe to open the valve. The pneumatic signal takes a finite time to travel down the pipe, so the solenoid valve and piping are considered as a 0.5 sec transit delay. The valve actuator turns on a flow of 150 m<sup>3</sup>/min for an applied pressure of 15 psi. We shall assume it is linear for other applied pressures. The actuator/valve along with the inertia of the water in the pipe appear as a first order lag of 4 sec time constant. The tank itself appears as an integrator from flow to level.

This system is dominated by the non linear nature of the level probe and the solenoid. The rest of the system can be considered linear if we combine the level comparator, relay and solenoid into a single element which switches 0 to 15 psi according to the sign of the error signal (15 psi for negative error, i.e. low level).

This non linear element will therefore have the response of *Figure 13.46*, when driven with a sinusoidal error signal. The output will have a peak to peak amplitude of 15 psi regardless of the error magnitude.

From Fourier analysis, the fundamental component of the output signal is a sine wave with amplitude  $4 \times 7.5/\pi$  psi as shown. The phase shift is zero at all frequencies. The non linear element of the comparator/relay/solenoid can thus be considered as an amplifier whose gain varies with the amplitude of the input signal.

For a 1 V amplitude error signal the gain is

$$(4 \times 7.5)/(\pi \times 1) = 9.55$$

For a 2 V amplitude error signal the gain is

$$(4 \times 7.5)/(\pi \times 2) = 4.78$$

In general, for an  $E$  volt error signal the gain is

$$(4 \times 7.5)/(\pi \times E) = 9.55/E \quad (13.18) \Leftarrow$$

*Figure 13.47* is a Nichols chart for the linear parts of the system. This has 180° phase shift for  $\omega = 0.3$  rads/sec, so if it was controlled by a proportional controller, it would oscillate at 0.3 rads/sec if the controller gain was sufficiently high. The linear system gain at this frequency is –7 dB, so a proportional controller gain of 7 dB would just sustain continuous oscillation.

Let us now return to our non linear level switch. This has a gain which varies inversely with error amplitude. If we are, for some reason, experiencing a large sinusoidal error signal the gain will be low. If we have a small sinusoidal error signal the gain will be high.

Intuitively we know the system of *Figure 13.44* will oscillate. The non linear element will add just sufficient gain to make the Nichols chart of *Figure 13.47* pass through the 0 dB/–180° origin. Self sustaining oscillations will result at 0.3 rads/sec. If these increase in amplitude for some reason, the gain will decrease causing them to decay again. If they cease, the gain will increase until oscillations recommence.

Figure 13.46 Action of solenoid valve in level control system

The system stabilises with continuous constant amplitude oscillation.

To achieve this the non linear element must contribute 7 dB gain, or a linear gain of 2.24. From Equation 13.18 above, the gain is  $9.55/E$  where  $E$  is the error amplitude. The required gain is thus given by an error amplitude of

$9.55/2.24 = 4.26$  V. This corresponds to an oscillation in level of 0.426 m.

The system will thus oscillate about the set level with an amplitude of 0.4 m (the assumptions and approximations give more significant figures a relevance they do not merit) and an angular frequency of 0.4 rads/sec (period fractionally above 20 s).

There is a hidden assumption in the above analysis that the outgoing flow is exactly half the available ingoing flow to give equal mark/space ratio at the valve. Other flow rates will give responses similar to Figure 13.48, exhibiting a form of pulse width modulation. The relatively simple analysis however has told us that our level control system will sustain constant oscillation with an amplitude of around half a metre and a period of about 20 sec at nominal flow.

Similar techniques can be applied to other non linearities; a limiter, shown on Figure 13.49(a) and (b), for example, will have unity gain for input amplitudes less than the limiting level. For increasing amplitude the apparent gain will decrease. The describing function when limiting occurs has a gain dependent on the ratio between the input signal amplitude and the limiting value as plotted on Figure 13.49(c). There is no phase shift between input and output.

Hysteresis, shown on Figure 13.50, introduces a phase shift, and a flat top to the output waveform. This is not the same waveform as the limiter; the top is simply levelled off at  $2a$  below the peak where  $a$  is half the dead zone width. If the input amplitude is large compared to the dead zone, the gain is unity and the phase shift can be approximated by

$$\phi \approx \sin^{-1}(a/V_i)$$

As the input amplitude decreases, the gain increases and becomes zero when the input peak to peak amplitude is

Figure 13.47 Nichols chart for linear portion of level control system

Figure 13.48 Response of level control system to changes in flow

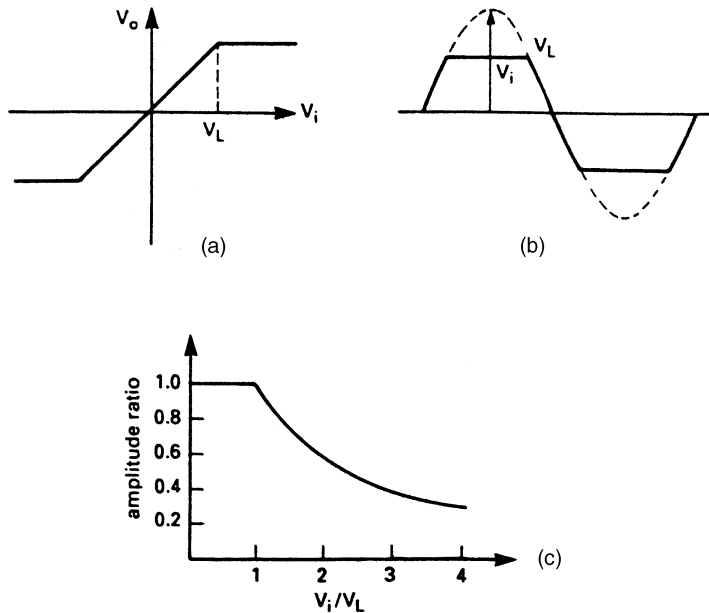

Figure 13.49 The limiter circuit: (a) relationship between input and output; (b) effect of limiting on a sine wave input signal; (c) 'Gain' of a limiter related to the input signal amplitude

less than the dead zone width. The exact relationship is complex, but is shown on *Figure 13.50(c)* and *(d)*.

Non linear elements generally have gains and phase shift which increase or decrease with input amplitude (usually a representation of the error signal). *Figure 13.51* illustrates the two gain cases. For a loop gain of unity, constant oscillations will result. For loop gains greater than unity, oscillations will increase in amplitude, for loop gain less than unity oscillations will decay.

In *Figure 13.51(a)*, the gain falls off with increasing amplitude. The system thus tends to approach point X as large oscillations will decay and small oscillations increase. The system will oscillate at whatever gain gives unity loop gain. This is called *limit cycling*. Most non linearities (bang-bang servo, saturation etc.) are of this form.

Where loop gain increases with amplitude as *Figure 13.51(b)*, decreasing gain gives increasing damping as the amplitude decreases, so oscillations will quickly die away. This response is sometimes deliberately introduced into level controls. If, however, the system is provoked beyond Y by a disturbance, the oscillation will rapidly increase in amplitude and control will be lost.

### 13.22.3 State space and the phase plane

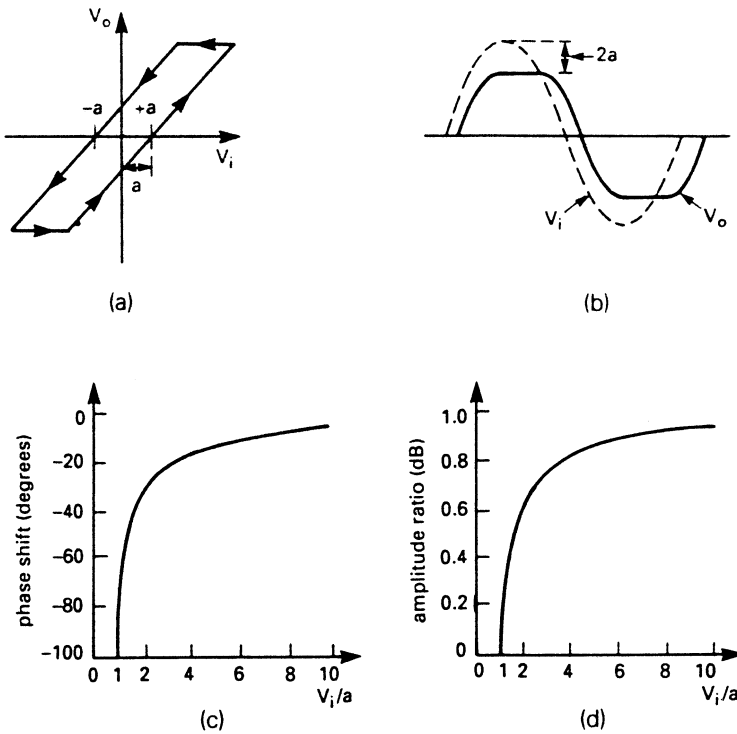

*Figure 13.52(a)* shows a simple position control system. The position is sensed by a potentiometer, and compared with a setpoint from potentiometer  $RV_1$ . The resulting error signal is compared with an error 'window' by comparators  $C_1, C_2$ . Preset  $RV_2$  sets the deadband, i.e. the width of the window. The comparators energise relays  $RL_F$  and  $RL_R$  which drive the load to the forward and reverse respectively.

Initially, we shall analyse the system with  $RV_2$  set to zero, i.e. no deadband. This has the block diagram of *Figure 13.52(b)*, with a first order lag of time constant  $T$  arising from the inertia of the system, and the integral action converting motor velocity to load position.

The system is thus represented by

$$x = \frac{\pm K}{s(1 + sT)} \quad (13.19)$$

where  $K$  represents the acceleration resulting from the motor torque and inertia with the sign of  $K$  indicating the sign of the error. This has the solution

**Figure 13.50** The effect of hysteresis: (a) relationship between input and output signals; (b) the effect of hysteresis on a sine wave input signal; (c) the relationship between phase shift and signal amplitude; (d) the relationship between 'gain' and signal amplitude

**Figure 13.51** Possible relationships between gain and signal amplitude: (a) gain decreases with increasing amplitude; (b) gain increases with increasing amplitude

$$x = x_0 - TK + TV_0 + Kt + T(K - V_0)e^{-t/T} \quad (13.20) \Leftarrow$$

where  $x_0$  and  $V_0$  respectively represent the initial position and velocity.

Differentiating gives the velocity,  $V$

$$V = K - (K - V_0)e^{-t/T} \quad (13.21) \Leftarrow$$

Equations 13.20 and 13.21 fully describe the behaviour of the system. These can be plotted graphically as Figure 13.53 with velocity plotted against position for positive  $K$  for various times from  $t=0$ . Each curve represents a different starting condition; curve D, for example, starts at  $x_0 = -5$  and  $v_0 = -2$

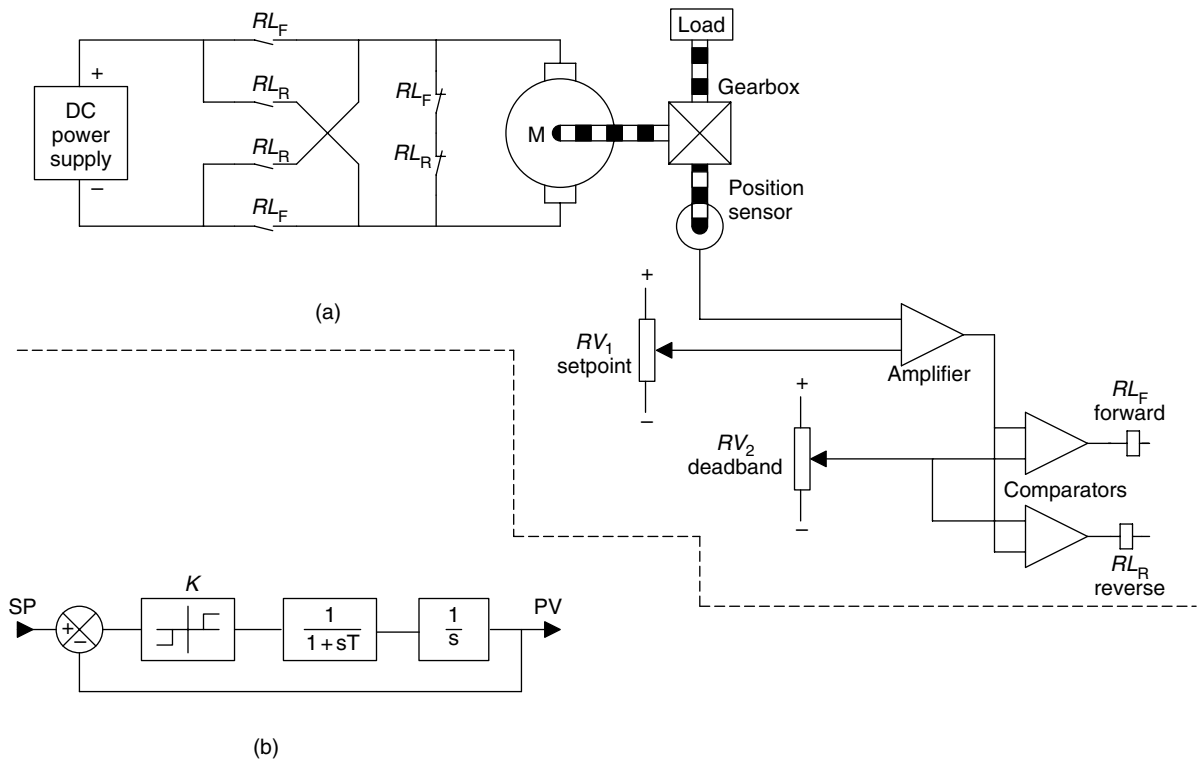

In each case, the curve ends towards  $v=2$  units/sec as  $t$  gets large. The family of curves have an identical shape, and the different starting conditions simply represent a horizontal shift of the curve.

A similar family of curves can be drawn for negative values of  $K$ . These are sketched on Figure 13.54. In this case, the velocity tends towards  $V = -2$  units/sec.

Given these curves, we can plot the response of the system. Let us assume that the system is stationary at  $x = -5$ , and the setpoint is switched to  $+5$ . The subsequent behaviour is shown on Figure 13.55. The system starts by initially following the curve passing through  $x = -5$ ,  $V = 0$  for positive  $K$ , crossing  $x = 0$  with a velocity  $1.5$  units/sec, reaching the setpoint at point X with a velocity of  $1.76$  units/sec. It cannot stop instantly however, so it overshoots.

At the instant the overshoot occurs  $K$  switches sign. The system now has a velocity of  $+1.76$ , with  $K$  negative, so it follows the corresponding curve of Figure 13.54 from point X to point Y. It can be seen that an overshoot to  $x = 7$  occurs. At point Y, another overshoot occurs and  $K$  switches

**Figure 13.52** A non-linear position control system: (a) system diagram; (b) block representation

**Figure 13.53** Relationship between position and velocity for positive values of  $K$  for various initial conditions

back positive. The system now follows the curve to Z with an undershoot of  $x = 4.1$ . At Z another overshoot occurs and the system spirals inwards as shown. The predicted step response is shown on Figure 13.56.

In Figure 13.57(a), the deadband control ( $RV_2$  on the earlier Figure 13.52) has been adjusted to energise  $RL_F$  for error voltages more negative than  $-1$  unit and energise

$RL_R$  for error voltages above  $+1$  unit. There is thus a dead-band 2 units wide around the setpoint.

Figure 13.57(b) shows the effect of this deadband. We will assume initial values of  $x_0 = 0$ ,  $v_0 = 0$  when we switch the setpoint to  $x = 5$ . The system accelerates to point U ( $x = 4$ ,  $v = 4.40$ ) at which point  $RL_1$  de-energises. The system loses speed ( $K = 0$ ) until point V, where the position

**Figure 13.54** Relationship between position and velocity for negative values of  $K$  for various initial conditions

**Figure 13.55** System behaviour following change of setpoint from  $x = -5$  to  $x = +5$

**Figure 13.56** Predicted step response following change of setpoint

passes out of the deadband and  $RL_R$  energises. The system reverses, and re-enters the deadband at point  $W$ , where  $RL_F$  de-energises. An undershoot then occurs ( $X$  to  $Y$ ) where the deadband is entered for the last time, coming to rest at point  $Z$  ( $x = 4.75$ ,  $v = 0$ ).

The position  $x$  and velocity  $dx/dt$  completely describe the system and are known as *state variables*. A linear system can be represented as a set of first order differential equations relating the various state variables. For a second order system there are two state variables, for higher order systems there will be more.

For the system described by Equation 13.19, we can denote the state variables by  $x$  (position) and  $v$  (velocity). For a driving function  $K$ , we can represent the system by Figure 13.58 which is called a *state space model*. This

describes the position control system by the two first order differential equations.

$$T \frac{dv}{dt} = K - x$$

and

$$v = \frac{dx}{dt}$$

Figure 13.56 and Figure 13.57 plot velocity against position, and as such are plots relating state variables. For two state variables (from a second order system) the plot is known as a *phase plane*. For higher order systems, a multi-dimensional plot, called *state space*, is required. Plots such as Figure 13.53 and Figure 13.54 which show a family of possible curves are called *phase plane portraits*.

**Figure 13.57** System with deadband and friction: (a) deadband response; (b) position/velocity curve for setpoint change from  $x=0$  to  $x=5$ . Note system does not attain the setpoint

**Figure 13.58** State variables for position control system

Similar phase planes can be drawn for other non linearities such as saturation, hysteresis etc. Various patterns emerge, which are summarised on *Figure 13.59*. The system behaviour can be deduced from the shape of the phase trajectory.

In a linear closed loop system stability is generally increased by adding derivative action. In a position control system this is equivalent to adding velocity ( $dx/dt$ ) feedback. The behaviour of a non linear system can also be improved by velocity feedback. In *Figure 13.60(a)* velocity feedback has been added to our simple Bang/Bang position servo.

The switching point now occurs where

$$S_P - \frac{1}{L}v = 0$$

or

$$v = \frac{1}{L}(S_P - \frac{1}{L}v)$$

This is a straight line of slope  $-1/L$ , passing through  $x=S_P$ ,  $v=0$  on the phase plane. Note that  $L$  has the units of time. The line is called the switching line, and advances the changeover as shown on *Figure 13.60(b)*, thereby reducing the overshoot. Too much velocity feedback as *Figure 13.60(c)*

simulates an overdamped system as the trajectory runs to the setpoint down the switching line.

## 13.23 Disturbances

### 13.23.1 Introduction

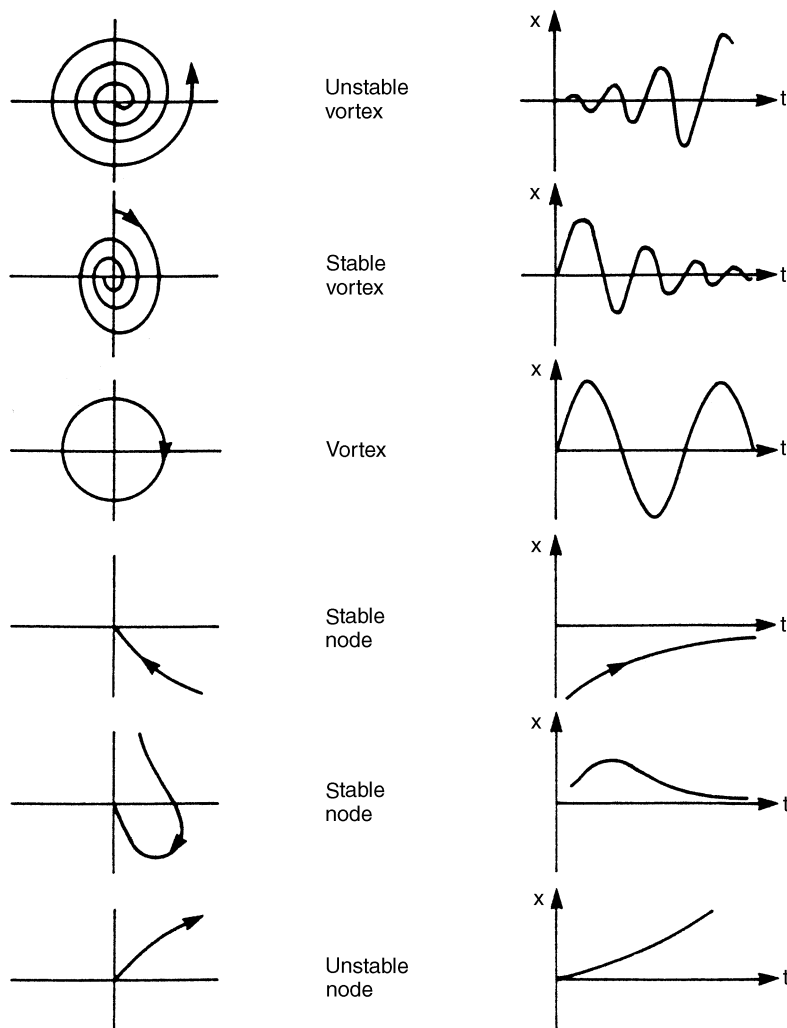

A closed loop control system has to deal with the malign effects of outside disturbances. A level control system, for example, has to handle varying throughput, or a gas fired furnace may have to cope with changes in gas supply pressure. Although disturbances can enter a plant at any point, it is usual to consider disturbances at two points; supply disturbances at the input to the plant and load/demand disturbances at the point of measurement as shown on *Figure 13.61(a)*.

The closed loop block diagram can be modified to include disturbances as shown on *Figure 13.61(b)*. A similar block diagram could be drawn for load disturbances or disturbances entering at any point by subdividing the plant block. By normal analysis we have

$$V = \frac{CPS_p}{1 + HCP} + \frac{PD}{1 + HCP} \quad (13.22) \Leftarrow$$

Equation 13.22 has two components; the first relates the plant output to the setpoint and is the normal closed loop transfer function  $GH/(1 + GH)$ . The product of controller and plant transfer function  $C.P.$  is the forward gain  $G$ . The second term relates the performance of the plant to disturbance signals. In general, closed loop control reduces the effect of disturbances. If the plant was run open loop, the effect of the disturbances on the output would be simply

$$V = PD$$

**Figure 13.59** Various possible trajectories and their response

From Equation 13.22 with closed loop control, the effect of the disturbance is

$$V = \frac{PD}{1 + HCP}$$

i.e. it is reduced providing the magnitude of  $(1 + HCP)$  is greater than unity. If the magnitude of  $(1 + HCP)$  becomes less than unity over some range of frequencies, closed loop control will magnify the effect of disturbances in that frequency range. It is important, therefore, to have some knowledge of the frequency spectra of expected disturbances.

### 13.23.2 Cascade control

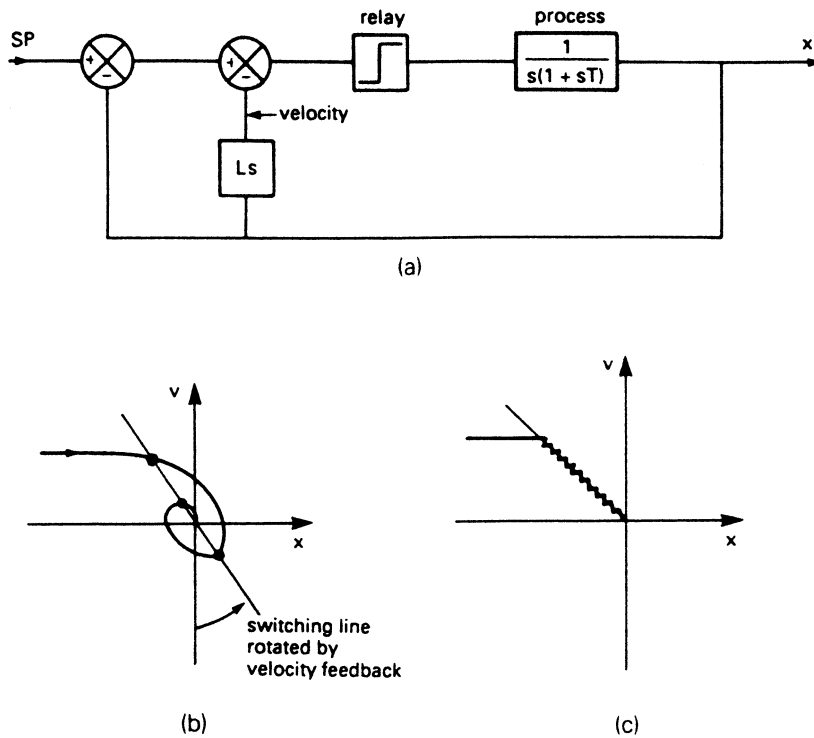

Closed loop control gives increased performance over open loop control, so it would seem logical to expect benefits from adding an inner control loop around plant items that are degrading overall performance. *Figure 13.62* shows a typical example, here the output of the outer loop controller becomes the setpoint for the inner controller. Any problems

in the inner loop (disturbances, non linearities, phase lag etc.) will be handled by the inner controller, thereby improving the overall performance of the outer loop. This arrangement is known as *cascade control*.

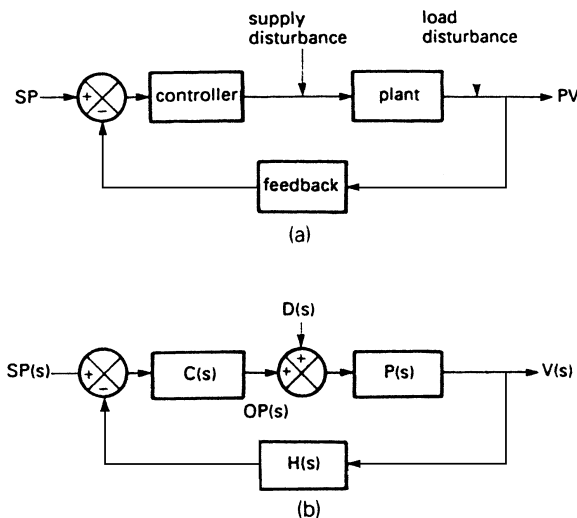

To apply cascade control, there must obviously be some intermediate variable that can be measured ( $P_{Vi}$  on *Figure 13.62*) and some actuation point that can be used to control it.

Cascade control brings several benefits. The secondary controller will deal with disturbances before they can affect the outer loop. Phase shift within the inner loop is reduced, leading to increased stability and speed of response in the outer loop. Devices with inherent integral action (such as a motorised valve) introduce an inherent  $-90^\circ$  integrator phase lag. This can be removed by adding a valve positioner in cascade. Cascade control will also reduce the effect of non linearities (e.g. non linear gain, backlash etc.) in the inner loop.

There are a few precautions that need to be taken, however. The analysis so far ignores the fact that components saturate and stability problems can arise when the inner

**Figure 13.60** Addition of velocity feedback to a non-linear system: (a) block diagram of velocity feedback; (b) system behaviour on velocity/position curve; (c) overdamped system follows the switching line

**Figure 13.61** The effect of disturbances: (a) points of entry for disturbances; (b) block diagram of disturbances

loop saturates. This can be overcome by limiting the demands that the outer loop controller can place on the inner loop (i.e. ensuring the outer loop controller saturates first) or by providing a signal from the inner to the outer controller which inhibits the outer integral term when the inner loop is saturated.

The application of cascade control requires an intermediate variable and control action point, and should include, if possible, the plant item with the shortest time constant. In general, high gain proportional only control will often suffice for the inner loop, any offset is of little concern as it will be removed by the outer controller. For stability, the inner loop must always be faster than the outer loop.

Tuning a system with cascade control requires a methodical approach. The inner loop must be tuned first with the outer loop steady in manual control. Once the inner loop is tuned satisfactorily, the outer loop can be tuned as normal. A cascade system, once tuned, should be observed to ensure that the inner loop does not saturate, which can lead to instability or excessive overshoot on the outer loop. If saturation is observed, limits must be placed on the output of the outer loop controller, or a signal provided to prevent integral windup as described later in Section 13.27.6

### 13.23.3 Feedforward

Cascade control can reduce the effect of disturbances occurring early in the forward loop, but generally cannot deal with load/demand disturbances which occur close to, or affect directly the process variable as there is no intermediate variable or accessible control point.

Disturbances directly affecting the process variable must produce an error before the controller can react. Inevitably, therefore, the output signal will suffer, with the speed of recovery being determined by the loop response. Plants which are difficult to control tend to have low gains and long integral times for stability, and hence have a slow response. Such plants are prone to error from disturbances.

Figure 13.62 A system with cascade control

In general a closed loop system can be considered to behave as a second order system, with a natural frequency  $\omega_n$ , and a damping factor. At frequencies above  $\omega_n$ , the closed loop gain falls off rapidly (at 12 dB/octave). Disturbances occurring at a frequency much above  $2\omega_n$  will be uncorrected. If the closed loop damping factor is less than unity (representing an underdamped system), the effect of disturbances with frequency components around  $\omega_n$  can be magnified.

Figure 13.63(a) shows a system being affected by a disturbance. Cascade control cannot be applied because there is no intermediate variable between the point of entry and the process variable. If the disturbance can be measured, and its effect known, (even approximately), a correcting signal can be added to the controller output signal to compensate for the disturbance as shown on Figure 13.63(b). This is known as *feedforward* control.

This correcting signal, arriving by blocks  $H$ ,  $F$ , and  $P_1$  should ideally exactly cancel the original disturbance, both in the steady state and dynamically under changing conditions. The transfer functions of the transducer  $H$  and plant  $P_1$  are fixed, with  $F$  a compensator block designed to match  $H$  and  $P_1$ .

In general, the compensator block transfer function will be

$$F = -\frac{1}{HP_1}$$

If the plant acts as a simple lag with time constant  $T$  (i.e.  $1/(1+sT)$ ), the compensator will be a simple lead  $(1+sT)$ . In many cases a general purpose compensator  $(1+sT_a)/(1+sT_b)$  is used.

The feedforward compensation does not have to match exactly the plant characteristics; even a rough model will give a significant improvement (although a perfect model will give perfect control). In most cases a simple compensator will suffice.

Cascade control can usually deal with supply disturbances and feedforward with load or demand disturbances. These neatly complement each other so it is very common to find a system where feedforward modifies the setpoint for the inner cascade loop.

## 13.24 Ratio control

### 13.24.1 Introduction

It is a common requirement for two flows to be kept in precise ratio to each other; gas/oil and air in combustion control, or reagents being fed to a chemical reactor are typical examples.

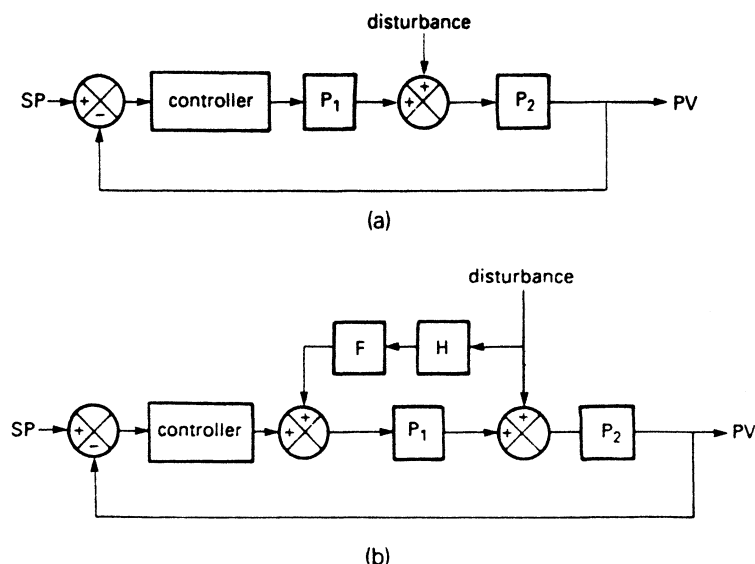

Figure 13.63 Effect of a disturbance reduced by feedforward: (a) a system to which cascade control cannot be applied being subject to a disturbance; (b) correcting signal derived by measuring the disturbance

### 13.24.2 Slave follow master

In simple ratio control, one flow is declared to be the master. This flow is set to meet higher level requirements such as plant throughput or furnace temperature. The second flow is a slave and is manipulated to maintain the set flow ratio.

The controlled variable here is ratio, not flow, so an intuitive solution might look similar to Figure 13.64 where the actual ratio  $A/B$  is calculated by a divider module and used as the process variable for a controller which manipulated the slave control valve.

This scheme has a hidden problem. The slave loop includes the divider module and hence the term  $A$ . The loop gain varies directly with the flow  $A$ , leading to a sluggish response at low flows and possible instability at high flow. If the inverse ratio  $B/A$  is used as the controller variable the saturation becomes worse as the term  $1/A$  now appears in the slave loop giving a loop gain which varies inversely with  $A$ , becoming very high at low flows. Any system based on Figure 13.64 would be impossible to tune for anything other than constant flow rates.

Ratio control systems are often based on Figure 13.65. The master flow is multiplied by the ratio to produce the

setpoint for the slave flow controller. The slave flow thus follows the master flow. Note that in the event of failure in the master loop (a jammed valve for example) the slave controller will still maintain the correct ratio.

The slave flow will tend to lag behind the master flow. On a gas/air burner, the air flow could be master and the gas loop the slave. Such a system would run lean on increasing heat and run rich on decreasing heat. To some extent this can be overcome by making the master loop slower acting than the slave loop, possibly by tuning.

In a ratio system, a choice has to be made for master and slave loops. The first consideration is usually safety. In a gas/air burner, for example, air master/gas slave (called *gas follow air*) is usually chosen as most failures in the air loop cause the gas to shut down. If there are no safety considerations, the slowest loop should be the master and the fastest loop the slave to overcome the lag described above. Since 'fuel' (in both combustion and chemical terms) is usually the smallest flow in a ratio system and consequently has smaller valves/actuators, the safety and speed requirement are often the same.

The ratio block is a simple multiplier. If the ratio is simply set by an operator this can be a simple potentiometer acting

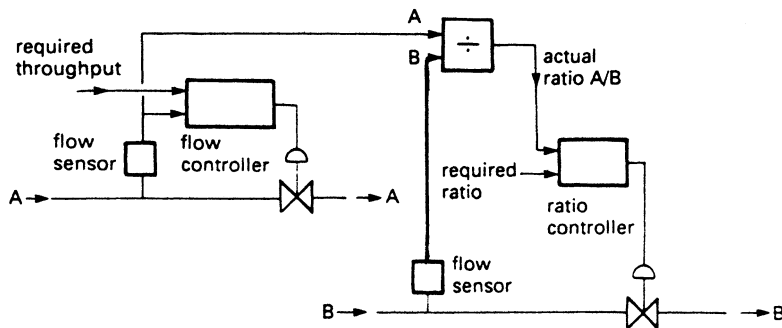

Figure 13.64 An intuitive, but incorrect, method of ratio control. The loop gain varies with throughput

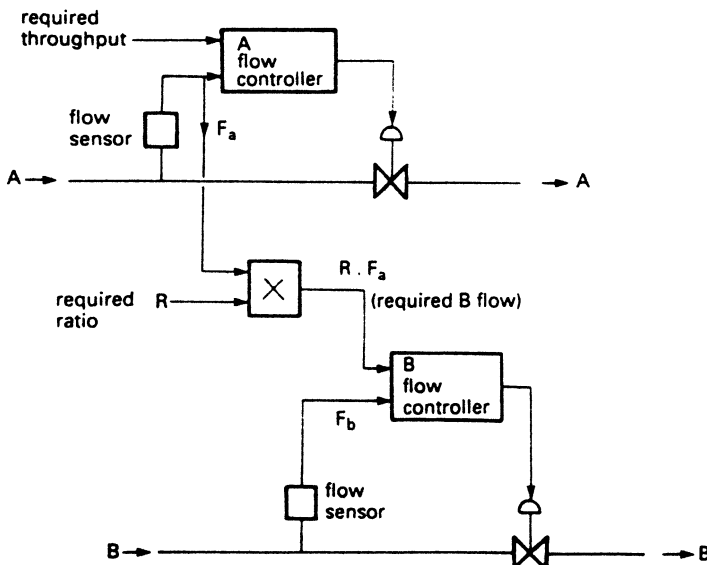

Figure 13.65 Master/slave ratio system with stable loop gains

as a voltage divider (for ratios less than unity) or an amplifier with variable gain (for ratios greater than unity). In digital control systems, of course, it is a simple multiply instruction. If the ratio is to be changed remotely (a trim control from an automatic sampler on a chemical blending system for example) a single quadrant analog multiplier is required.

Ratio blocks are generally easier to deal with in digital systems working in real engineering units. True ratios (an air/gas ratio of 10/1 for example) can then be used. In analog systems the range of the flow meters needs to be considered. Suppose we have a master flow with FSD of 12000 l/min, a slave flow of FSD 2000 l/min and a required ratio (master/slave) of 10/1. The required setting of  $R$  on Figure 13.65 would be 0.6. In a well designed plant with correctly sized pipes, control valves and flow meters, analog ratios are usually close to unity. If not, the plant design should be examined.

Problems can arise with ratio systems if the slave loop saturates before the master. A typical scenario on a gas follow air burner control could go; the temperature loop calls for a large increase in heat (because of some outside influence). The air valve (master) opens fully, and the gas valve follows correctly but cannot match the requested flow. The resulting flame is lean and cold (flame temperature falls off rapidly with too lean a ratio) and the temperature does not rise. The system is now locked with the temperature loop demanding more heat and the air/gas loops saturated, delivering full flow but no temperature rise. The moral is; the master loop must saturate before the slave. If this is not achieved by pipe sizing the output of the master controller should be limited.

### 13.24.3 Lead lag control

Slave follow Master is simple, but one side effect is that the mixture runs lean for increasing throughput and rich for

decreasing throughput because the master flow must always change first before the slave can follow. There is also a possible safety implication because a failure of the slave valve or controller could lead to a gross error in the actual ratio such as the fuel valve wide open and the air valve closed.

Better performance can be obtained with a system called *Lead-lag control* shown for an air/fuel burner on Figure 13.66. This uses cross linking and selectors to provide an air setpoint which is the highest of the external power demand signal or ratio'd fuel flow. The fuel setpoint is the lowest of the external power demand or ratio'd air flow.

This cross linking provides better ratio during changes, both air and fuel will change together. There is also higher security; a jammed open fuel valve will cause the air valve to open to maintain the correct ratio and prevent an explosive atmosphere of unburned fuel forming.

## 13.25 Transit delays

### 13.25.1 Introduction

Transit delays are a function of speed, time and distance. A typical example from the steel industry is the tempering process of Figure 13.67 where red hot rolled steel travelling at 15 m/sec is quenched by passing beneath high pressure water sprays. The recovery temperature, some 50 m downstream, is the controlled variable which is measured by a pyrometer and used to adjust the water flow control valve. There is an obvious transit delay of  $50/15 = 3.3$  sec in the loop. A transit delay is a simple time shift which is independent of frequency.

Transit delays give an increasing phase shift with rising frequency which is de-stabilising. If conventional controllers are used significant detuning (low gain, large  $T_i$ ) is necessary to maintain stability. The effect is shown on the

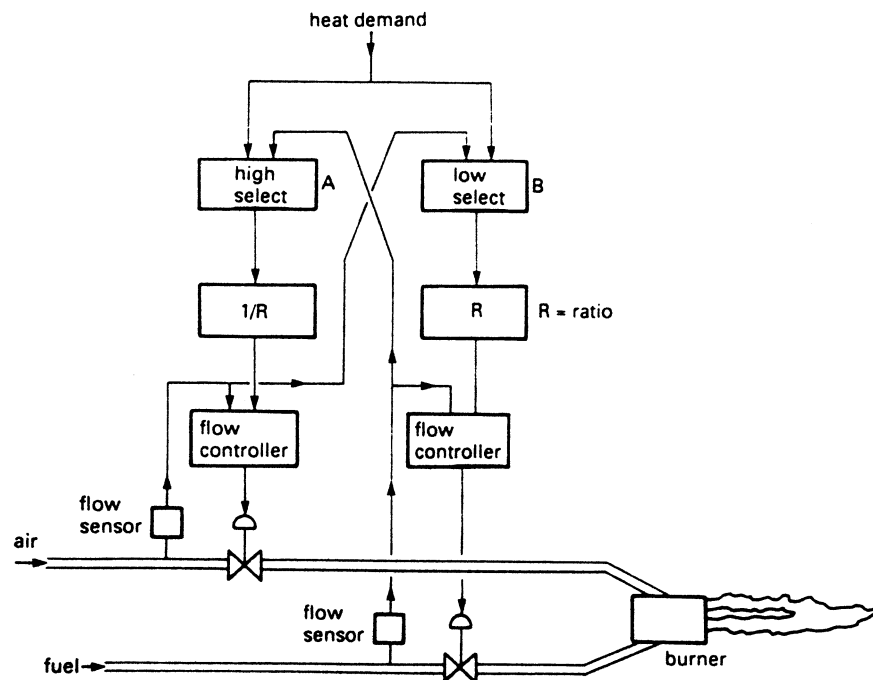

Figure 13.66 Lead/lag combustion control

Figure 13.67 A tempering system dominated by a transit delay

Nichols charts of Figure 13.68 for a simple system of two first order lags controlled by a PI controller. The de-stabilising effect of the increasing phase shift can clearly be seen. Derivative action, normally a stabilising influence, can also adversely affect a loop in which a transit delay is the dominant feature.

### 13.25.2 The Smith predictor

The effects of a transit delay can be reduced by the arrangement of Figure 13.69 called a *Smith predictor*. The plant is considered to be an ideal plant followed by a transit delay. (This may not be true, but the position of the transit delay, before or after the plant, makes no difference to the plant behaviour.) The plant and its associated delay are modelled as accurately as possible in the controller.

The controller output,  $O_p$ , is applied to the plant and to the internal controller model. Signal  $A$  should thus be the same as the notional (and unmeasurable) plant signal  $X$ , and the signal  $B$  should be the same as the measurable controlled variable signal  $Y$ .

The PID controller however, is primarily controlling the model, not the plant, via summing junction 1. There are no delays in this loop, so the controller can be tuned for tight operation. With the model being the only loop, however, the plant is being operated in open loop control, and compensation will not be applied for model inaccuracies or outside disturbances.

Signal  $Y$  and  $B$  are therefore compared by a subtractor to give an error signal which encompasses errors from both disturbances and the model. These are added to the signal  $A$  from the plant model to give the feedback signal to the PID control block.

Discrepancies between the plant model and the real plant will be compensated for in the outer loop, so exact modelling is not necessary. The poorer the model, however, the less tight the control that can be applied in the PID block as the errors have to be compensated via the plant transit delay.

Smith predictors are usually implemented digitally, analog transit delays being difficult to construct. A digital delay line is simply a shift register in which values are shifted one place at each sample.

The Smith predictor is not a panacea for transit delays; it still takes the delay time from a setpoint change to a change in the process variable, and it still takes the delay time for a disturbance to be noted and corrected. The response to change, however, is considerably improved.

Systems with transit delays can benefit greatly from feedforward described previously in Section 13.23.3. Feedforward used in conjunction with a Smith predictor can be a very effective way of handling control systems with significant transit delays.

## 13.26 Stability

### 13.26.1 Introduction

At first sight it would appear that perfect control can be obtained by utilising a large proportional gain, short integral time and long derivative time. The system will then respond quickly to disturbances, alterations in load and set point changes.

Unfortunately life is not that simple, and in any real life system there are limits to the settings of gain  $T_i$  and  $T_d$  beyond which uncontrolled oscillations will occur. Like many engineering systems, the setting of the controller is a compromise between conflicting requirements.

### 13.26.2 Definitions and performance criteria

It is often convenient, (and not too inaccurate), to consider that a closed loop system behaves as a second order system, with a natural frequency  $\omega_n$  and a damping factor  $\beta$ .

$$\frac{d^2x}{dt^2} + 2\beta\omega_n \frac{dx}{dt} + \omega_n^2 x = f(t) \Leftarrow$$

It is then possible to identify five possible performance conditions, shown for a set point change and a disturbance in Figure 13.70(a) and (b).

An unstable system exhibits oscillations of increasing amplitude. A marginally stable system will exhibit constant amplitude oscillations. An underdamped system will be somewhat oscillatory, but the amplitude of the oscillations decreases with time and the system is stable. (It is important to appreciate that oscillatory does not necessarily imply instability). The rate of decay is determined by the damping factor. An often used performance criteria is the 'quarter amplitude damping' of Figure 13.70(c) which is an underdamped response with each cycle peak one quarter of the amplitude of the previous. For many applications this is an adequate, and easily achievable response.

An overdamped system exhibits no overshoot and a sluggish response. A critical system marks the boundary between underdamping and overdamping and defines the fastest response achievable without overshoot.

For a simple system the responses of Figure 13.70(a) and (b) can be related to the gain setting of a  $P$  only controller, overdamped corresponding to low gain with increasing gain causing the response to become underdamped and eventually unstable.

It is impossible for any system to respond instantly to disturbances and changes in set point. Before the adequacy of a control system can be assessed, a set of performance criteria is usually laid down by production staff. Those defined in Figure 13.71 are commonly used.

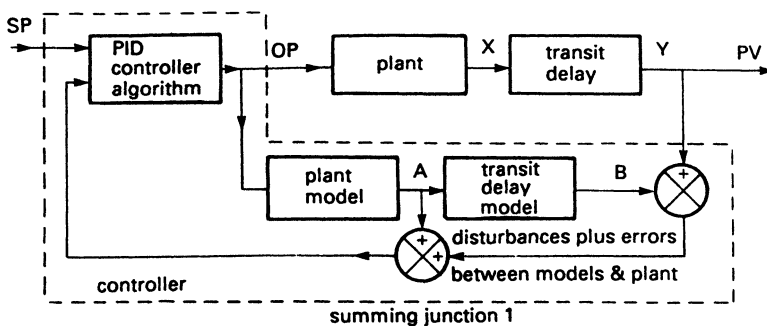

(a)

(b)

**Figure 13.68** The effect of a transit delay on stability: (a) sketch of a Nichols chart for a system comprising a PI controller ( $K=5$ ;  $T_i=5$ s) and two first order lags of time constants 5 secs and 2 secs. The system is unconditionally stable; (b) the same system with a one second transit delay. The transit delay introduces a phase shift which increases with rising frequency and makes the system unstable

**Figure 13.69** The Smith predictor used to reduce the effect of transit delays

**Figure 13.70** Various forms of system response: (a) step change in setpoint; (b) step change in load; (c) quarter amplitude damping

The 'rise time' is the time taken for the output to go from 10% to 90% of its final value, and is a measure of the speed of response of the system. The time to achieve 50% of the final value is called the 'delay time'. This is a function of, but not the same as, any transit delays in the system. The first overshoot is usually defined as a percentage of the corresponding set point change, and is indicative of the damping factor achieved by the controller.

As the time taken for the system to settle completely after a change in set point is theoretically infinite, a 'settling band', 'tolerance limit' or 'maximum error' is usually defined. The settling time is the time taken for the system to enter, and remain within, the tolerance limit. Surprisingly an underdamped system may have a better settling time than a critically damped system if the first overshoot is just within the settling band. Table 13.2 shows optimum damping factors for various settling bands. The settling time is defined in units of  $1/\omega_n$ .

**Table 13.2**

Settling band	Optimum 'b'	Settling time
20%	0.45	1.80
15%	0.55	2.00
10%	0.60	2.30
5%	0.70	2.80
2%	0.80	3.50

The shaded area is the integral of the error and this can also be used as an index of performance. Note that for a system with a standing offset (as occurs with a  $P$  only controller) the area under the curve will increase with time and not converge to a final value. Stable systems with integral action control have error areas that converge to a finite value. The area

Figure 13.71 Common definitions of system response

between the curve and the set point is called the *integrated absolute error* (IAE) and is an accepted performance criterion.

An alternative criterion is the integral of the square of the instantaneous error. This weights large errors more than small errors, and is called *integrated squared error* (ISE). It is used for systems where large errors are detrimental, but small errors can be tolerated.

The performance criteria above were developed for a set point change. Similar criteria can be developed for disturbances and load changes.

### 13.26.3 Methods of stability analysis

The critical points for stability are open loop unity gain and a phase shift of  $-180^\circ$ . It is therefore reasonable to give two figures of 'merit':

- The *Gain Margin* is the amount by which the open loop gain can be increased at the frequency at which the phase shift is  $-180^\circ$ . It is simply the inverse of the gain at this critical frequency, for example if the gain at the critical frequency is 0.5, the gain margin is two.
- The *Phase Margin* is the additional phase shift that can be tolerated when the open loop gain is unity. With  $-140^\circ$  phase shift at unity gain, there is a phase margin of  $40^\circ$ .

For a reasonable, slightly underdamped, closed loop response the gain margin should be of the order of 6–12 dB and the phase margin of the order of  $40$ – $65^\circ$ .

Any closed loop control system can be represented by Figure 13.72 where  $G$  is the combined block transfer function of the controller and plant and  $H$  the transfer function of the transducer and feed back components. The output will be given by:

$$P_V = \frac{G}{1 + GH} S_p$$

The system will be unstable if the denominator goes to zero or reverses in sign, i.e.  $GH < -1$ . This is not as simple a relationship as might be first thought, as we are dealing with the dynamics of the process. The response of the system (gain and phase shift) will vary with frequency; generally the gain will fall and the phase shift will rise with increasing frequency. A phase shift of  $180^\circ$  corresponds to multiplying a sine wave by  $-1$ , so if at some frequency the phase shift is  $180^\circ$  and the gain at that frequency is greater than unity the system will be unstable.

There are several methods of representing the gain/phase shift relationship, and inferring stability from the plot. Figure 13.73 is called a Bode diagram and plots the gain (in dB) and phase shift on separate graphs. Log-Lin graph paper

Figure 13.72 General block diagram of a closed loop control system

Figure 13.73 Gain and phase margins on the Bode diagram

(e.g. Chartwell 5542) is required. For stability, the gain curve must cross the 0 dB axis before the phase shift curve crosses the  $180^\circ$  line. From these two values, the gain margin and the phase margin can be read as shown.

Figure 13.74 is a Nichols chart and plots phase shift against gain (in dB). For stability, the 0 dB /  $-180^\circ$  intersection must be to the right of the curve for increasing frequency. Nichols charts are plotted on pre-printed graph paper (Chartwell 7514 for example) which allows the closed loop response to be read directly. If for example the curve is inside the closed loop 0 dB line damped oscillations will result. The gain and phase margins can again be read from the graph.

The final method is the Nyquist diagram of Figure 13.75. This plots gain again phase shift as a polar diagram (gain represented by distance from the origin). Chartwell graph paper 4001 is suitable. For stability the  $-180^\circ$  point must be

Figure 13.74 Gain and phase margins on a Nichols chart

Figure 13.75 Gain and phase margins on a Nyquist diagram

to the left of the graph for increasing frequency. Gain and phase margin can again be read from the graph.

## 13.27 Industrial controllers

### 13.27.1 Introduction

The commercial three term controller is the workhorse of process control and has evolved to an instrument of great versatility. This section describes some of the features of practical modern microprocessor based controllers.

### 13.27.2 A commercial controller

The description in this section is based on the 6360 controller manufactured by Eurotherm Process Automation Ltd of Worthing, Sussex.

The controller front panel is the 'interface' with the operator who may have little or no knowledge of process control. The front panel controls should therefore be simple to comprehend. Figure 13.76 shows a typical layout.

The operator can select one of three operating modes—manual, automatic or remote—via the three push buttons labelled M, A, R. Indicators in each push-button show the current operating mode.

In manual mode, the operator has full control over the driven plant actuator. The actuator drive signal can be ramped up or down by holding in the M button and pressing the  $\blacktriangle$  or  $\blacktriangledown$  buttons. The actuator position is shown digitally on the digital display, whilst the M button is depressed and continuously in analog form on the horizontal bargraph.

In automatic mode the unit behaves as a three term controller with a set point loaded by the operator. The unit is scaled into engineering units (i.e. real units such as  $^\circ\text{C}$ , psi, litres/min) as part of the set up procedure so that the operator is working with real plant variables. The digital display shows the set point value when the SP button is depressed and the value can be changed with the  $\blacktriangle$  and  $\blacktriangledown$  buttons.

Figure 13.76 Front panel operator controls on a typical controller

The set point is also displayed in bargraph form on the right-hand side of the dual vertical bargraph.

Remote mode is similar to automatic mode except the set point is derived from an external signal. This mode is used for ratio or cascade loops (see Sections 13.23 and 13.24) and batch systems where the setpoint has to follow a predetermined pattern. As before the setpoint is displayed in bargraph form and the operator can view, but not change, the digital value by depressing the SP button.

The process variable itself is displayed digitally when no push button is depressed, and continually on the left-hand bargraph. In automatic or remote modes the height of the two left-hand bargraphs should be equal, a very useful quick visual check that all is under control.

Alarm limits, (defined during the controller set up), can be applied to the process variable or the error signal. If either move outside acceptable limits, the process variable bargraph flashes, and a digital output from the controller is given for use by an external annunciator audible alarm of data logger.

Figure 13.77 shows a simple block diagram representation of a controller.

Input analog signals enter at the left-hand side. Common industrial signal standards are 0–10 V, 1–5 V, 0–20 mA and 4–20 mA. These can be accommodated by two switchable ranges 0–10 V and 1–5 V plus suitable burden resistors for the current signals (a 250 ohm resistor, for example, converts 4–20 mA to 1–5 V).

Figure 13.77 Block diagram of a typical controller

4–20 mA and 0–20 mA signals used on two wire loops require a DC power supply somewhere in the loop. A floating 30 V power supply is provided for this purpose.

Open circuit detection is provided on the main  $P_V$  input. This is essentially a pull up to a high voltage via a high value resistor. A comparator signals an open circuit input when the voltage rises. Short circuit detection can also be applied on the 1–5 V input (the input voltage falling below 1 V). Open circuit or short circuit  $P_V$  is usually required to bring up an alarm and trip the controller to manual, with the output signal driven high, held at last value, or driven low according to the nature of the plant being controlled. The open circuit trip mode is determined by switches as part of the set up procedure.

The  $P_V$  and remote  $S_P$  inputs are scaled to engineering units and linearised. Common linearisation routines are thermocouples, platinum resistance thermometers and square root (for flow transducers). A simple adjustable first order filter can also be applied to remove process or signal noise. The set point for the PID algorithm is selected from the

internal set point or the remote set point by the from panel auto and remote push button contacts A, R.

The error signal is obtained by a subtractor ( $P_V$  and  $S_P$  both being to the same scale as a result of the scaling and engineering unit blocks). At this stage two alarm functions are applied. An absolute input alarm provides adjustable high and low alarm limits on the scaled and linearised  $P_V$  signals, and a deviation alarm (with adjustable limits) applied to the error signal. These alarm signals are brought out of the controller as digital outputs.

The basic PID algorithm is implemented digitally and includes a few variations to deal with some special circumstances. These modifications utilise the additional signals to the PID block ( $P_V$ , hold, track, output balance) and are described later.

The PID algorithm output is the actuator drive signal scaled 0–100%. The PID algorithm assumes that an increasing drive signal causes an increase in  $P_V$ . Some actuators, however, are reverse acting, with an increasing drive signal reducing  $P_V$ . A typical example is cooling water valves which are designed to fail open delivering full flow on loss of signal. Before the PID algorithm can be used with reverse acting actuators (or reverse acting transducers) its output signal must be reversed. A set up switch selects normal or inverted PID output. Note that reverse action does not alter the polarity of the controller output, merely the sign of the gain.

The output signal is selected from the manual raise/lower signal or the PID signal by the front panel manual/auto/remote pushbuttons M, A, R. At this stage limits are applied to the selected output drive. This limiting can be used to constrain actuators to a safe working range. The output limit allows the controller output to be limited just before the actuator's ends of travel, keeping the  $P_V$  under control at all times.

Two controller outputs are provided, 0–10 V and 4–20 mA for use with voltage and current driven actuators. The linearised  $P_V$  signal is also retransmitted as a 0–10 V signal for use with the separate external indicators and recorders.

### 13.27.3 Bumpless transfer

The output from the PID algorithm is a function of time and the values of the set point and the process variable. When the controller is operating in manual mode it is highly unlikely that the output of the PID block will be the same as the demanded manual output. In particular the integral term will probably cause the output from the PID block to eventually saturate at 0% or 100% output.

If no precautions are taken, therefore, switching from auto to manual, then back to auto again some time later will result in a large step change in controller output at the transition from manual to automatic operation.

To avoid this 'bump' in the plant operation, the controller output is fed back to the PID block, and used to maintain a PID output equal to the actual manual output. This balance is generally achieved by adjusting the contribution from the integral term.

Mode switching can now take place between automatic and manual modes without a step change in controller output. This is known as *manual/auto balancing*, *preload* or (more aptly) *bumpless transfer*.

A similar effect can occur on set point changes. With a straightforward PID algorithm, a setpoint change of  $\Delta S_P$  will produce an immediate change in controller output of  $K \cdot \Delta S_P$  where  $K$  is the controller gain. In some applications this step change in output is unacceptable. In *Figure 13.78* a term  $K \cdot S_P$  is subtracted from the PID block output. The controller now responds to errors caused by changes in  $P_V$  in the normal way, but only reacts to changes in  $S_P$  via the integral and derivative terms. Changes in  $S_P$  thus result in a slow change in controller output. This is known as *setpoint change balance*, and is a switch selectable set up option.

This balance signal fed back from the output to the PID block is also used when the controller output is forced to follow an external signal. This is called *track mode*.

As before, the PID algorithm needs to be balanced to avoid a bump when transferring between track mode and automatic mode. The feedback output signal achieves this balance as described previously.

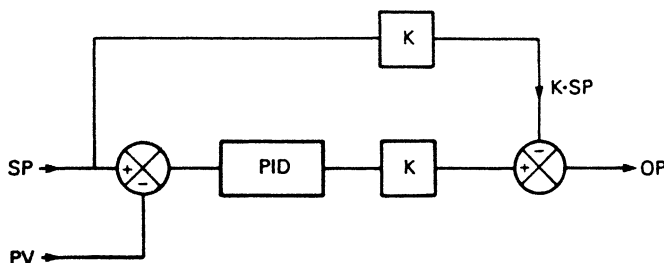

### 13.27.4 Integral windup and desaturation

Large changes in  $S_P$  or large disturbances to  $P_V$  can lead to saturation of the controller output or a plant actuator. Under these conditions the integral term in the PID algorithm can cause problems.

*Figure 13.79* shows the probable response of a system with unrestricted integral action. At time A a step change in set point occurs. The output  $O_P$  rises first in a step ( $K \times$  set point change) then rises at a rate determined by the integral time. At time B the controller saturates at 100% output, but the integral term keeps on rising.

At the time C  $P_V$  reaches, and passes, the required value, and as the error changes sign the integral term starts to decrease, but it takes until time D before the controller desaturates. Between times B and D the plant is uncontrolled, leading to an unnecessary overshoot and possibly even instability.

This effect is called '*integral windup*' and is easily avoided by disabling the integral term once the controller saturates either positive or negative. This is naturally a feature of all commercial controllers, but process control engineers should always be suspicious of 'home brew' control algorithms constructed (or written in software) by persons without control experience.

**Figure 13.78** Set point change balance, the controller only follows set point changes on the integral term giving a ramped response to a change of set point

Figure 13.79 The effect of integral windup

In any commercial controller, the integral term would be disabled at point B on Figure 13.80 to prevent integral windup. The obvious question now is at what point it is re-enabled again. Point C is obviously far too late (although much better than point D in the unprotected controller).

A common solution is to desaturate the integral term at the point where the rate of increase of the integral action equals the rate of decrease of the proportional and derivative terms. This occurs when the slope of the PID output is zero, i.e. when

$$e = -T_i \left( \frac{de}{dt} + T_d \frac{d^2e}{dt^2} \right) \quad (13.23)$$

with  $e$  being the error and  $T_i$  and  $T_d$  the controller constants.

Equation 13.23 brings the controller out of saturation at the earliest possible moment, but this can, in some cases, be too soon leading to an unnecessarily damped response. Some controllers allow adjustment of the desaturation point by adding an error limit circuit to delay the balance point to Equation 13.23 forcing the controller to remain in saturation for a longer time. The speed of desaturation and the degree of overshoot can thus be adjusted by the commissioning engineer.

### 13.27.5 Selectable derivative action

The term  $T_d (de/dt)$  in the three term controller algorithm can be rearranged as

$$T_d \left( \frac{dS_p}{dt} - \frac{dP_v}{dt} \right)$$

where  $S_p$  is the set point and  $P_v$  the process variable. The derivative term thus responds to changes in both the set point and the plant feedback signal.

This is not always desirable; in particular a step change in set point leads to an infinite spike controller output and a vicious 'kick' to the actuator. Commercial controller therefore include a selectable option for the derivative term to be based on true error ( $S_p - P_v$ ) or purely on the value of  $P_v$  alone.

There is generally no noticeable difference in plant performance between these options; stability or the ability to deal with disturbances or load changes are unaffected, and derivative on  $P_v$  is normally the preferred choice. The only occasion when true derivative on error is advantageous is where the  $P_v$  is required to track a continually changing  $S_p$ .

### 13.27.6 Variations on the PID algorithm

The theoretical PID algorithm is described by the equation

$$O_P = K \left( e + \frac{1}{T_i} \int e dt + T_d \frac{de}{dt} \right)$$

where  $e$  is the error,  $K$  is the gain,  $T_i$  is the integral time and  $T_d$  the derivative time. Unfortunately different manufacturers use different terminology and even different algorithms.

Many manufacturers define the gain as the *proportional band*, denoted as  $PB$  or  $P_B$ . This is the inverse of the gain expressed as a percentage, i.e.

$$P_B = \frac{100}{K} \%$$

A gain of two is thus the same as a proportional band of 50%, and decreasing the proportional band increases the gain.

The integral time is commonly expressed as '*Repeats per Minute*' or rpm. The relationship is given by:

$$\begin{aligned} \text{Repeats per min} &= 1/T_i \quad (\text{for } T_i \text{ in min}) \\ &= 60/T_i \quad (\text{for } T_i \text{ in sec}) \end{aligned}$$

The derivative time is often called the *rate* or *pre-act* term but these are all identical to  $T_d$ .

More surprisingly there are variations on the basic algorithm. Some manufacturers use a so called '*non interacting*' or '*parallel*' equation which can be expressed as:

$$O_P = K_e + \frac{1}{T_i} \int e dt + T_d \frac{de}{dt}$$

or

$$O_P = K_e + K_i \int e dt + K_d \frac{de}{dt}$$

In these the three terms are totally independent. In the second version  $K_i$  is called the integral gain and  $K_d$  the derivative gain. Note that increasing  $K_i$  has the same effect as decreasing  $T_i$ . It is tempting to think that the non interacting equations are simpler to use, but in practice the theoretical model is more intuitive. In particular, as the gain  $K$  is reduced in the non interacting equation, any integral action has more effect and contributes more phase shift. Increasing or decreasing the gain with a non interacting controller can thus cause instability.

There is yet a third form of PID algorithm known as the '*series*' equation. This can be expressed as:

$$O_P = K \left( e + \frac{1}{T_i} \int e dt \right) \left( 1 + T_d \frac{de}{dt} \right)$$

This algorithm is based on pneumatic and early electronic controllers, and some manufacturers have maintained it to give backward compatibility. This has the odd characteristic that the  $T_i$  and  $T_d$  controls interact with each other, with the maximum derivative action occurring when  $T_d$  and  $T_i$  are set equal. In addition the ratio between  $T_i$  and  $T_d$  interacts with the overall gain.

There are further variations on the way the derivative contribution is handled. We have already discussed the effect of derivative on process variable and derivative on error. Because the pure derivative term gives increasing gain with increasing frequency it amplifies any high frequency noise resulting in continual twitchy movements of the plant actuators. Many manufacturers therefore deliberately roll off the high frequency gain, either by filtering the signal applied to the derivative function or directly limiting the derivative action.

### 13.27.7 Incremental controllers

Diaphragm operated actuators can be arranged to fail open or shut by reversing the relative positions of the drive pressure and return spring. In some applications a valve will be required to hold its last position in the event of failure. One way to achieve this is with a motorised actuator, where a motor drives the valve via a screw thread.

Such an actuator inherently holds its last position but the position is now the integral of the controller output. An integrator introduces  $90^\circ$  phase lag and gain which falls off with increasing frequency. A motorised valve is therefore a destabilising influence when used with conventional controllers.

Incremental controllers are designed for use with motorised valves and similar integrating devices. They have the control algorithm

$$O_P = K \left( \frac{1}{T_i} e + \frac{de}{dt} + \frac{1}{T_d} \frac{d^2e}{dt^2} \right)$$

which is the time derivative of the normal control algorithm.

Incremental controllers are sometimes called *boundless controllers* or *velocity controllers* because the controller output specifies the actuator rate of change (i.e. velocity) rather than actual position.

Incremental controllers cannot suffer from integral windup per se, but it is often undesirable to keep driving a motorised valve once the end of travel is reached. End of travel limits are often incorporated in motorised valves to prevent jamming. The controller also has no real 'idea' of the valve true position, and hence cannot give valve position indication. If end of travel signals are available, a valve model can be incorporated into the controller to integrate the controller output to give a notional valve position. This model would be corrected whenever an end of travel limit is reached. Alternatively a position measuring device can be fitted to the valve for remote indication.

Pulse width modulated controllers are a variation on the incremental theme. Split phase motor drive valves require logic raise/lower signals, and normal proportional control can be simulated by using time proportional raise/lower outputs.

### 13.27.8 Scheduling controllers

Many loops have properties which change under the influence of some measurable outside variable. The gain of a flow control valve, (i.e. the change in flow for change in valve position) varies considerably over the stroke of a valve. The levitation effect of steam bubbles in a boiler drum causes the drum level control to have different characteristics under start-up, low load and high load conditions.

A scheduling controller has a built-in look up table of control parameters (gain, filtering, integral time etc.) and the appropriate values selected for the measured plant conditions.

### 13.27.9 Variable gain controllers

Process variable noise occurs in many loops; level and flow being possibly the worst offenders. This noise causes unnecessary actuator movement, leading to premature wear and inducing real changes in the plant state. Noise can, of course, be removed by first or second order filters, but

these reduce the speed of the loop and the additional phase shift from the filters can often act to de-stabilise a loop.

A controller with gain  $K$  will pass a noise signal  $K \cdot n(t)$  to the actuator where  $n(t)$  is the noise signal. One obvious way to reduce the effect of the noise is to reduce the controller gain, but this degrades the loop performance. Usually the noise signal has a small amplitude compared with the signal range, if it has not the process will be practically uncontrollable. What is intuitively required is a low gain when the error is low, but a high gain when the error is high.

Figure 13.80(a) shows how such a scheme operates. The noise amplitude lies in the range AB, so this is made a low gain region. Outside this band the gain is much higher. The gain in the region AB should be low, but not zero, to keep the process variable at the set point. With a pure deadband (i.e. zero gain in region AB) the process variable would cycle between one side of the centre band and the other.

Figure 13.80(b) shows a possible implementation. A comparator switches between a low gain and high gain controller according to the magnitude of the error. Note that integral balancing is required between the two controllers to stop integral windup in the unselected controller.

Figure 13.80 has two gain regions. It is possible to construct a controller whose gain varies continuously with error. Such a controller has a response

$$O_P = Kf(e) \left( e + \frac{1}{T_i} \int e dt + T_d \frac{de}{dt} \right)$$

where  $f(e)$  is a function of error.

A common function is

$$f(e) = \text{abs} \left( \frac{m + (1 - m)e}{100} \right) \quad (13.24) \Leftarrow$$

where  $e$  is expressed as a percentage (0–100%) and  $m$  is a user set linearity adjustment ( $0 < m < 1$ ). The *abs* operation (which always returns a positive sign) is necessary to prevent the controller action changing sign on negative error.

With  $m = 1$ ,  $f(e) = 1$  and Equation 13.24 behaves as a normal three term controller. With  $m = 0$ , the proportional part of Equation 13.24 follows a square law. Like Figure 13.80(a), this has low gain or small error (zero gain at zero error) but progressively increasing gain as the error increases.

Position control systems often need a fast response but cannot tolerate an overshoot. These often use Equation 13.24 with  $m$  at a low value approximating to the quadratic curve. This gives a high take off speed, but a low speed of approach.

### 13.27.10 Inverse plant model

The ideal control strategy, in theory, is one which mimics the plan behaviour. Given a totally accurate model of the plant, it should be possible to calculate what controller output is required to follow set point change, or compensate for a disturbance. The problem here is, of course, having an accurate plant model, but even a rough approximation should suffice as the controller output will converge to the correct value eventually.

One possible solution is shown in Figure 13.81. The process is represented by a block with transfer function  $K \cdot f(s)$  where  $K$  is the d.c. (low frequency) gain. Following a change in set point, the signal A should mimic exactly the process

Figure 13.80 Variable gain controller: (a) system response; (b) block diagram

variable  $B$ , leading to a constant output from the controller exactly correct to bring the plant to the set point without overshoot. With a perfect model, the change at  $A$  should match the change at  $B$  as the set point is approached.

The inverse plant model is usually implemented with a sampled digital system. The problem with this simple, and apparently ideal, controller is that it will probably demand actuation signals which will drive the controller output, the actuator or parts of the plant, into saturation. It also requires an accurate plant model. A more gentle version of this technique aims to get a fraction, say 0.1 of the way from the current value to the desired value of the process variables at each sample time. This approximates to an exponential response.

## 13.28 Digital control algorithms

### 13.28.1 Introduction

So far we have assumed that controllers deal with purely analog signals. Increasingly controllers are digital, with the analog signal from the transducer being sampled by an ADC, the control algorithm being performed by software and the analog output being obtained from a DAC. ADCs and DACs are described in Chapter 14, Section 14.9. The system does not therefore continually control but takes 'snapshots' of the system state. Such an approach is called a *sampled system*.

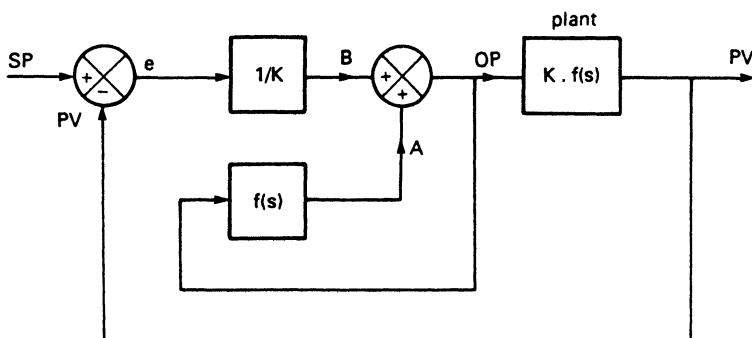

Figure 13.81 The inverse plant model

### 13.28.2 Shannon's sampling theorem

A sampled system only knows about the values of its samples. It cannot infer any other information about the signals it is dealing with. An obvious question, therefore, is what sample rate we should choose if our samples are to accurately represent the original analog signals.

In *Figure 13.82(a)* a sine wave is being sampled at a relatively fast rate. Intuitively one would assume this sampling rate is adequate. In *Figure 13.82(b)* the sample rate and the

frequency are the same. This is obviously too slow as the samples imply a constant unchanging output.

In *Figure 13.82(c)* the sample rate is lower than the frequency and the sample values are implying a sine wave of much lower frequency than the signal. This is called '*aliasing*'. A visual effect of aliasing can be seen on cinema screens where moving wheels often appear to go backwards. This effect occurs because the camera samples the world at about 50 times per second.

(a) Good sampling

(b) Sample rate too slow

(c) Aliasing

**Figure 13.82** The effect of the sampling rate: (a) good sampling rate; (b) sampling frequency same as signal frequency, too slow; (c) sampling rate much too slow, aliasing is occurring

Any continuous signal will have a bandwidth of interest. The sampling frequency should be at least twice the bandwidth of interest. This is known as *Shannon's sampling theorem*. Any real life system will not, however, have a well defined bandwidth and sharp cut-off point. Noise and similar effects will cause any real signal to have a significant component at higher frequencies. Aliasing may occur with these high frequency components and cause apparent variations in the frequency band of interest. Before sampling, therefore, any signal should be passed through a low pass *anti-aliasing filter* to ensure only the bandwidth of interest is sampled.

Most industrial control signals have a bandwidth of a few Hz, so sampling within Shannon's limit is usually not a problem. Normally the critical bandwidth is not known precisely so a sample rate of about 5 to 10 times the envisaged bandwidth is used.

### 13.28.3 Control algorithms

To achieve three term control with sampled signals we must find the derivative and the integral of the error. As shown on *Figure 13.83* we are dealing with a set of sampled signals,  $y_n, y_{n-1}, y_{n-2}$  etc. where  $y_n$  is the most recent. If the sample time is  $\Delta t$ , the slope is then given by:

$$\text{slope} = \frac{y_n - y_{n-1}}{\Delta t}$$

Integration is equivalent to finding the area under a curve as shown for an analog and digital signal on *Figure 13.83(b)*. The trapezoid integration of *Figure 13.83(c)* is commonly used where the area is given by:

$$\text{area} = \frac{\Delta t (y_n + y_{n-1})}{2}$$

Combining these gives a digital sampled PID algorithm

$$O_P = K \left( e_n + \frac{1}{T_i} \sum \frac{\Delta t (e_n + e_{n-1})}{2} + \frac{T_d}{\Delta t} (e_n - e_{n-1}) \right)$$

where  $e_n$  is the error for sample  $n$  and  $\Delta t$  the sample time as before.

## 13.29 Auto-tuners

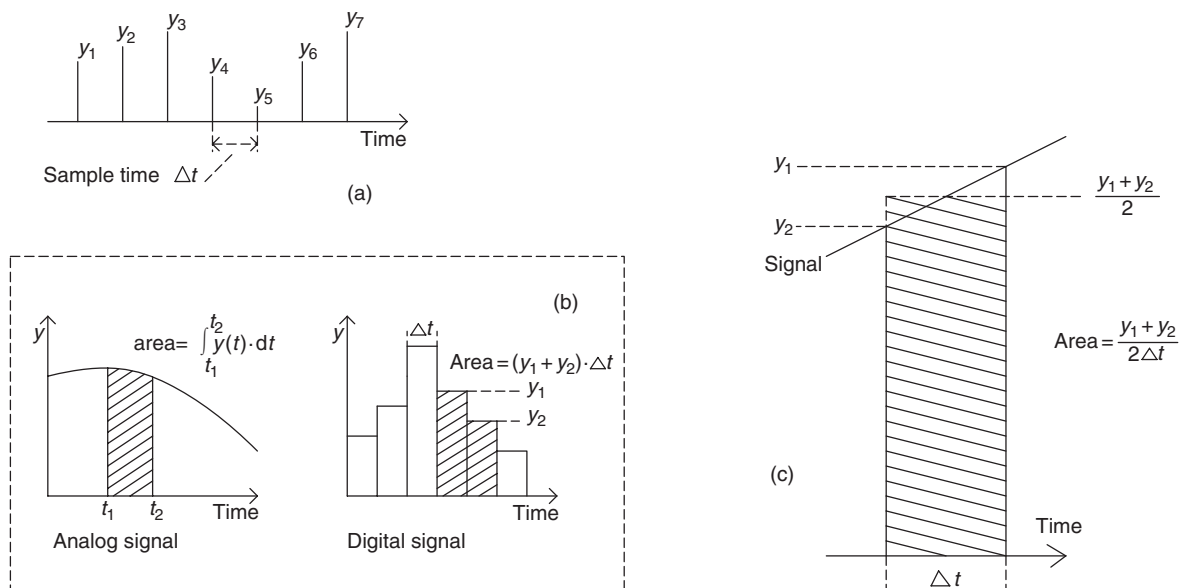

Tuning a controller is more of an art than an exact science and can be unbelievably time consuming. Time constants of tens of minutes are common in temperature loops, and lags of hours occur in some mixing and blending processes. Performing, say, the ultimate cycle test of Section 13.30.2 on such loops can take several days.

Self tuning controllers aim to take the tedium out of setting up a control loop. They are particularly advantageous if the process is slow (i.e. long time constants) or the loop characteristics are subject to change (e.g. a flow control loop where pressure/temperature changes in the fluid alter the behaviour of the flow control valve.)

Self tuning controllers give results which are generally as good, if not slightly better, than the manual methods of Section 13.30 (possibly because self tuning controllers have more patience than humans!). In the author's experience, however, the results from a self tuner should be viewed as recommendations or initial settings in the same way as the results from the manual methods described in the following sections. One early decision to be made when self tuners are used is whether they should be allowed to alter control parameters without human intervention. Many engineers (of whom the author is one) view self tuners as commissioning aids to be removed before a plant goes into production.

There are essentially two groups of self tuners. *Modelling self tuners* try to build a mathematical model of the plant (usually second order plus transit delay) then determine controller parameters to suit the model. These are sometimes called *explicit self tuners*.

Model identification is usually based on the principles of *Figure 13.84*. The controller applies a control action  $O_P$  to the plant and to an internal model. The plant returns a

**Figure 13.83** Control algorithm with sampled signals: (a) the sampled signals; (b) integration for an analog and digital signal; (c) trapezoid integration

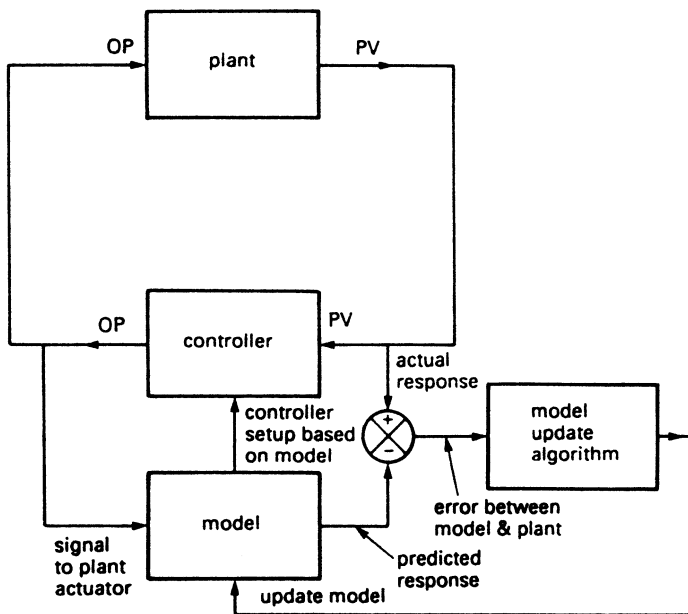

Figure 13.84 A modelling self tuning controller

process variable  $P_V$  and the model a prediction  $P_{Vm}$ . These are compared, and the model updated (often via the statistical least squares technique). On the basis of the new model, new control parameters are calculated, and the sequence repeated.

A model building self tuner requires actuation changes to update its model, so it follows that self tuners do not perform well in totally static conditions. In a totally stable unchanging loop, the model, and hence the control parameters, can easily drift off to ridiculous values. To prevent this, most self tuners are designed to 'kick' the plant from time to time, with the size and repetition rate of the kick being set by the control engineer. Less obviously, model building self tuners can be confused by outside disturbances which can cause changes in  $P_V$  that are not the result of the controller output.

The second group of self tuners (sometimes called *implicit tuners*) use automated versions of the manual tests described in Section 13.30, and as such do not attempt to model the plant. A typical technique will vary the controller gain until a damped oscillatory response is observed. The control parameters can then be inferred from the controller gain, the oscillation period and the oscillation decay rate.

The useful bang/bang test of Section 13.30.3 can be performed automatically by a controller which forces limit cycling in the steady state via a comparator. A limit block after the comparator restricts the effect on the plant.

Implicit self tuners, like their modelling brothers, do not perform well on a stable unchanging loop, and can be equally confused by outside disturbances.

## 13.30 Practical tuning methods

### 13.30.1 Introduction

Values must be set for the gain and integral/derivative times before a controller can be used. In theory, if a plant model is

available, these values can be determined from Nichols charts or Nyquist diagrams. Usually, however, the plant characteristics are not known (except in the most general terms) and the controller has to be tuned by experimental methods.

It should be noted that all these methods require pushing the plant to the limit of stability. The safety implications of these tests must be clearly understood. Tuning can also be very time consuming. With large chemical plants tuning of one loop can take days.

Most of the tests aim to give a quarter cycle decay and assume the plant consists of a transit delay in series with a second order block (or two first order lags) plus possible integral action.

In conducting the tests, it is useful to have a two pen recorder connected to the  $P_V$  (process variable) and  $O_P$  (controller output) as shown in Figure 13.85. The range of the pens (e.g. 0–10 V or 1–5 V) should be the same.

In the tests below, the gain is expressed as proportional band ( $P_B$ ) per cent. Time is used for integral and derivative

Figure 13.85 Suggested equipment setup for controller tuning

action. Conversion to gain or repeats per minute is straight-forward.

### 13.30.2 Ultimate cycle methods

The basis of these methods is determining the controller gain which just supports continuous oscillation, i.e. point *A* and gain *K* on the Nichols chart and Nyquist diagram of *Figure 13.86*. The method is based on work by J. G. Ziegler and N. B. Nichols and is often called the Ziegler Nichols method.

The integral and derivative actions are disabled to give proportional only control, and the control output manually adjusted to bring  $P_V$  near the required value. Auto control is selected with a low gain.

Step disturbances are now introduced and the effect observed. One way of doing this is to go back into manual, shift  $O_P$  by, say 5%, then reselect automatic control. At each trial the gain is increased. The increasing gain will give a progressively underdamped response and eventually continuous oscillation will result. Care must be taken in these tests to allow all transients to die away before each new value of gain is tried.

If the value of gain is too high, the oscillations will increase. The value of gain which gives constant oscillations neither increasing or decreasing is called the ultimate gain, or  $P_u$  (expressed as proportional band). The period of the oscillations  $T_u$  should also be noted from the chart recorder (or with a watch).

The required controller settings are:

Proportional only control

$$P_B \quad 2P_u \%$$

PI Control

$$\begin{array}{l} P_B \quad 2.2P_u \% \\ T_i \quad 0.8.T_u \end{array}$$

PID Control

$$\begin{array}{l} P_B \quad 1.67 . P_u \% \\ T_i \quad T_u/2 \\ T_d \quad T_u/8 \end{array}$$

$T_i = 4.T_d$  is a useful rule of thumb.

Other recommended settings for a PID controller are:

$$\begin{array}{l} P_B \quad 2P_u \% \\ T_i \quad T_u \\ T_d \quad T_u / 5 \end{array}$$

**Figure 13.86** Basis of the ultimate cycle test. Point A determines the frequency at which continuous oscillations will occur when gain *K* is applied: (a) Nichols chart; (b) Nyquist diagram

and

$$\begin{array}{l} P_B \quad 2P_u \% \\ T_i \quad 0.34T_u \\ T_d \quad 0.08T_u \end{array}$$

All of these values should be considered as starting points for further tests.

### 13.30.3 Bang/bang oscillation test

This is the fastest, but most vicious, test. It can, though, be misleading if the plant is non linear. Integral and derivative actions are disabled and the controller gain set as high as possible (ideally infinite) to turn the controller into a bang-bang controller. The controller output is set manually to bring the process value near the set point then the controller switch into automatic mode.

Violent oscillations will occur as shown on *Figure 13.87*. The period of the oscillations  $T_o$  is noted along with the peak to peak height of the process variable oscillations as a percentage  $H_o\%$  of full scale.

The required controller settings are:

Proportional control

$$P_B \quad 2.H_o\%$$

PI Control

$$\begin{array}{l} P_B \quad 3.H_o\% \\ T_i \quad 2.T_o \end{array}$$

PID Control

$$\begin{array}{l} P_B \quad 2.H_o\% \\ T_i \quad T_o \\ T_d \quad T_o/4 \end{array}$$

### 13.30.4 Reaction curve test

This is an open loop test originally proposed by American engineers Cohen and Coon. It assumes the plant consists of a measurable transit delay and a dominant time constant. It cannot be applied to plants with integral action (e.g. level control systems).

A chart recorder must be connected to the plant as shown earlier on *Figure 13.85* to perform the test. The controller output is first adjusted manually to bring the plant near to the desired operating point. After the transients have died away a small manual step  $\Delta O_P$  is applied which results in a small change  $\Delta P_V$  as shown on *Figure 13.88*.

The process gain  $K_p$  is then simply  $\Delta P_V / \Delta O_P$ .

Figure 13.87 The bang-bang oscillation test

Figure 13.88 The reaction curve test

A tangent is drawn to the process variable curve at the steepest point from which an apparent transit delay  $T_t$  and time constant  $T_c$  can be read. The settings for the controller are then given by:

Proportional  
 $P_B = 100.K_p.T_t/T_c \%$

PI  
 $P_B = 110.K_p.T_t/T_c \%$   
 $T_i = 3.3 T_t$

PID  
 $P_B = 80.K_p.T_t/T_c \%$   
 $T_i = 2.5 T_t$   
 $T_d = 0.4 T_t$

Because the test uses an open loop trial with a small change in the controller output it is the gentlest and least hazardous tuning method.

### 13.30.5 A model building tuning method

The closed loop tuning methods described so far require the plant to be pushed to, (and probably beyond), the edge of instability in order to set the controller. An interesting gentle tuning method was described by Yuwana and Seborg in the journal *AIChE* Vol 28 no 3 in 1982.

The method assumes the plant has gain  $K_M$  and behaves as a dominant first order lag  $T_M$  in series with a transit delay  $D_M$ . This assumption can give gross anomalies with plants with integral action such as level or position controls, but is commonly used for many manual and automatic/adaptive controller tuning methods. With the above warning noted, the suggested controller settings can be found from:

$$K = A(D_M/T_M)^{-B}/K_M$$

$$T_I = C T_M (D_M/T_M)^D$$

$$T_D = E (D_M/T_M)^F$$

where A, B, C, D, E, F are constants defined:

Mode	A	B	C	D	E	F
P	0.490	1.084				
PI	0.859	0.997	1.484	0.680		
PID	1.357	0.947	1.176	0.738	0.381	0.99

These apparently random equations and constants come from experimental work described by Miller *et al* in *Control Engineering* Vol 14 no 12.

The method of finding the plant gain, time constant and transit delay is based on a single quick test with the plant operating under closed loop control. The test is performed on the plant operating under proportional only control, with a gain sufficient to produce a damped oscillation as *Figure 13.89* when a step change in set point from  $R_0$  to  $R_1$  is applied.

The subsequent process maximum  $C_{P1}$ , minimum  $C_{M1}$  and next maximum  $C_{P2}$  are noted along with the time  $D_{T2}$  between  $C_{P1}$  and  $C_{P2}$ . The controller proportional band used for the test,  $P_B$ , is also recorded, from which the controller gain  $K_{PB} = 100/P_B$  is found.

Given the values from the test the method estimates the value of the plant steady state gain  $K_M$ , lag time constant  $T_M$  and the transit delay time  $D_M$ . The background mathematics is given at length in the original paper.

**Figure 13.89** Test performed for model building tuning test. Note that  $R_0$  and  $C_0$  need not be the same and  $DR$  can be positive or negative

The equations above are not very practical for manual use on site, so the original paper was developed into a program for the Hewlett Packard HP-67 calculator by Jutan and Rodriguez and published in the magazine *Chemical Engineering* September 1984. The nomenclature used in the above equations is based on this article.

### 13.30.6 General comments

The above test procedures do not give guaranteed results and should be viewed as a method of putting the engineer in the right area. They should be viewed as the starting point for further trials. The important thing in these trials is only change one thing at once.

With values set as above the effect of changing the gain should be tried first. It is always useful to have the proportional gain as high as possible to give the largest initial control action to changes and disturbances. However, a large gain can give undesirable changes in the controller output if the process variable is noisy. The gain should be adjusted to give the desired overshoot and damping.

Integral action should be adjusted next to give best removal of offset error. During these trials it is best to disable any derivative action. Decreasing the integral time reduces the time taken to remove the offset error. It may be necessary to reduce the gain again as integral time is decreased. A useful rule of thumb is that the ratio of  $T_i/\text{Gain}$  is an 'index' of stability for a given system, i.e. a  $T_i$  of 12 sec and a gain of 2 will give a similar damping to a  $T_i$  of 24 sec and a gain of 4.

The derivative action should be adjusted last. Many systems do not benefit from derivative action, particularly those with a noisy process variable signal which causes large controller output swings. Where derivative action is required,  $T_d = T_i/4$  is a good starting point. Many controllers allow the user to select derivative action on error or derivative action on process variable. The former is best for tracking systems, but gives large controller output swings for step changes in the set point. Derivative action on process variable is usually the best choice.

One final observation, based on experience rather than theory, is that a  $P_B$  of 200% (gain of 0.5),  $T_i$  of 20 sec and no derivative action is a good starting point for a majority of plants. Adjust the gain to give the required overshoot then adjust  $T_i$  to be as small as possible. Finally set  $T_d$ , if needed, to  $T_i/4$ .

## 14.1 Introduction

### 14.1.1 Analog and digital circuits

Signals in process control are conventionally transmitted as a pneumatic pressure or electrically as a voltage or current. These signals are said to be continuously variable in that they can take any value between the two extreme limits. Such systems are called analog systems.

Digital circuits are concerned with signals that can only take certain values. Most digital circuits deal with electrical signals that can only have two values; 5 V or 0 V for example. Many circuits are inherently of this type, a light can be on or off, a valve open or shut, a motor running or stopped.

### 14.1.2 Types of digital circuits

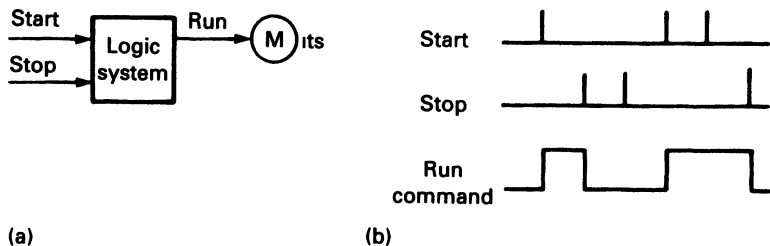

Digital applications can, in general, be classified into three types. The simplest of these are called *combinational logic* (or *static logic*), and can be represented by Figure 14.1. Such systems have several digital inputs and one or more digital outputs. The output states are uniquely defined for every combination of input states, and the same input combination always gives the same output states.

A *sequencing logic* system is superficially similar to Figure 14.1 but the output states depend not only on the inputs but also on what the system was doing last (i.e. its previous state). Sequencing systems therefore have memory and storage elements. A very simple example is the motor starter of Figure 14.2(a). The start input causes the motor to start running and keep running even when the start signal is removed. The stop input stops the motor. The action is summarised on Figure 14.2(b). Note that with neither signal present the motor could be running or stopped dependent on which signal occurred last; i.e. the output state is not defined solely by the present input states.

The final group of digital systems uses digital signals to represent, and manipulate, numbers. Such systems cover the range from simple counters and digital displays to complex arithmetic and computing circuits.

**Figure 14.1** Representation of a combinational logic system. The output states are defined only by the input state

**Figure 14.2** A simple sequencing system: (a) representation of a start/stop motor starter; (b) operation, the output depends not only on the input state, but also on the last operation

### 14.1.3 Logic gates

The simplest digital device is the electromagnetic relay, and it is useful to describe some of the fundamental ideas in terms of relay contacts. In Figure 14.3(a), the coil *Z* will energise when contact *A* and contact *B* and contact *C* are made. The series connection of contacts performs an AND function.

Similarly, in Figure 14.3(b) the coil *Z* will energise when contact *A* or contact *B* or contact *C* are made. The parallel connection of contacts performs an OR function.

In Figure 14.3(c), coil *Z* is energised when the push button is pressed. A normally closed contact of *Z* controls coil *Y*. When *Z* is energised, *Y* is de-energised and vice versa. The normally closed contact can be said to invert the state of its coil.

**Figure 14.3** Simple relay logic: (a) AND combination, relay *Z* is energised when *A* & *B* & *C* are all energised; (b) OR combination, relay *Z* is energised if *A* or *B* or *C* is energised; (c) Inversion, relay *Y* is energised when *PB1* is not made

Combinational logic circuits are built round combinations of AND, OR and INVERT circuit. In *Figure 14.4(a)*, for example,  $Z$  will be energised for:

( $A$  not energised) AND ( $B$  energised OR  $C$  energised)

Such verbal descriptions are impossibly verbose for more simplex combinations. Circuit operations are more conveniently expressed as an equation. Normally closed contacts are represented by a bar over the top of the contact name (e.g.  $\bar{A}$ , verbalised as  $A$  bar). The circuit of *Figure 14.4(a)* can then be represented as:

$$Z = \bar{A} \text{ AND } (B \text{ OR } C) \Leftarrow$$

Similarly the circuit of *Figure 14.4(b)* (commonly used for stairwell lighting) can be represented by:

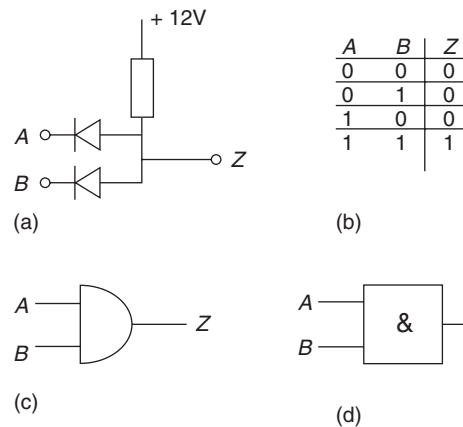

$$Z = (A \text{ AND } \bar{B}) \text{ OR } (\bar{A} \text{ AND } B) \Leftarrow$$

These are known as Boolean equations, a topic discussed further in Section 14.3.3.

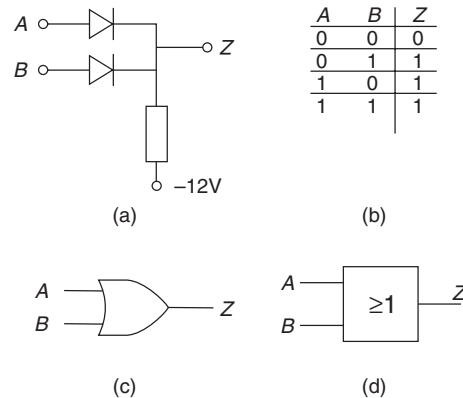

Relays can perform all logic functions but are slow (typically 10 to 20 operations per second), bulky and power hungry. Electronic circuits performing similar functions are called logic gates. These work with signals that can only have two states. A signal in CMOS logic, for example, can be at 12 V or 0 V and could represent a limit switch made or open. The two logic states can be called high/low, on/off, true/false and so on. The usual convention, however, is to call the higher voltage '1' and the lower voltage '0'. For a CMOS gate, therefore, 12 V is 1 and 0 V is 0.

*Figure 14.5(a)* shows the circuit of a simple AND gate. Neglecting diode drops, the output  $Z$  will be equal to the lower of the two input voltages. In other words, it will be a 1 if, and only if, both inputs are 1. This can be represented by *Figure 14.5(b)* (which is called a *truth table*). On circuit diagrams it is clearer to use logic symbols rather than the actual circuit diagram. The symbol for an AND gate is shown on *Figure 14.5(c)*; the output  $Z$  being 1 when  $A$  AND  $B$  are both 1.

On *Figure 14.6(a)* the output  $Z$  will be equal to the higher of the two inputs (again neglecting diode drops).  $Z$  will therefore be 1 if either input is 1 giving the truth table of

**Figure 14.5** A simple diode based AND Gate: (a) circuit; (b) truth table; (c) logic symbol; (d) BS logic symbol

**Figure 14.6** A simple diode based OR gate: (a) circuit; (b) truth table; (c) logic symbol; (d) BS logic symbol

**Figure 14.4** More complex relay logic: (a)  $Z$  is energised when ( $A$  is not energised) AND ( $B$  is energised OR  $C$  is energised); (b) Stairwell lighting circuit.  $A$  and  $B$  are the switches at the top and bottom of the stairs. Changing either switch will change the state of relay  $Z$

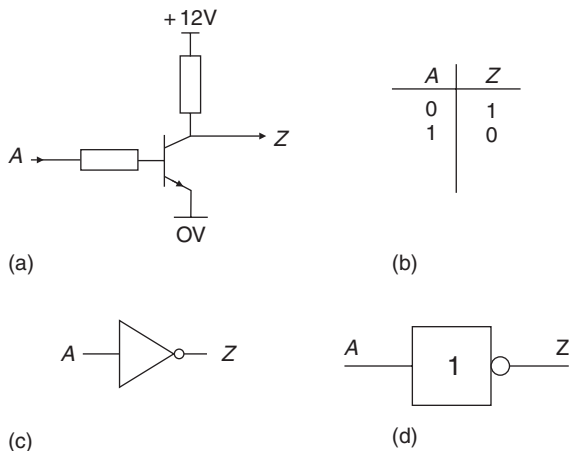

*Figure 14.6(b)*. The logic symbol for an OR gate is shown on *Figure 14.6(c)*.

The invert function is given by the simple saturating transistor of *Figure 14.7(a)*. When  $A$  is 0, the transistor is turned off and the output  $Z$  is pulled to a 1 state by the collector load resistor. When  $A$  is 1, the transistor is saturated on taking  $Z$  to 0 V; a 0. The circuit behaves as the truth table of *Figure 14.7(b)* and has the logic symbol of *Figure 14.7(c)*.

Combinational logic circuits can be drawn purely in terms of AND gates, OR gates and inverters. The stairwell lighting circuit of *Figure 14.4(b)* is drawn with logic symbols on *Figure 14.8(a)*. This behaves as the truth table of *Figure 14.8(b)* which shows that  $Z$  is 1 if only one input is 1. This circuit is known as an Exclusive OR and is sufficiently common to merit its own logic symbol shown on *Figure 14.8(c)*.

If an inverter is used after an AND gate as *Figure 14.9(a)*, the truth table of *Figure 14.9(b)* is produced. This arrangement is called a NAND gate (for NOT-AND) and has the logic symbol of *Figure 14.9(c)*. The NAND gate is probably the commonest logic gate.

Adding an inverter to an OR gate as *Figure 14.10(a)* gives the truth table of *Figure 14.10(b)*. This is known as a NOR gate (for NOT-OR) and is given the logic symbol of *Figure 14.10(c)*.

**Figure 14.7** A transistor inverter: (a) circuit; (b) truth table; (c) logic symbol; (d) BS logic symbol

Note that the logic symbols for NAND/NOR gates are similar to those of the AND/OR gates with the addition of a small circle on the output. The circle denotes an inversion operation.

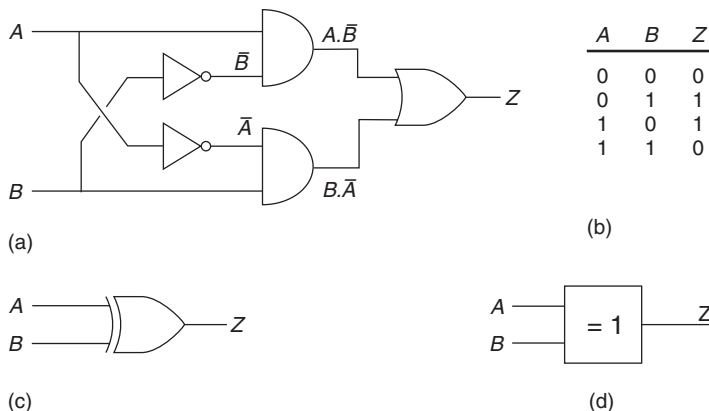

## 14.2 Logic families

### 14.2.1 Introduction

Most logic circuits are constructed from integrated circuits, and have high operating speed and well defined levels. Two logic families (TTL and CMOS) are widely used in industrial applications and a third family (ECL) may be encountered where very high speed is required. Before these are described, we must first examine how the various factors of a logic gates performance are specified.

### 14.2.2 Speed

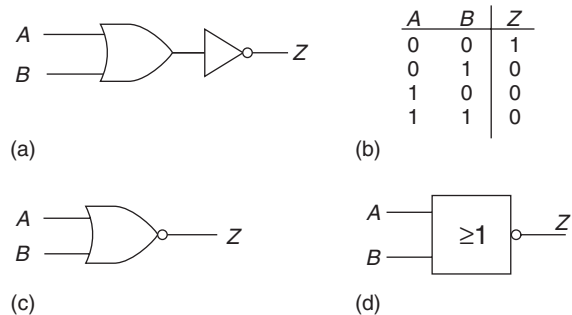

A logic gate does not respond instantly to a change at its input. For infinitely fast input signals the output will be delayed and the edges slowed as shown on *Figure 14.11*.

**Figure 14.8** An Exclusive OR (XOR) gate: (a) circuit; (b) truth table; (c) logic symbol; (d) BS logic symbol

**Figure 14.9** A NAND gate: (a) circuit; (b) truth table; (c) logic symbol; (d) BS logic symbol

**Figure 14.10** A NOR gate: (a) circuit; (b) truth table; (c) logic symbol; (d) BS logic symbol

The delay is called the *propagation delay* and is defined from the mid point of the input signal to the mid point of the output signal. Typical values are around 5 nS for TTL.

The edge speeds are defined by the *rise time* (for the 0 to 1 edge) and the *fall time* (for the 1 to 0 edge). These are measured between the 10% and 90% points of the output signal. Typical values are 2 nS for TTL.

Propagation delays and rise/fall times determine the maximum speed at which a logic family can operate. TTL can operate in excess of 10 MHz, basic CMOS around 5 MHz and ECL at over 500 MHz (although considerable care needs to be taken with board layout at speeds over 10 MHz).

**Figure 14.11** Speed definitions: (a) propagation delay ( $t_{pd}$ ); (b) rise and fall times ( $t_r$  and  $t_f$ )

Power consumption is related to speed, as increased speed is obtained by reducing RC time constants formed by stray capacitance, and by using non saturating transistors. CMOS, for example, has a power consumption of about 0.01 mW per gate compared with ECL's figure of 60 mW/gate.

### 14.2.3 Fan in/fan out

The output of a logic gate can only drive a certain load and remain within specification for speed and voltage levels. There is therefore a maximum number of gate inputs a given gate output can drive. A simple gate input is called a *standard load*, and is said to have a *fan in* of one. A gate output's drive capability is called its *fan out*, and is defined in unit loads. A TTL gate output, for example, can drive ten standard gate inputs and correspondingly has a fan out of ten.

Some inputs appear as a greater load than a standard gate. These are defined as a fan in of an equivalent number of standard gate inputs. An input with a fan in of three, for example, looks like three gate inputs. Obviously the sum of all the fan in loads connected to a gate output must not exceed the gate's fan out.

### 14.2.4 Noise immunity

Electrical interference may cause 1 signals to appear as 0 signals and vice versa. The ability of a gate to reject noise is called its *noise immunity*. Defining noise immunity is more complex than it might at first appear, but the method usually adopted is that shown on *Figure 14.12(a)*. The voltages given are those for a TTL gate which has a nominal 1 V of 4.5 V and a nominal 0 V of 0 V.

Next we define how far an output 1 can fall to (2.4 V) and a 0 rise to (0.4 V). These are respectively termed  $V_{OH}$  and  $V_{OL}$ . Finally we define how low a gate's input 1 can fall and an input 0 rise without allowing its output to go between  $V_{OH}$  and  $V_{OL}$ . These voltages are called  $V_{IH}$  (2.0 V) and  $V_{IL}$  (0.8 V). The noise immunity is then the smaller of  $(V_{OH} - V_{IH})$  or  $(V_{IL} - V_{OL})$ . For TTL the figure is 0.4 V. This is a worse case value, a more typical noise immunity is about 1.2 V.

A figure sometimes quoted is the *AC noise margin*. This is defined as the largest pulse that will not propagate down a chain of gates similar to *Figure 14.12(b)*. This gives a more favourable result than *Figure 14.12(a)*, but is a more realistic test.

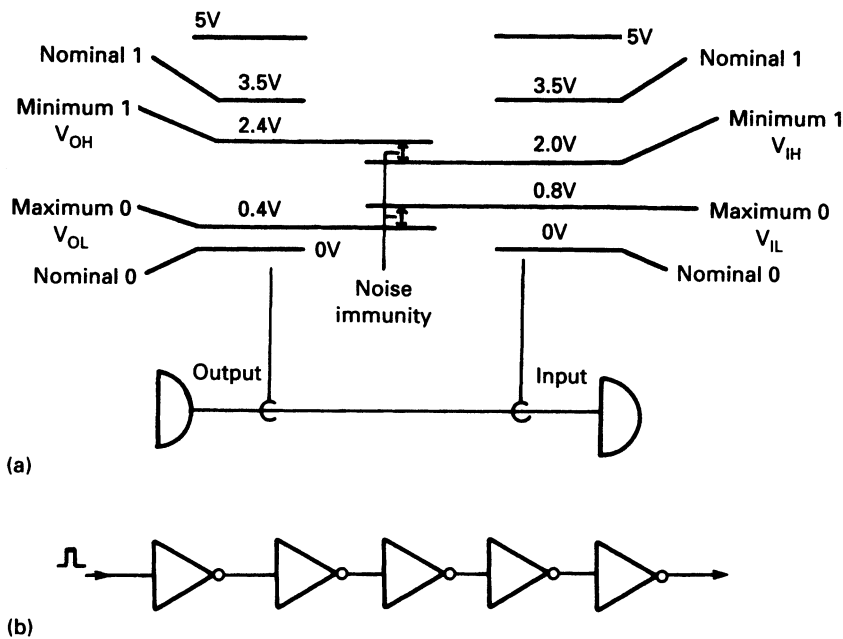

### 14.2.5 Transistor transistor logic (TTL)

TTL is NAND based logic, with the circuit of a 2 input NAND gate being shown on *Figure 14.13*. The rather odd looking dual emitter transistor can be considered as two transistors in parallel or three diodes as shown.

If both inputs are high,  $Q_2$  is turned on by current from  $R_1$  supplying base current to  $Q_3$ . The output is therefore nominally 0 V. With either input low,  $Q_1$  is turned on,  $Q_2$  turned off and  $Q_4$  pulls the output high to a nominal 4.5 V.

The output transistors  $Q_3$ ,  $Q_4$  are called a *totem pole output* and play a significant part in increasing the operating speed. When the output is a 0,  $Q_3$  acts as a saturated transistor. When the output is a 1,  $Q_4$  acts as an emitter follower. Both states have low output impedances which reduce RC time constants from stray capacitance.

There are at least six versions of TTL with differing speeds and power consumption. Schottky versions (with S as part of the suffix) use Schottky diodes within the gate to reduce hole

**Figure 14.12** Definitions of noise immunity: (a) D.c. noise margin. The voltages shown are for standard TTL; (b) A.c. noise immunity. The test sees what is the smallest pulse amplitude that will propagate through the chain

**Figure 14.13** Transistor transistor logic (TTL) circuit diagram the multi-emitter transistor can be considered to act as two transistors in parallel or three diodes

storage delays. All TTL are members of the so called 74 series (originally conceived by Texas Instruments) and have the same pin arrangements on the ICs. They can also be intermixed although care must be taken because of the different input loadings and output capability (an LS gate input, for example, looks like half a normal gate input). All run on a 5 V supply and use nominal logic levels of 4.5 V and 0 V.

#### 14.2.6 Complementary metal oxide semiconductor (CMOS) logic

CMOS is virtually the ideal logic family. It can operate on a wide range of power supplies (from 3 to 15 V), uses little power (approximately 0.01 mW at low speeds), has high noise immunity (about 4 V on a 12 V supply) and very large fan out (typically in excess of 50). It is not as fast as

TTL or ECL but its maximum operating speed of 5 MHz is adequate for most industrial purposes. (Too high a maximum speed can actually be a disadvantage as it makes a system more noise prone.)

CMOS is built around the two types of field effect transistors shown on *Figure 14.14*. From a logic point of view these can be considered as a voltage operated switch. These switches can be used to manufacture logic gates.

*Figure 14.15(a)* shows how an inverter can be implemented. With *A* low, *Q*<sub>1</sub> is turned on and *Q*<sub>2</sub> off. With *A* high *Q*<sub>2</sub> is turned on and *Q*<sub>1</sub> off.

Similarly a NAND gate can be constructed as *Figure 14.15(b)*. If *A* or *B* is low, *Z* will be high because one of the parallel pair *Q*<sub>1</sub>, *Q*<sub>2</sub> will be on, and one of the series pair *Q*<sub>3</sub>, *Q*<sub>4</sub> will be off. The output *Z* will be low only when both *A* and *B* are high when *Q*<sub>1</sub>, *Q*<sub>2</sub> are both off and *Q*<sub>3</sub>, *Q*<sub>4</sub> are both on.

Figure 14.14 Metal oxide semiconductor (MOS) transistors: (a) *n* channel; (b) *p* channel

Figure 14.15(c) shows a CMOS NOR gate. If *A* or *B* is high, one of  $Q_3$  or  $Q_4$  will be on taking the output *Z* low (with one of  $Q_1$ ,  $Q_2$  off). When both *A* and *B* are low,  $Q_1$ ,  $Q_2$  will both be on and  $Q_3$ ,  $Q_4$  off taking the output high.

The high input impedance of FETs can present handling problems, and early devices could be irreparably damaged by static electricity from, say, nylon clothing or leakage currents from unearthened soldering irons. Modern CMOS now includes protection diodes and can be treated like any other component.

Another effect of the high input impedance is the tendency for unused inputs to charge to an unpredictable voltage. All CMOS inputs must go somewhere; even unused inputs on unused gates on multigate packages must go to a supply rail thereby forcing a 1 or 0 state.

CMOS is generally sold in the so called 4000 series which is a rationalisation of the original RCA COSMOS and Motorola McMOS ranges. 'B' suffix CMOS denotes buffered signals and improved protection; needless to say the B devices are better suited for industrial systems.

### 14.2.7 Emitter coupled logic (ECL)

ECL is the fastest commercially available logic family, and with care it can operate at 500 MHz. At these speeds,

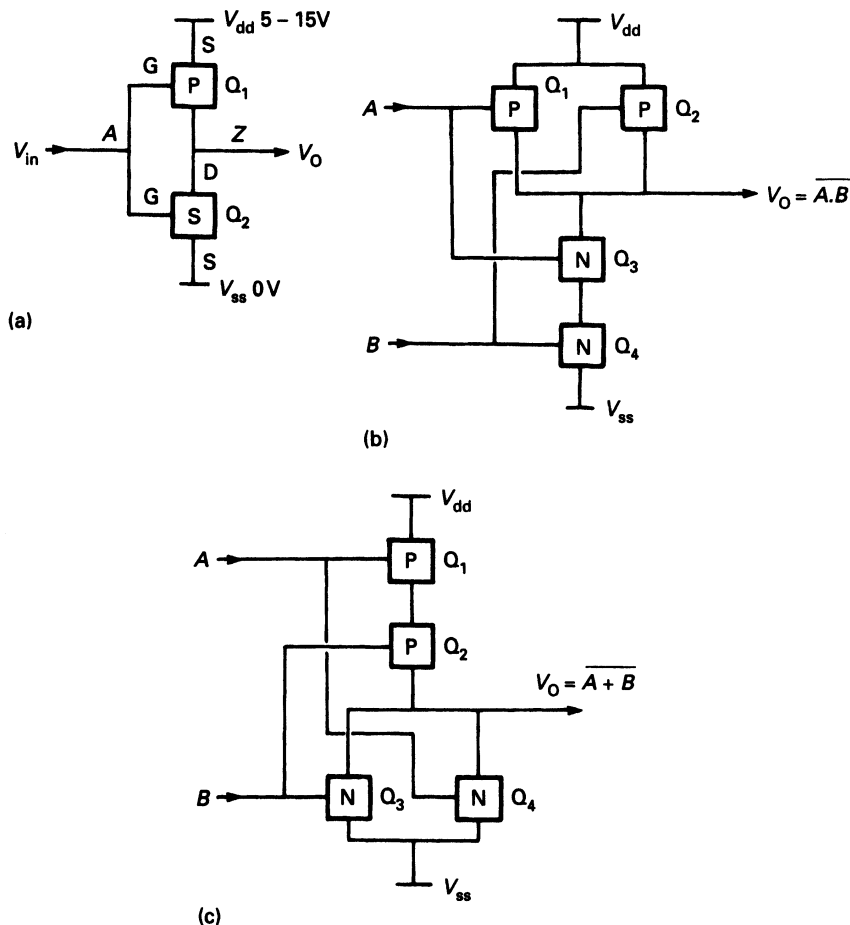

Figure 14.15 Complementary metal oxide semiconductor (CMOS) logic gates: (a) NAND gate; (b) NOR gate

however, extreme care needs to be taken with the circuit board layout to avoid crosstalk and power supply induced noise. ECL obtains its speed from the use of non saturating transistors and high power levels (around 60 mW per gate compared with CMOS figure of 0.01 mW). The logic levels in ECL are  $-0.8$  V and  $-1.6$  V (giving a rather poor noise immunity of 0.25 V). ECL is very fast, but its odd voltage levels, strict wiring and power supply requirements and poor noise immunity preclude its use in industrial applications except where very high speed is needed.

### 14.2.8 Open collector and tri-state outputs

The TTL NAND gate of *Figure 14.16(a)* has a single output transistor rather than the usual totem pole output. The output is connected to  $V_{cc}$  by an external pull up resistor. This is known as an open collector output. In *Figure 14.16(b)* the outputs of several open collector gates are connected in parallel with a single pull-up resistor. A half circle on the gate output symbol is often, but by no means universally, used to show an open collector output. The output  $Z$  will be high if, and only if, all the parallel gates have high outputs. Using positive logic conventions the paralleled outputs provide a positive AND function on the outputs of the input gates.

Another description of the operation is the output  $Z$  will be low if any of the outputs are low. This will occur if ( $A$  and  $B$  are high) OR ( $C$  and  $D$  are high) OR ( $E$  and  $F$ ) are high. The linking of collectors can be considered to perform a negative OR function on the outputs of the input gates and can give a possibly complex function for the cost of a single pull up resistor. Its main disadvantage is a poor rising edge (caused by the RC time constant of the pull up resistor and stray capacitance) and a slight degradation of noise immunity.

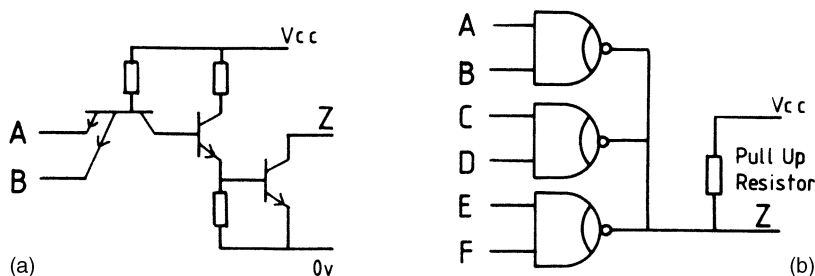

Open collector gates are a possible solution for applications where many devices communicate via a bus system, the backplane of a computer is a typical application. A more common approach for bus systems though is the tri-state gate. Strictly speaking tri-state is a registered trade mark of National Semiconductors. The term tri-state is a bit of a misnomer as the gate does not have three logic levels but rather three logic states: high, low and disconnected. A tri-state gate has normal inputs plus a separate control input which enables the gate or puts the output into a high impedance (disconnected) state. *Figure 14.17(a)* shows the symbol for a tri-state two input NAND gate and *Figure 14.17(b)* shows three tri-state buffers which are used to route data from  $A$ ,  $B$  or  $C$  to output  $Z$  as selected by control inputs  $L$ ,  $M$  or  $N$ . It should be noted that this is fundamentally different from the wire AND open collector circuit of *Figure 14.16*.

### 14.2.9 Schmitt triggers

Many logic elements require fast edges to operate correctly. Edges can be degraded for a variety of reasons; stray capacitance or a non digital device for example. The Schmitt trigger always gives fast edges on its output signals regardless of the edge speed of the input signals.

The transfer function of a conventional gate is shown on *Figure 14.18(a)*. The transfer function of a Schmitt trigger incorporates hysteresis and is shown on *Figure 14.18(b)*. *Figure 14.18(d)* shows a slow changing input and the resulting output, which always has fast clean edges.

A Schmitt trigger has the conventional logic symbol with an added hysteresis loop similar to *Figure 14.18(c)*. Schmitt triggers are usually available in hex inverter or quad two input gate ICs. The 74123, for example, is a popular quad two input Schmitt trigger NAND gate.

**Figure 14.16** An open collector TTL NAND gate: (a) circuit diagram; (b) logic function using open collector gates. The linking of the collectors gives a positive AND or negative OR function depending on the interpretation of the logic states

**Figure 14.17** Tri-state gates: (a) tri-state NAND; (b) tri-state data selection

**Figure 14.18** The Schmitt trigger: (a) operation of a conventional inverter; (b) operation of an inverter with hysteresis; (c) logic symbol; (d) use of a Schmitt trigger to convert a slowly changing signal to a crisp digital signal

Comparison of *Figures 14.18(a)* and *14.18(b)* shows that a Schmitt trigger has better noise immunity than a conventional gate. They are therefore commonly used for interfacing to slow and possibly noisy signals from the outside world.

#### 14.2.10 Choosing a logic family

Until the latter part of the 1980s the designer really had to choose between TTL (with the low powered Shottky (LS) family being the popular choice) and CMOS. The latter was slower and had a much smaller range of devices, but had the advantages of very low power consumption, better noise immunity and a wide supply tolerance. Since then, though, there has been a tendency for the families to merge.

The trend started with the 74C series of CMOS which provided CMOS devices with the same pinning as TTL, but with CMOS B series electrical characteristics (slower than TTL, but with 3 to 15 V supply). These were useful, but the major impact was the introduction of the 74HC, 74AC, 74HCT and 74HCT families. These use improved technologies, were as

fast as TTL, and (as their name implies) they follow the 74 series pinning. Taking them in turn:

74AC is the high speed member of the family, capable of operating at speeds of 125 MHz. The voltage supply range is 3 to 6 V (essentially TTL with a wider tolerance), and the transfer characteristic is the standard CMOS near ideal symmetrical curve of *Figure 14.19(a)*.

74HC is a near replacement for LS TTL with an operating speed of 30 MHz. Other characteristics are similar to 74AC.

As mentioned earlier, the output levels of TTL, shown on *Figure 14.19(b)*, are approximately 0.5 V in the 0 state, and 4.5 V in the 1 state. Standard forms of TTL can, just, connect to 74AC or 74HC devices, but the resultant noise immunity is poor. Two further forms of CMOS were developed with a transfer function whose input side mimicked a TTL device. These are known as 74ACT (high speed version) and 74HCT (practically a direct replacement for LS TTL). These should NOT be viewed as a family to be used for a complete project, as to do so would give the poorer TTL noise immunity. They are, though, exceedingly useful when a circuit has to mix TTL and CMOS devices.

**Figure 14.19** Transfer functions for CMOS and TTL: (a) CMOS; (b) TTL and CMOS ACT/HCT

In CMOS, therefore, there is now:

Family	Supply	Speed (MHz)	Comments
4000B	3 to 15 V	2	Useful for battery circuits, slow, seems unlikely to develop further
74C	3 to 15 V	2	As 4000B with TTL pinning
74AC	2 to 6 V	125	Very fast. TTL pinning. Power rises with speed so normal CLOS low power may not be relevant. Care needed with layout
74HC	2 to 6 V	30	Designed as direct replacement for LS TTL (but with CMOS signal levels)
74ACT	2 to 6 V	125	As 74AC with TTL input levels
74HCT	2 to 6 V	30	As 74HC with TTL input levels

An interesting development is the view that the corner supply pins on TTL are not the best arrangement for power supply and ground noise, and there seems to be a move toward centre pinning on some high speed CMOS circuits.

There are four TTL families in common current use; LS, ALS, F and AS. It is worth listing these in tabular form:

Family	Speed (MHz)
74LS	25
74ALS	35
74F	100
74AS	105

All require a 5 V  $\pm$  0.25 V supply. The suffix in the above table appears as part of the device identification; a 74LS06, for example, is a low power Schottky gate.

Choosing a device is quite straightforward. First where there is little choice; for out and out speed use ECL (but remember the precautions needed to avoid noise). For high speed, use 74AC (but again take care with the layout).

Battery circuits are best designed with 4000B or 74C devices, the supply is less critical, and both will run on a 9 V battery until it is flat without the need of a regulator circuit. Being slower they are also less prone to noise.

For 'cooking' logic, 74HC seems best suited with a reasonable speed, lower power and better noise immunity than LS TTL. The only problem is an incomplete coverage of the TTL family at present (the useful 7490/92 counters are missing for example), so the odd LS or ALS TTL circuit may be needed, with 74HCT devices being used as interfaces between TTL and CMOS.

Figure 14.20 shows a comparison between these families.

## 14.3 Combinational logic

### 14.3.1 Introduction

Combinational logic is based around the block diagram of Figure 14.21(a). Such systems have several inputs and one, or more, outputs. The output states are uniquely defined for each and every combination of inputs and the 'block' does not contain any device such as storage, timers or counters. We therefore have  $n$  inputs  $I_1$  to  $I_n$  and  $Z$  outputs  $Q_1$  to  $Q_z$ . In systems with multiple outputs it is usually easier to consider each separately as Figure 14.21(b), allowing us to consider the circuit as  $Z$  blocks, each different but represented by Figure 14.21(c).

The number of possible input states depends on the number of inputs:

For two inputs there are four input combinations

For three inputs there are eight input combinations

For four inputs there are sixteen input combinations

Figure 14.20 Comparison of logic families operating at about 1 MHz

**Figure 14.21** Combinational logic block diagrams: (a) the generalised problem with  $n$  inputs and  $Z$  outputs; (b) problem split into  $Z$  independent circuits; (c) one of the  $Z$  circuits with a single output

and so on. Not all of these may be needed. There are frequently only a certain number of input combinations that may occur because of physical restrictions elsewhere in the system.

The design of combinational logic systems first involves examining all the input states that can occur and defining the output states that must occur for each and every input state. A logic design to achieve this is then constructed from the gates described in Section 14.1.3. In many systems the design can be done in an intuitive manner, but the rest of this section describes more formal design procedures.

Few real life systems need pure combinational logic, most need storage and similar dynamic functions. Such systems can be analysed and designed considering them as smaller subsystems linked together. The design of dynamic systems is discussed in Section 14.8.

A	B	C	Z	
0	0	0	0	
0	0	1	0	
0	1	0	0	
0	1	1	1	<-
1	0	0	0	
1	0	1	1	<-
1	1	0	1	<-
1	1	1	1	<-

It can be seen that  $Z$  is 1 for:

	$\bar{A}$ and $B$ and $C$
or	$A$ and $\bar{B}$ and $C$
or	$A$ and $B$ and $\bar{C}$
or	$A$ and $B$ and $C$

**14.3.2 Truth tables**

A truth table is a useful way of representing a combinational logic circuit, and can be used to design the circuit needed to achieve a desired function.

Suppose we have three contacts monitoring some event (overpressure in a chemical reactor for example) and we wish to construct a majority vote circuit. If the three switches are called  $A$ ,  $B$ ,  $C$  and the majority vote  $Z$  this would have the truth table:

The desired logic function can then be constructed directly from the truth table as *Figure 14.22*. In general, the circuit derives from a truth table will consist as a set of AND gates whose outputs are OR'd together. This form of circuit is known as a *Sum of Products* (see Section 14.4.3),

**Figure 14.22** Non minimal implementation of majority vote logic direct from the truth table

**Figure 14.23** Sum of products (AND/OR) logic implementation based solely on NAND gates: (a) required function; (b) NAND based circuit; (c) representation of a NAND gate; (d) circuit b redrawn in the style of representation c. The inverters cancel giving the required function

and one of the reasons for the popularity of NAND gates is that an  $s$  of  $p$  expression can be formed purely with NAND gates.

A truth table design always gives a design which works and is logically correct, but does not always give a circuit which uses the minimum combination of gates. To do this we need one of the other techniques described below.

Consider the expression

$$Z = (A \& B) \text{ OR } (C \& D)$$

This has the simple circuit of *Figure 14.23(a)*, which obviously fulfils the logic function. Consider, however, the totally NAND based circuit of *Figure 14.23(b)*. Straightforward, if laborious, testing of all possible sixteen input states will show that it behaves identically to *Figure 14.23(a)*. In some mysterious way, the right-hand NAND gate is behaving as an OR gate.

This rather surprising fact is a result of De Morgan's theorem, described in the next section. Intuitively, however, we can see the reason by drawing up the truth table for the OR gate preceded by inverters as *Figure 14.23(c)*:

A	B	Z
0	0	1
0	1	1
1	0	1
1	1	0

This is the same as a NAND gate, so a NAND gate can, with legitimacy, be drawn as *Figure 14.23(c)*.

The circuit of *Figure 14.23(b)* could now be drawn as *Figure 14.23(d)* with the ingoing NANDs drawn as ANDs followed by an inverter, and the outgoing NAND by the arrangement of *Figure 14.23(c)*. Obviously the intermediate inverters cancel, leaving the equivalent circuit of *Figure 14.23(a)*.

### 14.3.3 Boolean algebra

In the nineteenth century a Cambridge mathematician and clergyman George Boole, devised an algebra to express and manipulate logical expressions. His algebra can be used to represent, design and minimise combinational logic circuits.

The AND function is represented by a dot ( $\cdot$ ), so

$$Z = A \cdot B$$

means  $Z$  is 1 when  $A$  is 1 AND  $B$  is 1. Often the dot is omitted (e.g.  $Z = AB$ )

The OR function is represented by an addition sign ( $+$ ), so

$$Z = A + B$$

means  $Z$  is 1 when  $A$  is 1 OR  $B$  is 1.

The invert function is represented by a bar  $\neg$ , so

$$Z = \neg A$$

means  $Z$  takes the opposite state to  $A$ . Some sources use the  $\bar{A}$  to denote inversion so  $A$  and  $A'$  both mean the inverse of  $A$ .

Boolean algebra allows complex expressions to be written in a concise manner and can also be used to simplify expressions. To achieve this, a series of rules are used. The first eleven of these are self obvious (or can be visualised by considering the equivalent relay circuits).

- $A \cdot 1 = A$
- $A \cdot 0 = 0$
- $A + 1 = 1$
- $A + 0 = A$
- $A \cdot A = A$  (e and f are known as the *Idempotent laws*)
- $A + A = A$
- $\neg \neg A = A$  (known as the *Involution law*)
- $A \cdot \neg A = 0$  (h and i are known as the *Complementary laws*)
- $A + \neg A = 1$
- $A + B = B + A$  (j and k are known as the *Commutative laws*)
- $A \cdot B = B \cdot A$

The next two laws, called the *Associative laws*, allow us to group brackets around variables with the same operator

- $(A + B) + C = A + (B + C) = A + B + C$
- $(A \cdot B) \cdot C = A \cdot (B \cdot C) = A \cdot B \cdot C$

The next two laws are called the *Absorption laws*, and tell us what happens if the same variable appears with AND and OR operators

- $A + A \cdot B = A$
- $A \cdot (A + B) = A$

The next laws, called the *Distributive laws*, tell us how to factorise Boolean equations

- $A + B \cdot C = (A + B) \cdot (A + C)$
- $A \cdot (B + C) = A \cdot B + A \cdot C$

In general, Boolean expressions can be expressed in two forms. The first form, called *product of sums*, or P of S, brackets OR terms and ANDs the results for example:

$$Z = (A + \bar{B}) \cdot (B + C + D) \cdot (\bar{A} + \bar{D}) \Leftarrow$$

The second form, called *sum of products*, or S of P, groups AND terms and ORs the results, for example:

$$Z = (A \cdot B \cdot \bar{D}) + (\bar{B} \cdot C) + (A \cdot \bar{D}) \Leftarrow$$

Truth tables, described in Section 14.4.2, inherently give an S of P result.

The complementary function of a Boolean expression yields the inverse of the expression (i.e. where the expression yields 1, the complement yields 0). The expressions  $(A + B)$  and  $(\bar{A} \cdot \bar{B})$  for example, can be shown to be complementary by simply constructing their truth tables.

The last two laws, known as *De Morgan's theorem*, show how to form the complement of a given expression (and gives one way to interchange S of P and P of S forms).

$$(r) \quad \overline{(A + B)} = \bar{A} \cdot \bar{B}$$

$$(s) \quad \overline{(A \cdot B)} = \bar{A} + \bar{B}$$

In its formal representation, De Morgan's theorem appears rather daunting. It can be more easily expressed:

To form the complement of an expression

- (1) Replace each '+' in the original expression with '.' and vice versa.
- (2) Complement each term in the original expression.

For example, to complement the expression  $\bar{A} + B \cdot C$ :

Step 1, replace '+' by '.' and '.' by '+' giving:

$$\bar{A} \cdot (B + C) \Leftarrow$$

Step 2, complement each term

$$A \cdot (\bar{B} + \bar{C}) \Leftarrow$$

which is the result.

Boolean Algebra can be used to minimise logical expressions, but the method is rarely obvious, and it is easy to make errors with double bars and swapping of '.'s and '+'s. Minimisation by Boolean algebra makes good examination questions, but is rarely used in practice. An easier way to achieve minimisation is to use the graphical Karnaugh map, described below.

### 14.3.4 Karnaugh maps

A Karnaugh map is an alternative way of presenting a truth table. The map is drawn in two dimensions; two, three and four variable maps are shown on Figure 14.24.

Figure 14.24 Karnaugh maps: (a) two variable; (b) three variable; (c) four variable

Each square within the map represents one line on the truth table. For example:

square X represents  $A = 1, B = 0$  which can be written  $A \cdot \bar{B}$   
square Y represents  $A = 0, B = 1, C = 1$  which can be written  $\bar{A} \cdot B \cdot C$   
square Z represents  $A = 1, B = 0, C = 1, D = 0$  which can be written  $A \cdot \bar{B} \cdot C \cdot \bar{D}$

The essential feature of a Karnaugh map is the way in which the axes are labelled. It will be seen that only one variable changes for a move between any adjacent horizontal or vertical squares

The use of this feature is not immediately apparent, but consider Figure 14.25. This contains four terms giving a 1 output. These are:

$$A \cdot \bar{B} \cdot C \cdot \bar{D}, \quad A \cdot B \cdot C \cdot \bar{D}, \quad A \cdot \bar{B} \cdot C \cdot D, \quad A \cdot B \cdot C \cdot D$$

so we could write (quite correctly)

$$Z = A \cdot \bar{B} \cdot C \cdot \bar{D} + A \cdot B \cdot C \cdot \bar{D} + A \cdot \bar{B} \cdot C \cdot D + A \cdot B \cdot C \cdot D$$

Examination of the map, however, shows that the  $D$  variable and  $B$  variable can change state without affecting the output. The circled squares, in fact, represent  $AC$ , so the above expression can be simplified to

$$Z = AC$$

Groups of two adjacent cells on a three variable map represent some combination of TWO of the three variables. On Figure 14.26(a), groupings for  $A \cdot B$  and  $C \cdot \bar{B}$  are shown. This map represents

$$Z = \bar{A} \cdot B + C \cdot \bar{B}$$

Two adjacent cells on a four variable map represent some combination of three of the four variables. On Figure 14.26(b), groupings for  $\bar{A} \cdot B \cdot C$ ,  $B \cdot \bar{C} \cdot \bar{D}$ ,  $A \cdot \bar{B} \cdot \bar{D}$  and  $\bar{B} \cdot C \cdot D$  are shown. This map thus represents

$$Z = \bar{A} \cdot B \cdot C + B \cdot \bar{C} \cdot \bar{D} + A \cdot \bar{B} \cdot \bar{D} + \bar{B} \cdot C \cdot D$$

Figure 14.25 Minimisation of  $Z = A \cdot \bar{B} \cdot C \cdot \bar{D} + A \cdot B \cdot C \cdot \bar{D} + A \cdot \bar{B} \cdot C \cdot D + A \cdot B \cdot C \cdot D$  to  $Z = AC$  using a Karnaugh map

Figure 14.26 Grouping of two adjacent cells: (a) on a three variable map; (b) on a four variable map

Groups of four adjacent cells on a three variable map represent a single variable. The group on Figure 14.27(a) represents the variable  $A$ , hence

$$Z = A$$

Groups of four adjacent cells on a four variable map represent some combination of two of the four variables. The groups on Figure 14.27(b) represent  $\bar{B}D$  and  $BD$ . The map represents

$$Z = \bar{B}D + BD$$

A group of eight adjacent cells on a four variable map represent a single variable. The group on Figure 14.28 represents  $C$  and  $\bar{B}$ , so

$$Z = C + \bar{B}$$

It is important to realise that top and bottom edges are considered adjacent as are right and left sides. Grouping can therefore be made around the tops and sides as Figure 14.29 which represents

$$Z = \bar{A}C + AC$$

The rules for minimisation using Karnaugh maps are simple and straightforward:

- (1) Plot the Boolean expression or truth table onto the Karnaugh map
- (2) Form new groups of 1s on the map. Groups must be rectangular and contain 1, 2, 4 or 8 cells. Groups should

Figure 14.28 Grouping of eight adjacent cells

Figure 14.27 Grouping of four adjacent cells: (a) on a three variable map; (b) on a four variable map

Figure 14.29 Top and bottom sides are adjacent

be as large as possible and there should be as few groups as possible. Do not forget overlaps and possible round the edge groupings.

- (3) From the map, read off the expression for each group. The minimal expression is then obtained in S of P form, and can be directly implemented in AND/OR gates or NAND gates

Figure 14.30(a) shows a majority vote circuit (2 out of 3) plotted onto a Karnaugh map and grouped as Figure 14.30(b). It will be seen that this has three terms giving the simple NAND based circuit of Figure 14.30(c).

### 14.3.5 Conversion between P of S and S of P representations

It is occasionally required to translate an S of P expression into a P of S expression and vice versa

These are most conveniently handled in the form

$$Z = \sum (N_1, N_2, N_3 \dots) \text{ for S of P}$$

and

$$Z = \prod (N_1, N_2, N_3 \dots) \text{ for P of S}$$

where  $N_i$  is the numerical equivalent of the binary pattern at the corresponding gate input. If, for example, a gate input is  $C, B, A$ ,  $N$  will be 6 corresponding to 110.

The first step is to note the largest number, which determines how many bits we are dealing with (three bits for seven or less, four bits for fifteen or less and so on.) Call the maximum number corresponding to this number of bits  $N_{\max}$  (seven, fifteen, thirty-one etc.).

Note the *unused* numbers in the expression to be converted. For each unused number  $N_{\text{un}}$  there will be a number  $(N_{\max} - N_{\text{un}})$  in the expression in the other form. For example, to convert the S of P expression

$$Z = \sum (1, 4, 5, 6) \leftarrow$$

to P of S form we first note  $N_{\max}$  is seven (three bits). The terms in the P of S representation will be given by

$$\begin{array}{ll} \text{Unused S of P} & 0 \ 2 \ 3 \ 7 \ N_{\text{un}} \\ \text{P of S} & 7 \ 5 \ 4 \ 0 \ (N_{\max} - N_{\text{un}}) \end{array}$$

Giving a P of S representation of

$Z = \prod (0, 4, 5, 7)$  which is the equivalent to the original S of P expression.

The method for reverse conversion is identical.

### 14.3.6 Formal minimisation, the Quine-McCluskey method

The Karnaugh map is an excellent way of minimising combinational logic, but is essentially limited to five inputs and relies on human intuition. More formal methods are needed for more complex functions. The most common of these is Quine-McCluskey. The method can deal with any number of inputs, but is lengthy and error prone for direct human implementation. It is, however, ideally suited for computer implementation.

The start point is an S of P expression in the form

$$Z = \sum (N_1, N_2, N_3 \dots) \leftarrow$$

(a)

(b)

(c)

Figure 14.30 The majority vote circuit: (a) plotted onto Karnaugh map with grouping; (b) AND/OR implementation; (c) equivalent NAND based implementation

From this the minterms are grouped according to whether they have one, two, three etc. 1s in them. For example, with

$$Z = \sum (2, 3, 4, 5, 6, 7, 9, 11, 12, 13) \leftarrow$$

we would group them

Minterms with one 1

0010 (2)  
0100 (4)

Minterms with two 1s

0011 (3)  
0101 (5)  
0110 (6)  
1001 (9)  
1100 (12)

Minterms with three 1s

0111 (7)  
1011 (11)  
1101 (13)

Each term in each group is compared with each term in the group immediately below. If one *and only one* digit difference is found, a new entry in the lower group is formed with X replacing the single differing digit. Comparing 0010 with 0011 gives a new entry of 001X in the lower table. For the above groups this gives:

One 1

0010 a, b  
0100 c, d, e

Two 1s

	Created
0011 a :f, g	a 001X n
0101 c, :h, I	b 0X10 o
0110 b, d :j	c 010X p, s
1001 :k, l	d 01X0 q
1100 e :m	e X100 r .

Three 1s

	Created
0111 f, h, j	f 0X11 o
1011 g, j	g X011 #
1101 i, l, m	h 01X1 q
	i X101 r
	j 011X n, p
	k 10X1 #
	l 1X01 #
	m 110X s
	n 0X1X #
	o 0X1X duplicate
	p 01XX #
	q 01XX duplicate
	r X10X #
	s X10X duplicate

The letters a, b, c etc. show the comparisons made and the groups created. Any group which does not create a new group is called a *prime implicant*, denoted by # above. These are X011, 10X1, 1X01, 0X1X, 01XX, X10X (representing DCBA, A being the least significant as usual) with X denoting don't care. X011 is thus  $\overline{C}.B.A$ . An S of P circuit based on these prime implicants will work, but is not necessarily minimal.

Next a chart is drawn of these prime implicants, as shown on Figure 14.31 where each prime implicant is represented by a ♦. For four bit numbers, each minterm with full four bits will have one ♦, with one X there will be two ♦s and with two crosses four ♦s. X011, for example, represents minterms 3 and 11. The first stage is to identify columns with only a single ♦. The corresponding prime implicants MUST be in the final expression. These are noted down and all the corresponding ♦s marked for each row as these are now covered.

For each column, if there is a marked ♦ in the column, all ♦s in the column can now be marked, as this minterm has been included. If a prime implicant has all its ♦s marked it is redundant and can be deleted (e.g. 01XX).

There will probably be one or more ♦s left unmarked. Choose from the remaining prime implicants to give the best grouping. Give preference to minterms with the largest number of Xs, and remember that once a single ♦ is marked in a column, all the ♦s in the column can be marked. When all ♦s have been marked a solution has been reached.

Following this procedure for Figure 14.31 gives:

$$Z = \overline{A}\overline{C}D + B\overline{D} + \overline{B}C$$

a result which could, in all honesty, have been arrived at much faster with a Karnaugh map and common sense. The procedure is, however the basis of computer minimisation of logic circuits as used in PLA and PAL configuration programs.

### 14.3.7 Hazards, races and glitches

Gate propagation delays discussed in Section 14.2.2 can cause unwanted random pulses to appear in logic circuits. These unwanted pulses are known variously as *hazards*, *races* or *glitches*.

The logical output of Figure 14.32(a) should always be zero since

$$Z = \overline{A}.A = 0$$

In practice, however,  $\overline{A}$  will be delayed by the propagation delay of an inverter giving the possible waveforms of Figure 14.32(b). As A changes a small pulse may appear at the output.

Glitches are not always immediately obvious. A similar problem can occur with the NAND based AND/OR circuit of Figure 14.33(a). This implements the relationship

$$Z = \overline{A}.B + \overline{A}.C$$

As before  $\overline{A}$  must be obtained from some form of inverter as Figure 14.33(b). The circuit is logically correct but if  $B = \overline{C} = 1$  then the circuit is behaving in a similar way to Figure 14.32(a). If B and C are both 1 and A changes state a small pulse will probably appear at the output.

Plotting Figure 14.33 onto a Karnaugh map as Figure 14.34(a) shows a way to identify and eliminate glitches. There are two groups on the map; AB and AC. Moving between  $AB = 11$  and  $AB = 01$  we move between groups. This corresponds to A changing from 1 to 0 or 0 to 1. A potential glitch has adjacent 1s not covered by the same group.

**Figure 14.31** Prime implicant chart after essential implicants and subsequent minterms have been marked

**Figure 14.32** An obvious glitch producing circuit: (a) logic diagram, the output should always be '0'; (b) actual circuit behaviour

**Figure 14.33** Non obvious glitch producing circuit: (a) logic diagram; (b) redrawn to show source of the glitch

To remove the risk of a glitch we add an additional group as *Figure 14.34(b)*. There are now no adjacent 1s not in the same group. The resulting circuit is shown on *Figure 14.34(c)*. Note that the group  $BC$  is logically redundant and is included solely to prevent glitches when  $A$  changes state with  $B = C = 1$ . Glitch free circuits are often non minimal.

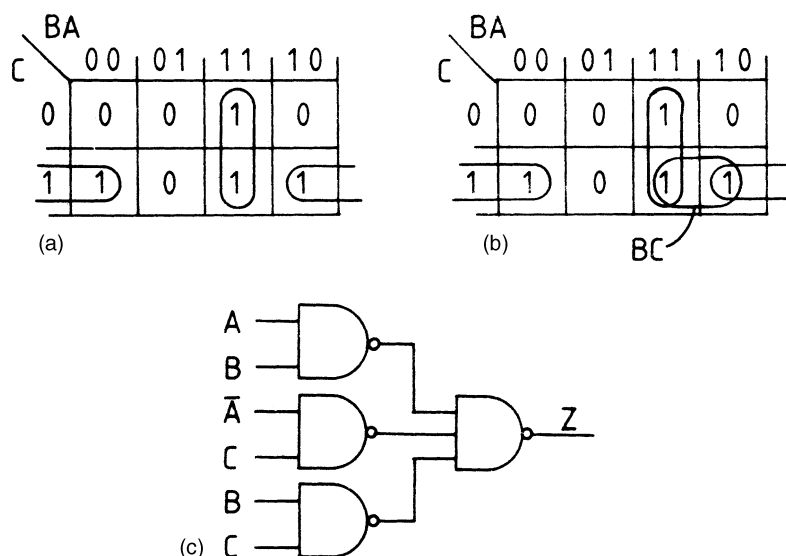

Glitches may not always be important. In general, if the output of a glitch prone circuit is not feeding directly (or indirectly) a counter, storage device or timer the glitches will probably have no effect. Glitches can also be ignored by using clocked synchronous systems. Different logic families have different propensities for generating and ignoring glitches. The important factor is the relationship between edge speeds and propagation delays. CMOS, with edge speed similar to or longer than the propagation delay, has a useful tendency to ignore glitches. ECL, with very fast edge speeds, is very prone to glitches.

### 14.3.8 Integrated circuits

Many complex functions are available in IC form, and a circuit designer should aim to minimise cost and the number of IC packages rather than the number of gates. A minimisation exercise, whether by Boolean algebra or Karnaugh map, should always be preceded by a search of an IC catalogue for a suitable off the peg device.

### 14.3.9 UCLAs, PALs and PLAs

An integrated circuit consists of a small slice of silicon into which is etched the various individual unconnected components required to make the required circuit. These are then connected by a thin metallised layer to form the required device function. An UCLA (for *uncommitted logic array*, also known as an ULA) consists initially of a large

**Figure 14.34** Glitch free design using a Karnaugh map: (a) original minimal grouping; (b)  $BC$  term added to remove the glitch. The final grouping is non minimal; (c) the resulting glitch free, but non minimal, logic

number of assorted gates, storage and memories but without the metallised interconnection layer. The user specifies the required circuit which is then formed by the design of the metallised layer. The basic IC silicon slice (which is the expensive part) is thus common to many users and the relatively cheap metallisation layer is specific to one user's application. UCLAs therefore allow designers to have their own ICs at a reasonable price. They are, though, only cost effective for reasonable volume production runs.

An alternative approach, suitable for smaller volumes, is *programmable logic*. These are essentially a combination of true/complement inputs with an AND/OR output as shown on Figure 14.35. Each connection point is originally linked, but can be blown open by the designer (using a programming terminal) to leave the desired function. The original devices were based on bipolar construction, and literally used small metallic fuses. Once blown, they could not be re-used. Later MOS devices can be erased by UV light in a similar way to EEPROMs.

The simplest devices use a programmable AND combination (selected from the true/complement inputs) with a fixed AND/OR logic. These are known as *Programmable Array Logic*, or PALs. The more versatile (but more complex) arrangement of Figure 14.36 uses programmable AND plus programmable OR connections. These are known as *Programmable Logic Arrays* or PLAs, (this distinction is not quite true, the terms PLA and PAL are used interchangeably by some manufacturers).

Figures 14.35 and 14.36 are essentially combinational logic in sum of product (S of P) form (see Section 14.3.2). Sequential programmable logic is also available, and is typically of the form of the Figure 14.37 based around an AND/OR/D-type circuit. These are known as *registered* or *sequential* PALs. They are very useful for building logic networks built around state transition diagrams (see Section 14.8).

There are some disadvantages. Early devices had a voracious power appetite, several hundred mA for some. The later MOS devices are better, but their use should be questioned on battery driven devices. There is also a one-off

investment needed in a programming terminal, and programming languages such as ABEL, CUPL and PALASM. These work out the required link blowing from a designer specified logic function defined in combinational or state transition form. They do not, however, check out for glitches and even seem to encourage them by aiming for truly minimal logic. Some care is needed by the designer, but the languages do allow redundant combinations to be specified to give glitch free circuits.

With bipolar devices, it should also be remembered that bipolar devices cannot be reprogrammed if an error is made. Mistakes with bipolar programmable logic are not cheap, and even with MOS versions, erasure with UV light is not instantaneous.

Programmable logic is very popular where standard boards (with fixed connections to the outside world) can be used in different applications. Typical examples are vending and ticket machines, interface devices or testing of a logic circuit before building the final version.

## 14.4 Storage

### 14.4.1 Introduction

Most logic systems require some form of memory. A typical relay circuit is the motor starter circuit of Figure 14.38 which 'remembers' which of the two operator push buttons was pressed last. The memory is achieved by the latching contact A1.

### 14.4.2 Cross coupled flip flops

The logical equivalent of Figure 14.38 is the cross coupled NOR gate circuit of Figure 14.39(a). Assume both inputs are 0, and output  $Q$  is at a 1 state. The output of gate a will be 0, and the two 0 inputs to gate b will maintain  $Q$  in its 1 state. The circuit is therefore stable. If the reset input is now taken to a 1,  $Q$  will go to a 0, and  $\bar{Q}$  to a 1. Similar

Further inputs  
←

Figure 14.35 The basis of programmable logic

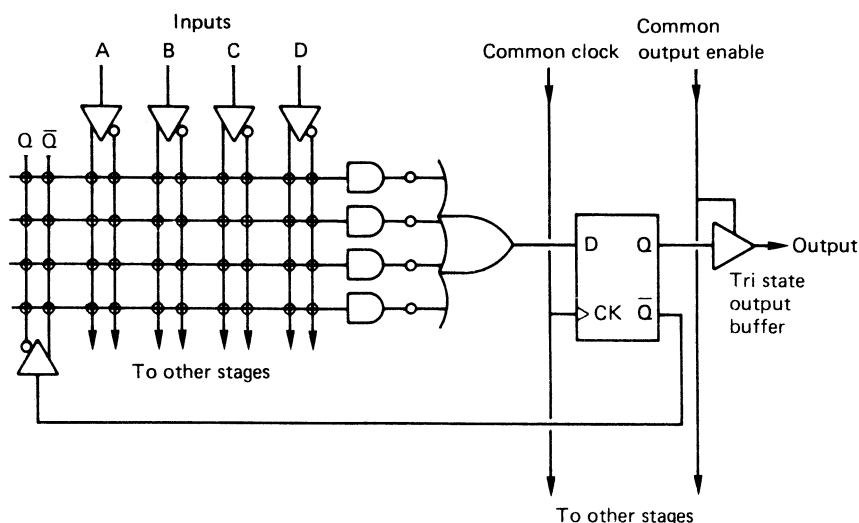

Figure 14.36 A programmable logic array with AND/OR inputs both programmable

**Figure 14.37** Sequential programmable logic with tri-state outputs. A typical device would have eight inputs and eight D type flip flops

**Figure 14.38** A simple relay storage circuit used to start a motor. The circuit remembers which button (Start or Stop) was last pressed

analysis to that above will show that the circuit is stable in this state, even when the reset input goes back to a 0.

The set input can be used now to switch the  $Q$  output to 1 and the  $\bar{Q}$  back to a 0. The set and reset inputs cause the output to change state, with the outputs indicating which input was last at a 1 state as summarised by Figure 14.39(b). If both inputs are 1 together, both outputs go to a 0, but this condition is normally disallowed.

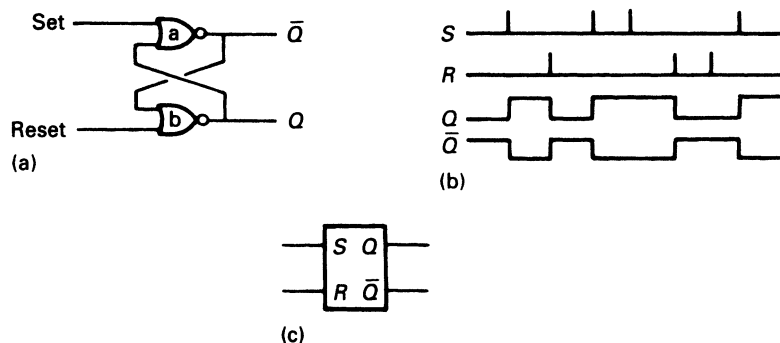

The cross coupled NOR gate circuit is called an *RS Flip Flop*, and is shown on logic diagrams by the symbol of Figure 14.39(c).

It is also possible to construct a cross coupled flip flop from NAND gates as Figure 14.40(a). Analysis will show that this behaves similar to Figure 14.39, but the circuit remembers which input last went to a 0 as shown on Figure 14.40(b). The logic symbol for a NAND based RS flip flop is shown on Figure 14.40(c); the small circles on the input showing that the flip flop responds to 0 inputs.

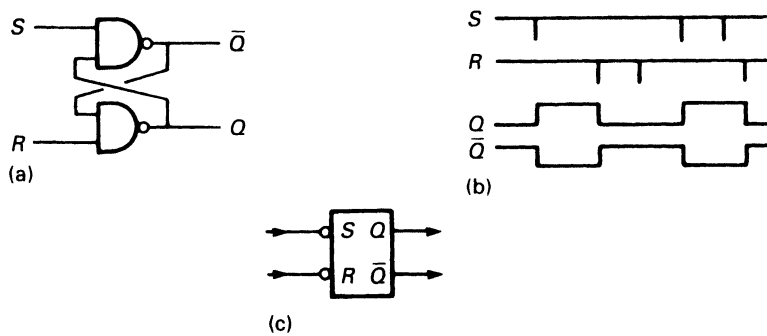

### 14.4.3 D type flip flop

The D type flip flop shown on Figure 14.41(a) has a single data input ( $D$ ), a clock input and the usual  $Q$  and  $\bar{Q}$  outputs. Superficially this is similar to the latch memory above, but the clock operates in a more subtle way. The operation of a typical D type flip flop is shown on Figure 14.41(b). The clock samples the  $D$  input when the clock input goes from a 0 to 1, but the output changes state when clock goes from 1 to 0. The significance of this is explained below in Section 14.4.6.

There are several ways in which a D type flip flop can be implemented. A common circuit uses the master/slave arrangement of Figure 14.41(c). When the clock input is 1, the  $D$  input sets, or resets, the master flip flop. When the

**Figure 14.39** A NOR based RS flip flop. This circuit remembers which input was last a '1': (a) logic diagram; (b) operation; (c) logic symbol

**Figure 14.40** A NAND based RS flip flop. This circuit remembers which input was last a '0': (a) logic diagram; (b) operation; (c) logic symbol

**Figure 14.41** The D type flip flop: (a) logic symbol; (b) operation; (c) logic diagram for a master/slave D type

clock input is 0 the state of the master flip flop is transferred to the slave flip flop (and the outputs take up the state of  $D$  when the clock input was 1). Note that the master flip flop is isolated from the  $D$  input whilst the clock is 0.

Although it would be feasible to construct a master/slave flip flop from discrete gates, integrated circuit  $D$  types (such as the TTL 7474 or the CMOS 4013) are readily available.

#### 14.4.4 The JK flip flop

In Section 14.4.2 the NOR based RS flip flop was described, and it was stated that the input state  $R=S=1$  was normally disallowed. The JK flip flop, shown on *Figure 14.42(a)* is a clocked RS flip flop with additional logic to cover this previously disallowed state. The clock input acts as described

above for the D type flip flop, i.e. sampling the inputs on one edge, and causing the outputs to change on the other.

The outputs after a clock pulse for  $J=1, K=0, J=0, K=1, J=0, K=0$  are as would be expected for a clocked RS flip flop. If  $J=K=1$  the outputs toggle; that is the states of the  $Q$  and  $\bar{Q}$  interchange. This action is summarised on *Figure 14.42(b)*.

The toggle state is the basis for counters, described in Section 14.7.

#### 14.4.5 Clocked storage

The D type and JK flip flops described above are examples of clocked storage. The advantages, and implications of this are probably not immediately obvious.

**Figure 14.42** The JK flip flop: (a) logic symbol; (b) operation

**Figure 14.43** Clocked storage. Data moves one position for each pulse on the move line

In all but the simplest systems, data is often required to be moved around from one storage position to another. In *Figure 14.43*, for example, data is to be moved through stores A, B, C in an orderly manner. If simple flip flops were used along with a signal enable as shown, the data would shoot straight through all the stages. If clocked storage is used, the data will sequence from A to B to C, moving one position for each clock pulse.

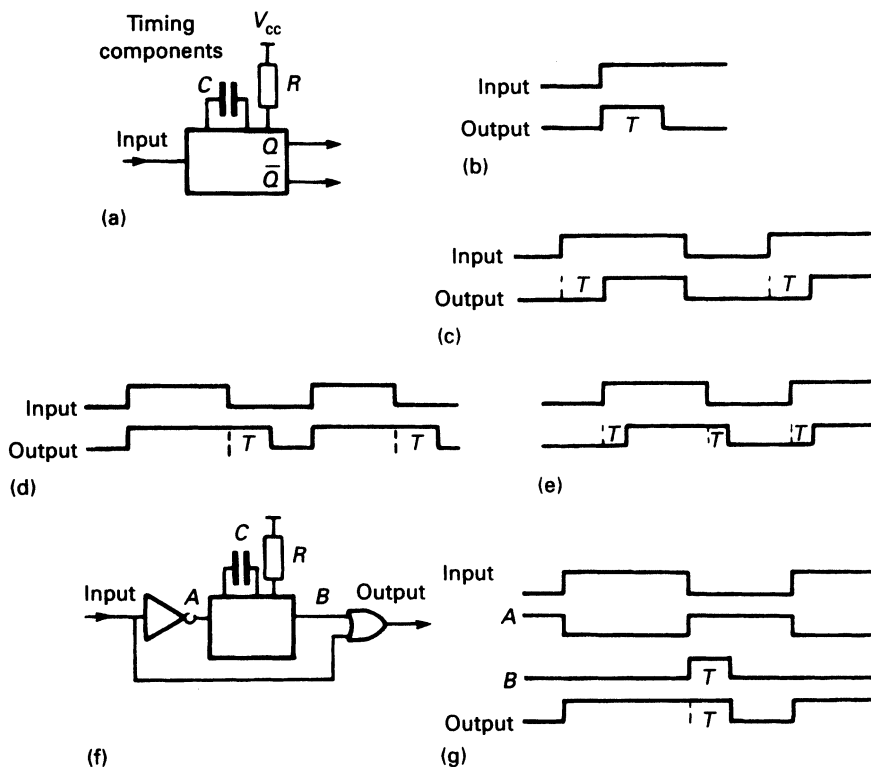

## 14.5 Timers and monostables

Control systems often need some form of timer. Timing functions in logic circuits are provided by devices called monostables or delays. There are many types of delay, although all can be considered as *Figure 14.44(a)*, to consist of an input,  $Q$  and  $\bar{Q}$  outputs and an RC network which determines the delay period.

The commonest timer, often called the one shot or monostable, gives an output pulse, of known duration, for an input edge. The user can select which edge (0→1 or 1→0) triggers the circuit. On *Figure 14.44(b)* a 0→1 edge is used. Monostables are the basis of all other delay circuits and are widely available (74121, 74122 in TTL, 4047, 4098 in CMOS). Pure delays are shown on *Figure 14.44(c–e)*, and these can be constructed by adding gates to monostable outputs. *Figure 14.44(f/g)* shows the circuit for a delay off.

A variation of the monostable is the retriggerable monostable. In most monostables circuits the timing logic ignores further input edges once started. In a retriggerable monostable each edge sets the timing circuit back to the start again. The action of a retriggerable and normal monostable are compared on *Figure 14.45*.

The time delay of any timer is of the order of RC seconds where R is the value of the timing resistor in ohms and C is the value of the timing capacitor in farads. For delays of more than a few seconds very large values of R and C are

**Figure 14.44** Various forms of timers and monostables: (a) basic form of a timer. The timer duration is determined by the values of R and C and is usually of the order of RC seconds; (b) one shot timer, often called a monostable; (c) delay on timer; (d) delay off timer; (e) delay on and off timer; (f) delay off timer built using a simple monostable; (g) timing waveforms for circuit f

Figure 14.45 A re-triggerable monostable. Each input 0 to 1 edge re-starts the timing function

Figure 14.46 Implementation of a long period timer

required. High value resistors are prone to changes in value from leakage and large value capacitors must be electrolytics with problems from leakage, size and long term drift. For periods of more than a few seconds it is usually better to produce a time delay with an oscillator and counter as Figure 14.46. The oscillator produces a free running pulse chain which is normally blocked by gate 2. A start pulse sets flip flop 3 and resets the counter. With flip flop 3 set, pulses are passed to the counter which counts up. When the counter reaches a pre-determined count it resets the flip flop. The Q output of the flip flop thus goes high for a time

$$T = N \times P \text{ seconds}$$

where  $N$  is the count preset and  $P$  the oscillator period. Integrated circuits based on this principle, such as the ZN1034, are available giving very long delays (up to days) with reasonable value components and little problems from drift.

## 14.6 Arithmetic circuits

### 14.6.1 Number systems, bases and binary

In previous sections, logic signals have been assumed to represent events such as printer ready, or low oil level. Digital signals can also be used to represent, and manipulate numbers.

We are so used to the decimal number system that it is hard to envisage any other way of counting. Normal every day arithmetic is based on multiples of ten. For example, the number 9156 means:

$$\begin{aligned} 9 \text{ thousands} &= 9 \times 10 \times 10 \times 10 \\ \text{plus } 1 \text{ hundred} &= 1 \times 10 \times 10 \\ \text{plus } 5 \text{ tens} &= 5 \times 10 \\ \text{plus } 6 \text{ units} &= 6 \end{aligned}$$

Each position in a decimal number represents a power of ten. Our day to day calculations are done to a base of ten because we have ten fingers. Counting can be done to any base, but of special interest are bases 8 (called *octal*), 16 (called *hex* for *hexadecimal*) and two (called *binary*).

Octal uses only the digits 0–7, the octal number 317, for example, means

	$3 \times 8 \times 8$	= decimal 192
plus	$1 \times 8$	= decimal 8
plus	7	= decimal 7
	<b>TOTAL</b>	<b>decimal 207</b>

Hex uses the letters A–F to represent decimal ten to fifteen, so hex C52, for example, means

	$12 \times 16 \times 16$	= decimal 3072
plus	$5 \times 16$	= decimal 90
plus	2	= decimal 2
	<b>TOTAL</b>	<b>decimal 3164</b>

Binary needs only two symbols, 0 and 1. Each position in a binary number represents a power of two and is called a *bit*, for BInary digiT, most significant to the left as usual, so 101101 is evaluated:

	$1 \times 2 \times 2 \times 2 \times 2 \times 2$	= 32
plus	$0 \times 2 \times 2 \times 2 \times 2$	= 0
plus	$1 \times 2 \times 2 \times 2$	= 8
plus	$1 \times 2 \times 2$	= 4
plus	$0 \times 2$	= 0
plus	1	= 1
	<b>TOTAL</b>	<b>decimal 45</b>

Fractions can also be represented in binary, although this is not commonly encountered. Taking fractions as powers of two we get  $1/2$  (0.1 in binary),  $1/4$  (0.01 in binary),  $1/8$  (0.001) and so on. The binary number 110.101 is thus 6 plus 0.5 plus 0.125 giving 6.625.

Conversion from decimal to binary is achieved by successive division by two noting the remainders. Reading the remainders from the top (LSB) to bottom (MSB) gives the binary equivalent. For example, decimal 23

```

23
11 r 1 (LSB)
 5 r 1
 2 r 1
 1 r 0
 0 r 1 (MSB)

```

Decimal 23 is binary 10111.

Octal and hex give a simple way of representing binary numbers. To convert a binary number to octal, the binary number is written in groups of three (from the LSB) and the octal equivalent written underneath, for example 11010110

```

grouped in threes    11    010    110
                    Octal    3      2      6

```

Hex conversion is similar, but groupings of four are used. Taking again the binary number 11010110;

```

grouped in fours    1101    0110
                    Hex      D      6

```

The octal number 326 and the hex number D6 are both representations of the binary number 11010110.

## 14.6.2 Binary arithmetic

Consider the decimal sum:

```

 345
+ 272
----
 617

```

This is evaluated in three stages:

```

5 + 2 = 7    no carry
4 + 7 = 11   one down (as result)
           plus carry
3 + 2 + carry = 6

```

At each stage we consider three 'inputs'; two digits and a possible carry from the previous stage. Each stage has two outputs, a sum digit and a possible carry to the next, more significant state. A single digit adder can therefore be considered as *Figure 14.47(a)*. Several single digit adders can be cascaded, as *Figure 14.47(b)*, to give an adder of any required number of digits. Note the carry out of the most significant stage becomes the most significant digit.

Binary addition is similar, except that there are only two possible values for each digit. If *Figure 14.47(a)* is a binary adder, there are eight possible input combinations:

Inputs			Outputs	
D1	D2	Carry	Sum	Carry
0	0	0	0	0
0	1	0	1	0
1	0	0	1	0
1	1	0	0	1
0	0	1	1	1
0	1	1	0	1
1	0	1	0	1
1	1	1	1	1

An example of binary arithmetic is

```

  1 0 1 1 0 1 0
+ 0 1 0 1 0 1 1
-----
1 0 0 0 0 1 0 1   Sum (result)
1 1 1 1 0 1 0     Carry

```

The implementation of the adder truth table is a simple problem of combinational logic; one possible solution is shown on *Figure 14.47(c)*. In practice, of course, adders such as the TTL 7483 are readily available in IC form.

Negative numbers are generally represented in a form called *two's complement*. The most significant digit represents the sign, being 1 for negative numbers and 0 for positive numbers. The value part of the number is complemented and 1 added. For example:

+12 in two's complement is 01100 (the MSB 0 indicating a positive number).

To get to two's complement for -12 we complement 1100 giving 0011, set the MSB to 1 giving 10011 then add 1 giving 10100 which is the two's complement representation of -12.

Similarly

```

      +43    0101011
Complement 1010100
Add 1      1010101   which is -43.

```

In each case, addition of the positive and negative number will give the result zero, e.g.

```

+43    0 1 0 1 0 1 1
-43    1 0 1 0 1 0 1
-----
± 0 0 0 0 0 0 0

```

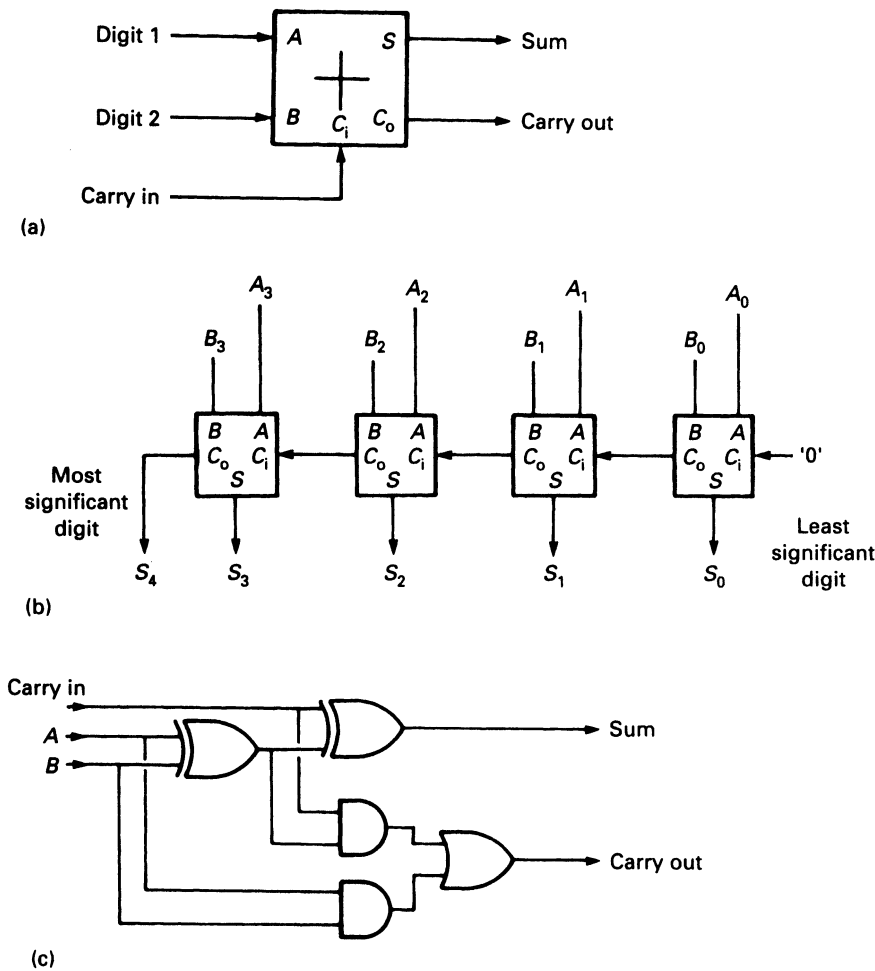

The top carry is lost, giving the correct result of zero.

Two's complement representation allows subtraction to be done by adding a negative number, for example  $12 - 3$

```

  0 1 1 0 0   +12
+ 1 1 1 0 1   -3
-----
± 0 1 0 0 1

```

**Figure 14.47** Adder circuits: (a) representation of a one digit adder. This block diagram will be the same regardless of the number base used; (b) construction of a four digit adder from four identical one digit adders; (c) one bit (i.e. one digit) binary adder logic diagram

The top bit is lost giving the correct result of +9.

Multiplication and division are rarely required in simple logic systems and are generally best implemented with some form of microprocessor assembly in conjunction with specialist mathematical co-processors such as the AMD9511. If a hardware solution is required it can be based on the addition of weighted partial sums. Consider the decimal multiplication

456	Multiplicand
123	Multiplier
---	
45600	Partial sums
9120	
1368	
-----	
56088	Result

The multiplicand is multiplied by each digit of the multiplier in turn and the part results added with appropriate weighting to give the result. Binary multiplication is similar

but simpler in that only four multiplication results need to be considered:

$$1 \times 1 = 1, \quad 1 \times 0 = 0, \quad 0 \times 1 = 0, \quad 0 \times 0 = 0$$

A typical binary multiplication is therefore

1011	Multiplicand (decimal 11)
1001	Multiplier (decimal 9)
----	
1011000	(1011 × 1)
0000000	(1011 × 0)
0000000	
1011000	
-----	
1100011	Result (decimal 99)

Note that multiplying two four bit numbers can give an eight bit result. If two binary numbers A & B are to be multiplied, therefore, partial sums are obtained by multiplying

(i.e. gating) A by each bit of B to form as many partial sums as there are bits in B. These partial sums are then weighted and added to give the result as above.

The fastest multiplication can be obtained by using Read Only Memories (ROMs) programmed with an entire multiplication table. The multiplicand and the multiplier then act as the ROM address and the result is simply read. Two 1 k bit ROMs can form a four by four multiplier with no additional logic. The 74284 & 74285 are integrated circuits designed specifically for this purpose.

Division is even rarer, but can also be performed using ROMs.

### 14.6.3 Binary coded decimal (BCD)

A single decimal digit can take any value between 0 and 9. Four binary digits are therefore needed to represent one decimal digit. In BCD, each decimal digit is represented by four bits. For example:

9	4	0	7	6
1001	0100	0000	0111	0110

BCD is not as efficient as pure binary. 12 bits in pure binary can represent 0–4095, compared with 0–999 in BCD. BCD, however, has advantages where decimal numbers are to be read from decade switches or sent to digital displays.

### 14.6.4 Unit distance codes

Figure 14.48 shows a possible application of binary coding. The position of a shaft is to be measured to 1 part in 16 by means of an optical grating moving in front of four photocells. The photocell outputs give a binary representation of the shaft angular position.

Consider what may happen as the shaft goes from position 7 (0111) to position 8 (1000). It is unlikely that all the cells will switch together, so we could get

0111 > 0000 > 1000  
or 0111 > 1111 > 1000

or any other lengthy sequence of four bits. These possible incorrect intermediate states can be avoided by using a code in which only one bit changes between adjacent positions. Such codes are called *unit distance codes*.

The commonest unit distance code is the *Gray code*, shown in four bit form below.

It will be noted that the code is reflected about the centre. Sometimes the term '*reflected code*' is used for unit distance

**Figure 14.48** Encoding an angular position into a binary signal with a shaft encoder

codes. A unit distance code can be constructed to any even base by taking an equal number of combinations above and below the centre point of a Gray code. A decimal version (called the *XS3 cyclic BCD code*) is also shown. In this code zero is 0010, one is 0110, two is 0111 and so on to nine which is 1010.

Conversion between binary and Gray code is straightforward, and is achieved with XOR gates as shown on Figure 14.49(a) and (b).

Decimal	Gray
0	0000
1	0001
2	0011
3	0010 )
4	0110 )
5	0111 )
6	0101 )
7	0100 ) decimal

10	1111 )
11	1110 )
12	1010 )
13	1011
14	1001
15	1000

## 14.7 Counters and shift registers

### 14.7.1 Ripple counters

Counters are used for two basic purposes. The first, and obvious, use is the counting, or totalising, of external events. The second use of counters is the division of a frequency to give a new, lower frequency.

The 'building block' of all counters is the toggle flip flop which changes state each time its clock input is pulsed. Usually the toggling occurs on the negative edge as shown on Figure 14.50(a). A toggle flip flop can be constructed from JK or D type flip flops as shown on Figure 14.50(b, c).

If the *Q* output of a toggle flip flop is connected to the clock input of the next stage as shown on Figure 14.51(a), a simple binary counter can be constructed to any desired length. Figure 14.51 is a 3 bit counter with A the LSB and C the MSB. This counts:

Pulse	C	B	A
0	0	0	0
1	0	0	1
2	0	1	0
3	0	1	1
4	1	0	0
5	1	0	1
6	1	1	0
7	1	1	1

Figure 14.49 Conversion between binary and Gray codes: (a) binary to Gray; (b) Gray to binary

Figure 14.50 The toggle flip flop: (a) operation, the output changes state for each input pulse; (b) a JK toggle flip flop; (c) a D type connected to make a toggle flip flop

Another pulse will take it to state 0 again. It can be seen that *Figure 14.51* is counting up. To count down, the  $\bar{Q}$  outputs are connected to the input of the following stage and the signal outputs taken from the  $Q$  lines.

There are two limitations to the speed at which a counter chain similar to *Figure 14.51* can operate. The first is the maximum speed at which the first (fastest) stage can toggle. The second restriction is not so obvious.

Consider the case of an 8 bit counter going from 01111111 to 10000000. The LSB toggling causes the next to toggle and so on to the MSB. The change has to propagate through all 8 bits of the counter, so circuits similar to *Figure 14.51* are called *ripple counters*. During the 'ripple' the counter will assume invalid states and cannot be sensibly read. Obviously the propagation delay through all the stages should be considerably less than the input

period. High speed applications use synchronous counters, described below.

In *Figure 14.51* the frequency of output  $C$  is precisely one eighth of the input frequency. A simple ripple counter can therefore also act as a frequency divider. If we define

$$N = f_{in}/f_{out}$$

then  $N = 2^m$  for  $m$  binary stages.

It will also be seen that the output of any stage of a binary counter has equal mark space ratio regardless of the input mark/space providing the input frequency is constant.

Although it is feasible to construct ripple counters with D type and JK flip flops it is usually more cost effective to use MSI ICs such as the TTL 7493 4 bit counter or the CMOS 4024 7 bit counter. These incorporate features such as a reset line to take the counter to a zero state.

Figure 14.51 A simple three bit binary ripple counter constructed from three toggle flip flops

### 14.7.2 Synchronous counters

Ripple counters are limited in both speed and length by the cumulative ripple through propagation delay and also temporarily exhibit invalid outputs. Although these limitations are not important in slow speed applications, they can cause difficulties in high speed counting.

These restrictions can be overcome by the use of a synchronous counter where all required outputs change simultaneously. There is no ripple propagation delay through the counters and no transient false count stages. The only speed restriction is the toggling frequency of the first stage.

The building block of a synchronous counter is the JK flip flop/AND gate arrangement of Figure 14.52(a). If the  $T$  input is 1, the JK flip flop will toggle on the receipt of a clock pulse. If the  $T$  input is 0, the flip flop will not respond to a clock pulse. The carry output is 1 if  $T$  is 1 and  $Q$  is 1.

A synchronous up counter is constructed as Figure 14.52(b), which is simply the circuit of Figure 14.52(a) repeated. Note that the clock input is common to all stages, and the carry from one stage is the  $T$  input of the next.

It will be seen that the  $T$  inputs,  $T_b, T_c, T_d$  will be 1 when all the preceding outputs are 1.  $T_c$  will be 1, for example,

when  $A$  and  $B$  are both 1. This is the condition when a counter stage should toggle, taking  $DCBA$  from, say, 0011 to 0100.

It is also possible to construct a synchronous down counter by counting the AND gate input of Figure 14.52(a) to the  $\bar{Q}$  output rather than the  $Q$ , and observing the counter state on the  $\bar{Q}$  output. A synchronous up/down counter with selectable direction can be constructed as Figure 14.53. If the direction line is a 1, gates 1, 2, 3 are enabled, the  $Q$  outputs pass to the next stage and the counter counts up. If the direction line is a 0, gates 4, 5, 6 are enabled, the  $\bar{Q}$  outputs pass to the next stage and the counter counts down.

### 14.7.3 Non binary counters

Counting to non binary bases is often required, a BCD count is probably the most common requirement. When the required count is a subset of a straight binary count, (e.g. BCD), the circuit of Figure 14.54(a) can be used. The counter output is decoded by external logic. When the counter reaches the desired maximum count the decoder

Figure 14.52 Synchronous counters: (a) basic circuit for a synchronous counter; (b) four bit series connected synchronous up counter

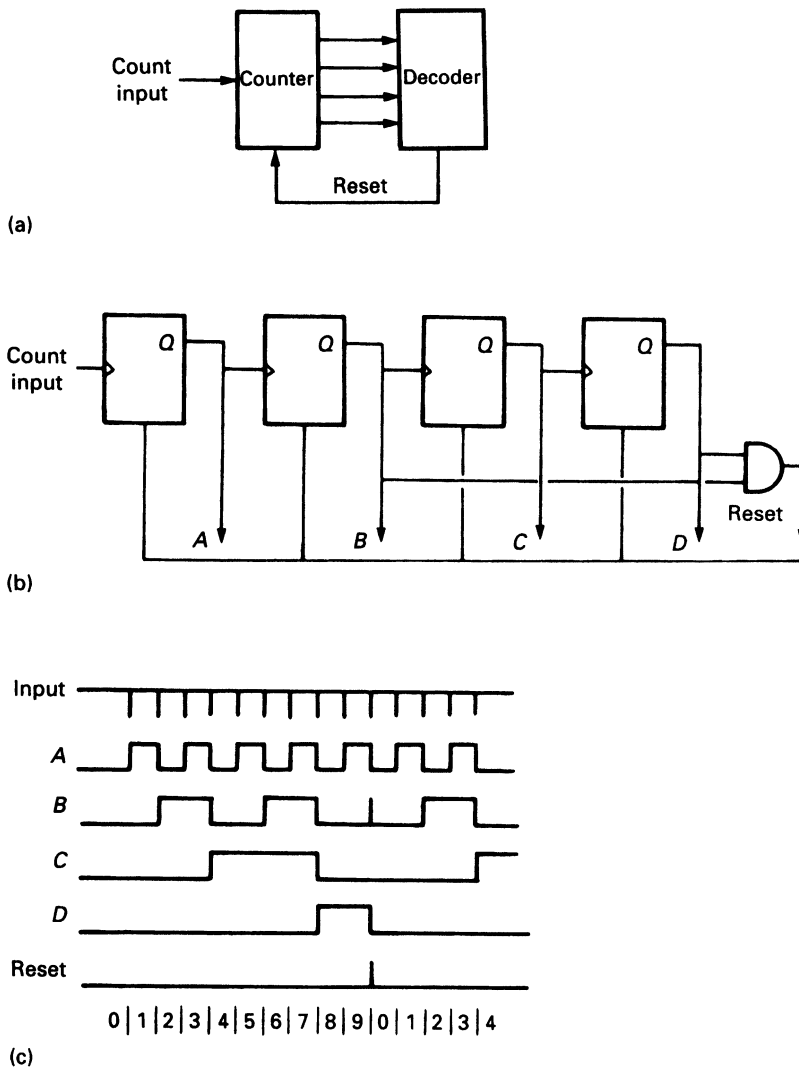

Figure 14.53 Synchronous selectable up/down counter

**Figure 14.54** Non binary counters: (a) principle of operation; (b) logic diagram for a BCD up counter; (c) counter operation

output forces the counter to its zero state (which is 0000 for a BCD counter, but need not be for other counters).

A single BCD stage constructed on these principles is shown on *Figure 14.54(b)*. The circuit shown is a ripple counter, but could equally well be a synchronous counter. Gate A detects a count of ten (binary 1010) and resets the counter to zero via direct reset inputs on the JK flip flops. Waveforms are shown on *Figure 14.54(c)*.

Where a non binary count is needed (e.g. a Gray code count), it is best to use synchronous counters and an arrangement similar to *Figure 14.55*. This is drawn for D type flip flops, but JK based design is similar.

A combinational logic network looks at the counter outputs and sets the *D* inputs for the next state. If the counter, say, was required to step from 1101 to 0011, the combinational logic output to the *D* inputs would be 0011 for an input of 1101. Effectively there are four combinational circuits in the network, one for each *D* input.

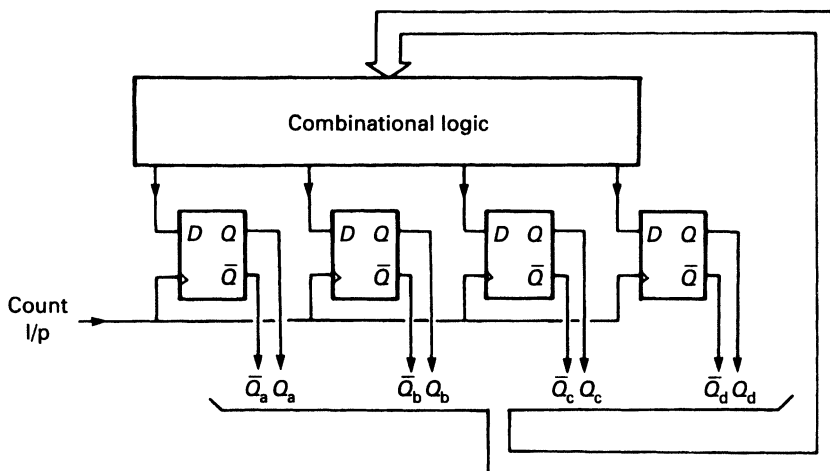

#### 14.7.4 Shift registers

A simple shift register is shown on *Figure 14.56(a)*. Data applied to the serial input, *S* in, will move one place to the right on each clock pulse as shown on the timing diagram of *Figure 14.56(b)*.

Shift registers are used for parallel/serial and serial/parallel conversions. They are also the basis of multiplication and division circuits as a shift of one place towards the MSB is equivalent to a multiplication by 2, and one place towards the LSB an integer division of 2.

### 14.8 Sequencing and event driven logic

Many logic systems are driven by randomly occurring external events, and follow a sequence of operations. In such systems, the output states do not depend solely on the input

**Figure 14.55** Generalised synchronous non binary counter using D type flip flops. Any count pattern can be produced with this arrangement. The principle can also be implemented using JK flip flops.

(b)

**Figure 14.56** Simple shift register constructed from D type flip flops: (a) logic diagram; (b) operation

states, but also on what the system was doing last. These types of systems are said to be sequencing and event driven logic. Sequencing logic is designed using a state diagram. This shows the possible conditions the system can be in, the conditions that are required to move from one state to the next, and the outputs required in each state.

Figure 14.57 shows a possible state diagram for a gas burner control. When the start PB is pressed a 15 second air purge is given (set by timer 1). The pilot valve is opened, and the igniter started for 4 seconds (timer 2). If, at the end of this time, the flame detector shows the flame to be lit, the main gas valve is opened. At any time the stop button terminates the sequence. A non valid signal from the flame detector (i.e. flame present in states 1 and 2 or no flame in

state 4) puts the system to an alarm state, as does the incorrect signal from the air flow switch. Note that these are checked for being 'unfrigg'd' at the start of the sequence.

Event driven logic is built around flip flops, usually one for each state. The flip flop corresponding to state 4 is shown on Figure 14.58(a), and is set by the required conditions from state 3 and reset by the possible next states (1 and 5). Outputs are simply obtained by ORing the necessary states. The pilot output, shown on Figure 14.58(b), is simply State 3 OR State 4.

It is possible to minimise event driven circuits to use fewer flip flops, but such an approach is usually not required as it makes the operation more difficult to understand. A straightforward state diagram similar to Figure 14.57

Inputs: Start PB ( $ST$ ), Stop PB ( $SP$ ), Flame present ( $F$ ), Reset PB ( $R$ ),  
Timer 1 complete ( $T_1$ ), Timer 2 complete ( $T_2$ ), Air flow SW ( $A$ )

Outputs:

State	Description	Air	Pilot valve	Ignition	Gas valve	Start timer 1	Start timer 2	Alarm bell
1	Off	0	0	0	0	0	0	0
2	Air purge	1	0	0	0	1	0	0
3	Ignition	1	1	1	0	0	1	0
4	On	1	1	0	1	0	0	0
5	Alarm	1	0	0	0	0	0	1

Figure 14.57 State diagram and output table for control of a gas burner

Figure 14.58 Implementation of a state diagram: (a) one of the five states of the gas burner control. Each state is represented by a flip flop and is set by transitions to the state and reset by transitions from the state; (b) one of the seven outputs. Each is simply an OR function of the states in which it is energised. The pilot valve is energised in states 3 and 4.

is easy to design, understand and modify and simplifies fault finding for maintenance personnel.

State diagrams are being formalised by the International Electrotechnical Commission (IEC) and the British Standards Institute (BSI), and already exist with the French Standard Grafset. These are basically identical to the approach outlined above, but introduce the idea of parallel routes which can be operated at the same time. Figure 14.59(a) is called a *divergence*; state 0 can lead to state 1 for condition 's' OR to state 2 for condition 't' with transitions 's' and 't' mutually exclusive. This is the form of the state diagrams described so far.

Figure 14.59(b) is a *simultaneous divergence*, where state 0 will lead to state 1 AND state 2 simultaneously for transition 'u'. States 1 and 2 can now run further sequences in parallel.

Figure 14.59(c) again corresponds to the state diagrams described earlier, and is known as a *convergence*. The sequence can go from state 5 to state 7 if transition 'v' is true OR from state 6 to state 7 if transition 'w' is true.

Figure 14.59(d) is called a *simultaneous convergence* (note again the double horizontal line) state 7 will be entered if the left-hand branch is in state 5 AND the right-hand branch is in state 6 AND transition 'x' is true.

The state diagram is so powerful that most medium size PLCs include it in their programming language in one form or another. Telemecanique give it the name Grafset (with a 'c'), others use the name Sequential Function Chart (SFC) (Allen Bradley) or Function Block (Siemens). The IEC have adopted state diagrams as one of their formalised methods of PLC programming in IEC 1131.

**Figure 14.59** State transition diagram symbols: (a) divergence; (b) simultaneous divergence; (c) convergence; (d) simultaneous convergence

## 14.9 Analog interfacing

### 14.9.1 Digital to analog conversion (DAC)

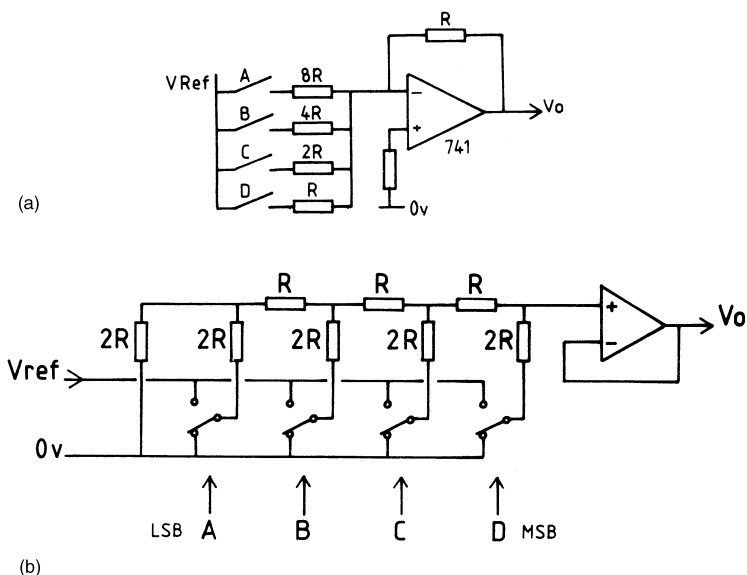

A binary number can represent an analog voltage. An 8 bit number, for example, represents a decimal number from 0 to 255 (or  $-128$  to  $+127$  if two's complement representation is used). An 8 bit number could therefore represent a voltage from 0 to 2.55 V, say, with a resolution of 10 mV. A device which converted a digital number to an analog voltage is called a *digital to analog converter*, or DAC.

Common DAC circuits are shown on *Figure 14.60*, in each case the output voltage is related to the binary pattern

on the switches. In practice, FETs are used for the switches, and usually an IC DAC is used. The R-2R ladder circuit is particularly well suited to IC construction.

### 14.9.2 Analog to digital converters (ADCs)

There are several circuits which convert an analog voltage to its binary equivalent. The two commonest are the *ramp ADC* and the *successive approximation ADC*. Both of these compare the output voltage from a DAC with the input voltage.

**Figure 14.60** Digital to analog converters: (a) weighted resistors with OpAmp adder; (b) R-2R ladder

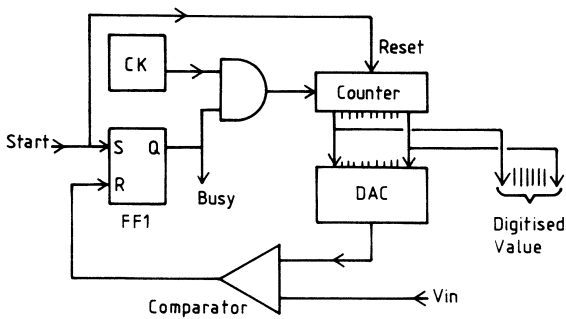

Figure 14.61 Ramp ADC block diagram

The operation of the ramp ADC, shown on Figure 14.61, commences with a start command which sets FF1 and resets the counter to zero. FF1 gates pulses to which counts up. The counter output is connected to a DAC whose output ramps up as the counter counts up. The DAC output is compared with the input voltage, and when the two are equal FF1 is reset, blocking further pulses and indicating the conversion is complete. The binary number in the counter now represents the input voltage. A variation of the ramp ADC, known as a *tracking ADC* uses an up/down counter that continuously follows the input voltage.

The ramp ADC is simple and cheap, but relatively slow (typical conversion time  $> 1$  mS). Where high speed, or high accuracy is required a successive approximation ADC is used. The circuit, shown on Figure 14.62 uses an ordered trial and error process. The sequence, shown on Figure 14.63, starts with the register cleared. The MSB is set, and the comparator output examined. If the comparator shows the DAC output is less than, or equal to,  $V_{in}$ , the bit is left set. If the DAC output is greater than  $V_{in}$ , the bit is reset. Each bit is similarly tested, in order from MSB to LSB, causing the DAC output to quickly home in on  $V_{in}$  as shown. In total the number of comparisons is equal to the number of bits, so the conversion is much faster than the ramp ADC.

Successive approximation ADCs are fast (conversion times of a few  $\mu$ S) and accurate (0.01% is easily achievable). Unlike the ramp ADC, the conversion time is constant. They are, however, more complex and expensive than the simpler ramp ADC.

The *flash converter* is the fastest ADC available, but is not widely used for high accuracy applications because the circuit complexity increases rapidly with the number of bits. Commercial eight bit flash encoders such as the MC10135 are to be found in digital television and digital audio applications. Figure 14.64 shows a simple three bit converter with a resolution of one part in eight.

The input signal is compared simultaneously with seven equally spaced voltages, for our simple example these are 1, 2, 3 V etc. If, for example, the input signal is 3.6 V, comparators a, b and c will all give a '1' output, and comparators d to g will give a '0' output.

The outputs from the seven comparators are converted to a three bit binary output by an encoder. This is simple combinational logic, output C, for example, being given by

$$C = \bar{a} + \bar{c} + \bar{e} + \bar{g}$$

The complexity of the combinational logic goes up considerably with the number of bits and the degree of internal checking required.

The flash converter is very fast with conversion times of a few nanoseconds, the only constraint being the propagation

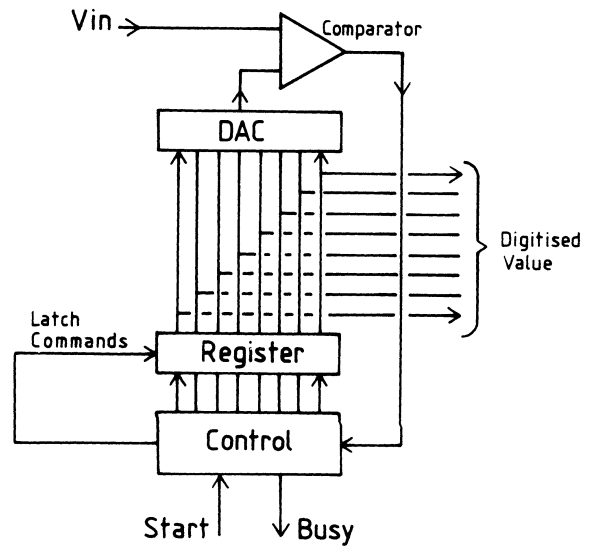

Figure 14.62 Successive approximation ADC block diagram

Figure 14.63 Operation of a successive approximation ADC

delays through the comparators and the encoder logic. It is, however, prone to giving invalid transitory states if the input signal is varying, going, say, 011 to 111 to 100 for an input change from three to four volts. For this reason a flash converter is usually preceded by a sample and hold circuit to freeze the analog input circuit whilst the measurement is being made.

## 14.10 Practical considerations

Real life digital systems have to connect to the outside world, and this can often bring problems when noise and effects such as contact bounce are encountered. Precautions also need to be taken against inadvertent introduction of high voltages into logic systems via inter-cable faults on the plant.

All signals between a logic system and the outside world should use a technique called *opto isolation* when cable lengths are longer than a few metres. Figure 14.65 shows

Figure 14.64 Three bit flash ADC

typical input and output circuits. In both, the signal is electrically isolated by using a coupled LED and photo-transistor. Because the plant side power supply and digital power supply are totally separate, the system will withstand voltages of up to 1 kV without damage to the digital equipment (although such voltages would probably damage the plant side components of course). The absence of ground loops and relatively high current levels (around 20 mA) also gives excellent noise immunity.

Opto isolation devices (such as the TIL 107) are usually constructed in a 6 pin IC, and are characterised by a *current transfer ratio*. This is defined as the ratio between the photo transistor collector current to the LED current. A typical value is 0.3, so 20 mA input current will give 6 mA, output current. If Darlington phototransistors are used, transfer ratios as high as 1.2 can be obtained.

Noise can also enter digital systems via the power supply rails so excellent filtering is necessary, both the d.c. side and (with LC filter) on the a.c. supply side. It is particularly important to adopt a sensible segregation of 0 V rails such that digital logic, relays/lamps and analog circuits have separate 0 V returns to some common earth points. Under no circumstances should high currents flow along logic 0 V lines, or the logic 0 V be taken outside its own cubicle.

Digital ICs can also generate their own noise on power supplies (TTL is particularly troublesome). It is therefore highly desirable to provide each IC with its own local 0.01  $\mu$ F capacitor. A single large value electrolytic has no effect as the noise is caused by rapid  $di/dt$  and the PCB track inductance.

Mechanical contacts from switches, relays etc, do not make instantly but 'bounce' rapidly for 1 to 4 ms due to dirt and the uneven constant surfaces. In many purely combinational logic systems this does not matter, but where counting, sequencing or arithmetic circuits are used, trouble can ensue.

Contact bounce can be removed by RC filters, but the best solution is to use a bounce removing flip flop as Figure 14.66. Provided break before make contacts are used, the circuit gives totally bounce free true and complement

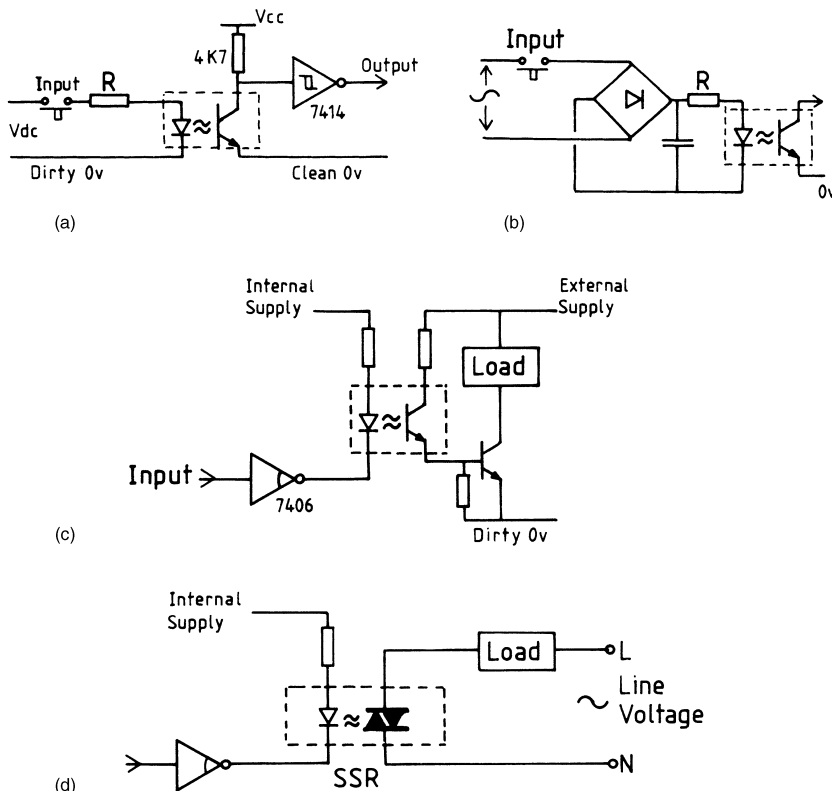

Figure 14.65 Optical isolation between digital system and outside world: (a) d.c. input circuit; (b) a.c. input circuit; (c) d.c. output circuit; (d) a.c. output circuit

Figure 14.66 Bounce removing flip-flop

outputs. If the contacts are some distance from the digital system opto isolation should, of course, be used before the flip flop.

### 14.11 Data sheet notations

The following abbreviations are commonly (but by no means universally) used on logic data sheets:

A, B, C, D...	Data inputs. Where a number is implied, A = 4, B = 4, C = 8 etc.
a, b, c, d, e, f, g	Seven segments display signals
BCD	Binary coded decimal
BI	Blanking input
C	Capacitor for timer or monostable
Cin, Cout	Carry in, Carry out
CD	Count down input (on up/down counter)
CEP	Count enable parallel input
CER	Count enable ripple input
CK	Clock (often with > symbol)
CS	Chip select
CU	Count up input (on up/down counter)
CY	Carry out
D	Data input on D type flip flop
DEC	Decrement input (on up/down counter)
DIS	Disable tri-state output
EN	Enable
GND	Ground or 0 V
I/O	Input/output (often on bidirectional buffer)
INC	Increment input (on up/down counters)
INH	Inhibit
J, K	Inputs on JK flip flop
LE	Latch enable

LT	Lamp test
MR	Master reset
OEN	Output enable (for tri-state gate or buffer)
OF, OV	Overflow
PE	Parallel enable
PH	Phase input for liquid crystal display drivers
P/S	Parallel/Serial selection
Qn	Output with weighting (e.g. Qb)
R	Reset or Resistor for timer or monostable
RBI	Ripple blanking input
RBO	Ripple blanking output
RC	Resistor/capacitor for timer or monostable
RCO	Ripple carry out
S	Set input or sum output
SDL	Serial input data to shift register shift left
SDR	Serial input data to shift register shift right
Si	Serial input
SQ (or Qs)	Serial output
SR	Synchronous reset
ST	Strobe
T	Trigger
TC	Terminal count output
U/D	Up/Down mode control for counter
Vcc	Positive supply
Vdd	Positive supply
Vss	Usually 0 V
Vee	Negative supply
WE	Write enable
X	Data inputs for data selector
$\overline{\text{A}}$	Schmitt trigger action
$\Sigma$	Sum output
>C	Clock input

## 15.1 Introduction

Digital systems are used to process discrete elements of information. They are built from digital electronic circuits that process discrete electrical signals using simple logic and arithmetic operations. A digital electronic system can also be used to hold or store discrete elements of information and this gives the system a memory capability. The ability to store information or data and to process the data by logical or arithmetic operations is central to the design of nearly all digital information-processing systems including digital computers. The function of a digital system is determined by the sequence of operations that are performed on the information or data being processed. A digital system can be classified by the way in which its sequence of operations is implemented.

A digital system is considered to be hardwired if the sequence of operations is governed by the physical interconnection of the digital processing elements. For example, in hardwired logic systems the physical interconnections of the elements govern the routes by which data flows between the processing elements and thus the sequence of processing operations performed on the data. Conventionally, a hardwired system is considered to be inflexible because the design is specific to a particular processing function: if the processing function is changed, then the processing elements and their interconnections have to be altered.

The flexibility of hardwired systems has been much improved by the introduction of programmable (i.e. configurable) logic devices such as Programmable Logic Arrays (PLAs) and Field Programmable Gate Arrays (FPGAs) that can be programmed or configured to implement an application-specific digital signal processing function. Flexibility has been improved further with the introduction of re-programmable (i.e. re-configurable) devices that can be reprogrammed easily during fast-prototype system development, and can be reprogrammed after a product has been deployed to provide enhanced features or performance. Progress in this area has been rapid and the latest generation of re-programmable FPGA device can be configured with a wide variety of communication interfaces. This opens the possibility of using advanced communication technology, such as the Internet, to re-program or re-configure a remote hardwired system.

A digital system is considered to be genuinely programmable if a prescriptive program of instructions (i.e. software) can be used to control the data-processing function of the system. This type of system usually incorporates a general-purpose processing element which is programmed to implement a specific function in a predetermined way. The coded instructions are normally stored in the memory part of the system and the program forms an integral part of the system. The ability to define the function of the digital system by programming introduces considerable flexibility into the system because the programming operation can take place after the general-purpose digital elements have been designed. It also means that identical hardware designs can be used in a number of different applications, the system being tailored to the individual tasks by the applications program. A wide range of simple fixed-function programmable systems, such as sequencers and micro-programmed controllers, are used as controllers in embedded electronic systems. In this type of application the sequence of instructions is usually held in read-only memory (i.e. firmware) which increases the robustness of the system.

The digital computer is a very important class of stored program system. The computer or microprocessor is distinguished by the fact that its processing function depends on

both the prescriptive sequence of coded instructions and the value of the data being processed. In effect, the program prescribes a number of possible sequences of operations and the conditions under which they may be carried out. The computer, under program control, assesses the data and determines which specific sequence of instruction is to be executed. It is the ability of the computer to take into account the value of the data being processed, when taking decisions about the type of processing to be performed, which makes the computer such a significant and powerful information-processing device.

All three forms of digital electronic system find widespread application. Traditionally hardwired logic has been used extensively to provide the control and interface logic for more complex digital components such as microprocessors and other very large scale integration (VLSI) devices. It is also used in the design of high-speed signal processing circuits for FPGA implementation. Increasingly, hardwired logic is used to provide the interface circuits between the main functional components within a complex FPGA. Where flexibility is required, it is common to use reconfigurable systems particularly in more complex applications.

Programmable systems are used in an extremely large range of applications. The simpler fixed-function programmable systems are often used in repetitive tasks such as input scanning and data acquisition. They are also used in mass-produced products and as components of larger systems such as telephony equipment. However, the continually increasing computational power of the microprocessor and its derivatives, such as digital signal processing (DSP) devices or powerful reduced instruction set (RISC) processors, has led to many of these applications being designed using fully programmable digital systems. In addition, commercial off-the-shelf (COTS) microprocessors are commonly used in both stand-alone and embedded systems. Such systems are providing economic solutions to design problems in an increasingly wide range of application.

The increase in size of VLSI logic circuits has led to a new generation of reconfigurable devices that are large enough to contain a complete digital processing system within a chip, called System on Chip (SoC) devices. An SoC device can be configured to include an embedded digital RISC processor, memory, communication interfaces, clock management, application-specific digital signal processing (hardwired logic functions), and appropriate internal interfaces and data buses. This allows the designer to partition a design into those parts that will be implemented as software executing on the embedded processor and those parts that will be implemented in hardware as high-speed application-specific logic circuits. This design approach, known as co-design or co-ware, has the significant advantage that established and high-performance parts of the design can be committed to application-specific hardware, and more adventurous parts of the design or low-speed functions can be committed to easily changed software. This minimises risk, facilitates time-to-market which gives competitive advantage, and provides a good path to post-deployment upgrades of the system's capabilities and performance.

## 15.2 Structured design of programmable logic systems

The design of an application-specific digital system typically involves the so-called 'top-down' approach and starts from a specification which includes a statement of the problem and the identification of the principal functional parts of

the system. This can be elaborated as an architectural specification which identifies the major components of the data or signal processing system and a control specification which describes an algorithm or procedure for the functional control of the processing system.

Traditionally a systems-level design approach is adopted and the design is developed through a structured process of elaboration and refinement. During this process, the data- or signal-processing specification is translated into a set of digital signal processing modules or circuits. Similarly, the control algorithm is depicted as a finite state machine (FSM) and is translated into a sequential logic circuit that generates the sequence of control signals which coordinate and synchronise the signal processing modules. In large designs the process of design refinement through analysis and decomposition can be applied repeatedly to form a hierarchy of functional descriptions. The process of decomposition is conventionally terminated when the granularity of the description matches that of commonly used digital electronic building blocks such as arithmetic circuits and memory elements, or sets of logic gates. However, modern programmable devices, such as complex programmable logic devices (CPLDs) and FPGAs, have complex internal structures that are purpose designed for the efficient implementation of large functional units such as multipliers or ALUs. Therefore, it is often counter-productive to elaborate a design down to gate level without taking into account the logic structure of the target device.

Figure 15.1 shows the general organisation of a system designed using such an approach. It comprises external inputs and outputs, the controlled circuit which performs the data or signal processing, the controller which governs its behaviour, and internal signal paths which transfer condition or status information from the controlled circuit to the controller and control signals generated by the controller to the controlled circuit. The FSM controller is a simple sequential circuit that comprises: a state register which stores the current value of the state variables, combinational logic for generating the next value of the state variables, a clock signal which synchronises the transition from the current state to the next state, and combinational logic for generating the value of the outputs (which are either a function of the current state or a function of the inputs and the current state).

Structured design techniques are well suited to computer-aided design (CAD) or electronic design automation (EDA) procedures. In particular, the hierarchical decomposition techniques used during the design phase have a one-to-one correspondence with the hierarchical CAD techniques used in traditional schematic diagram-based approaches to the capture, simulation, layout and routing, implementation, test and validation of complex circuit designs. Increasingly CAD tools provide high level specification capture facilities, such as graphical state machine (FSM) editors, to help capture design features in a tangible and user friendly manner.

The trend is to write the system specification using either a formal notation, or a programming language such as C or concurrent extensions of C, or a hardware description language (HDL) such as VHDL or Verilog. These notations provide constructs that facilitate the description of complex logic systems or algorithms and an underlying mathematical structure that can be used to reason about the behaviour of the systems. The use of such abstract or high-level notations has been found to facilitate design by allowing the designer to focus attention on the functional aspects of the design without the need to bind the design to a particular implementation technology. This is supported by modern CAD tools that allow high-level behavioural specifications to be simulated to verify the function of the system (i.e. using symbolic simulation) before the high level description is compiled (i.e. synthesised) into a logic circuit. It is conventional to use the high-level description language to describe both the design (or unit-under-test) and a test-bench (test sequence generator and response analyser). Thus the highest level in the design hierarchy comprises both the design and a test-bench.

Design synthesis CAD tools are commonly used to translate high-level behavioural digital systems specifications into logic circuits. The synthesis process is not easy, and modern synthesis tools typically use artificial intelligence techniques and employ deep knowledge of the architecture of the FPGA in order to synthesise sensible, efficient and fast logic circuits. Once synthesised, the design can be incorporated into the conventional logic design process of post-synthesis simulation, routing, implementation, test and validation.

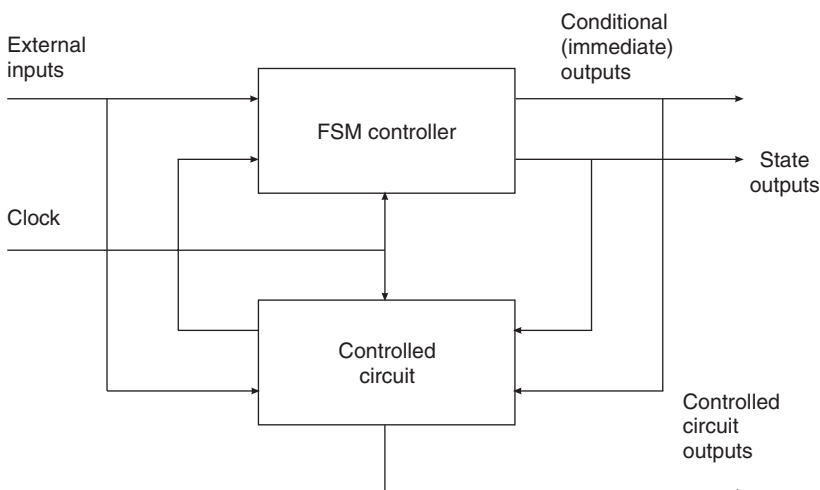

Figure 15.1 General organisation of a structured digital design

### 15.2.1 Design for test

It is normally a principal design requirement that the circuit should be testable. In most structured design methods the derivation of the functional specification goes hand-in-hand with the specification of tests to verify that the designed circuit functions as intended. The problem of testing a circuit is made more difficult when it is implemented as an ASIC because the limited number of pins on the integrated circuit restricts access to test points in the circuit. In particular, the constraint that test inputs must be applied via the external input pins limits the controllability of internal parts of the circuit under test. Similarly, the constraint that the response of the circuit must be observed using the output pins limits the ability to observe the state of internal parts of the circuit under test. For testability, it is necessary to ensure that the accessible or primary inputs can drive each node of the circuit (the property of controllability) and that each node can be observed from the accessible or primary outputs (the property of observability).

Combinational logic is tested by applying a set of test patterns to the inputs of the circuit, measuring the circuit's response at its outputs, and comparing its response with its predefined fault-free function. In order to test a testable circuit, it is necessary to generate a set of inputs (test vectors) which can be applied to the primary inputs and drive each node of the circuit. Observability problems may arise if redundant logic is added to a circuit to provide hazard cover.

The problem of testing sequential logic is considerably more complex because the state of a sequential circuit is a function of both the current inputs and the previous state of the circuit. To reduce the problem of testing such circuits, it is desirable to open the feedback paths (which are essential to sequential behaviour) and thus change the problem to one of testing the constituent next-state and state-output combinational logic. This requires the introduction of additional gates to inhibit the feedback paths, to allow the assertion of test states, to ensure the direct control of the clock, and to allow the observation of the next-state variables. This approach tests the combinational components and memory elements but does not provide a full-speed test of the actual sequential circuit and additional tests are required to ensure that the circuit is free of race hazards.

In the case of structured designs, a primary concern is the test of the controller which coordinates and synchronises the data or signal processing modules. In a typical FSM, the function of the controller is clearly defined by the control algorithm and the finite state machine controller is relatively easily tested once the feedback loops of the sequential part of the circuit are opened. Furthermore, the state register can easily be reconfigured in the test mode to form a shift register for the entry of test data and the capture of test results. This is shown in *Figure 15.2* for a controller with two state variables; the test mode select signal TMS causes the reconfiguration of the D-type state register to form a test vector shift register (shown in bold). This technique, which is known as scan path testing, can be applied

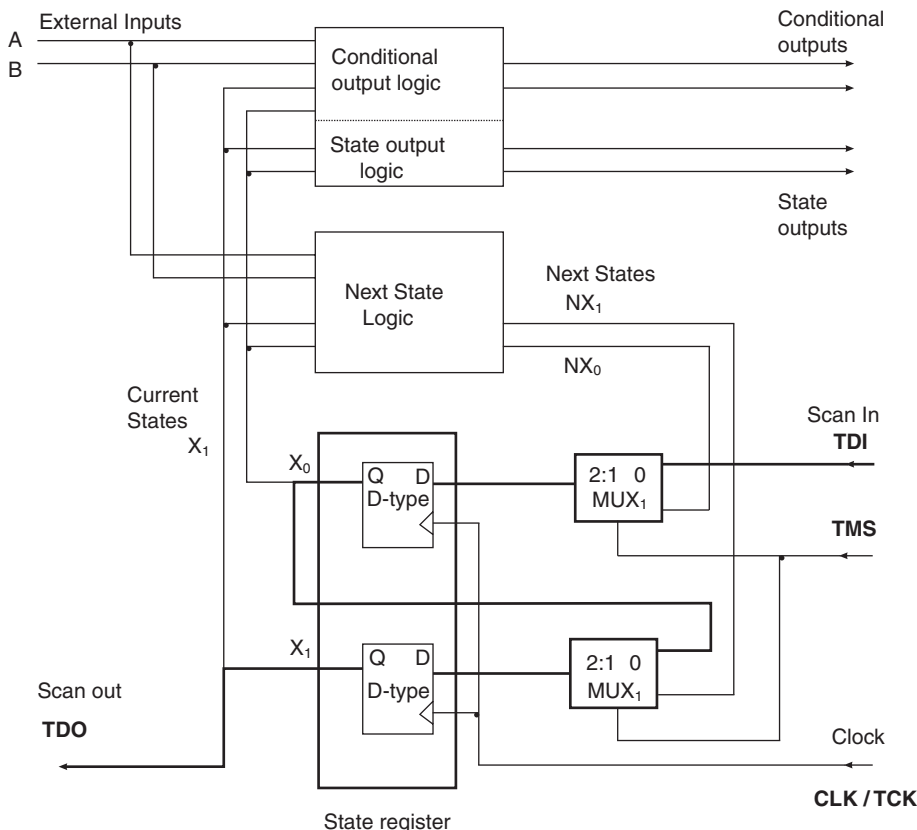

Figure 15.2 Scan-path design for an FSM controller

to a wide range of circuit and there are many variations of the theme, such as random scan and level sensitive scan techniques.

In general, significant increases in controllability and observability can be obtained if serial input and output techniques are used to load test data into an ASIC and remove capture response data from the ASIC. This can be achieved by incorporating a general-purpose shift register with serial-load/parallel-out, and parallel-load/serial-out facilities within the ASIC. In a typical test, the ASIC circuit would be put into test mode and the test stimuli or vector would be serial loaded into the shift register. The ASIC would then be switched into normal mode and the test data present at the parallel output of the shift register would be allowed to excite the circuit. When the response had stabilised, observation data would be latched into the shift register using the parallel-load facility. The ASIC would then be put into test mode and the response would be output using the serial-output facility of the shift register. Clearly, the additional test circuits must be built into the ASIC as part of the design. This method requires up to five pins on the integrated circuit to be dedicated for test purposes: test mode select (TMS), serial test data in (TDI), serial test data out (TDO), direct control of the relevant clock circuits (TCK), and a reset (TRST). The use of such signals is consistent with the JTAG/IEEE standard 1149.1 which provides a framework for test at board and chip test level, primarily using the Boundary Scan technique that is commonly provided as a built-in component of modern VLSI and ASIC devices.

15.3 Microprogrammable systems

A typical digital system's design can be decomposed into a set of signal or data processing elements and a set of Finite State Machines (FSMs) which coordinate and control the signal- or data-flow and processing. To do this, the FSM controllers monitor any necessary signals (such as inputs or status signals) and generate the control signals necessary to coordinate, synchronise and control the signal- or data-processing elements. It follows that the FSMs form a crucial part of such designs, and a variety of structured design methods have been devised for capturing and synthesising the FSM controllers. These include traditional algorithmic state machine or ASM design methods, and state-transition diagram methods that allow direct synthesis of the design from Mealy or Moore diagrams. In addition, many HDL synthesis tools include program analysis tools that are designed to detect FSM-like structures and specifically synthesise FSM components. A key point in all these design methods is the assignment of a unique binary coding to each state of the system and the design of a bespoke finite state machine to generate the required state sequences and state outputs.

The need for bespoke hardware can be removed by designing a general-purpose controller (or finite state machine) which can be 'programmed' to produce the necessary control functions. To accommodate such an approach, a simple FSM can be reduced to a networks of states, state outputs, and single-qualifier decisions by replacing any conditional or immediate outputs by state outputs and by inserting additional states where necessary to ensure that only one qualifier is associated with each decision. A unique state identifier is then assigned to each state according to a normal binary count (as far as possible) so that the state-machine design can then be implemented using a counter,

with appropriate controls, instead of with a state register and combinational next state logic. The modified FSM can then be reduced to a set of 'instructions' by identifying commonly occurring structures and their associated counter control logic as follows:

- (1) *Sequence of states*: increment counter unconditional (IUC).
- (2) *Decision*: increment or branch conditional (IBC).
- (3) *Wait until condition*: hold or increment conditional (HIC).
- (4) *Branch unconditional*: branch unconditional (BUC).
- (5) *Loop forever*: hold unconditional (HUC).

The counter is normally controlled using two control lines, 'counter enable' (CE) and 'counter load' (LD). On the next clock, the counter is incremented if CE is asserted or a branch address is loaded into the counter if LD is asserted. Thus, the counter control logic necessary for each construct or primitive instruction defined above can be readily determined. The use of mnemonics (such as IUC, HIC etc.) to represent commonly occurring structures allows the FSM to be replaced by a list of primitive symbolic 'instructions'. Each instruction will define the present state identifier or location count, the mnemonic describing the control operation to be performed on the counter, the identity of any qualifier, the name or value of any branch address, and the name or value of the state outputs. A typical instruction format is shown in *Figure 15.3*.

A suitable processing architecture for the above primitive instructions is shown in *Figure 15.4*. The state register is implemented with a controlled counter and, as only one instruction is needed per state, the input and output logic is efficiently implemented in ROM. The relevant input (or qualifier) for each state is chosen by addressing a multiplexer. Before the contents of the ROM (or RAM) can be defined, each instruction must be assigned a binary code or 'opcode' and each input must be assigned a MUX address. The instruction decoder is needed to translate the instructions into suitable control signals for the counter. In the case of conditional instructions, the counter control signals depend on both the instruction type and the qualifier or 'flag'.

Thus, each instruction stored in ROM comprises an opcode, the binary MUX address for the input qualifier, the binary branch-location address, and the binary values of the state outputs. This form of instruction is known as a *microinstruction*. The function of the controller can be changed by simply altering the microinstructions, and this process is known as *microprogramming*. Microprogramming is tedious and error prone and software development tools such as assembly language generators are often used to allow programming using symbolic notations.

In practice, a number of proprietary microprogrammable controllers have been developed. They are often equipped with a primitive stack to allow a limited procedure or sub-routine facility. This requires additional instructions such as 'call procedure' or 'branch to procedure' and 'return from procedure' and mechanisms to increment the current counter (or ROM address) and save the incremented address in the stack, to load the procedure start address or value into

Location	Opcode	MUX address	Branch address	Outputs
----------	--------	-------------	----------------	---------

Figure 15.3 Microinstruction format

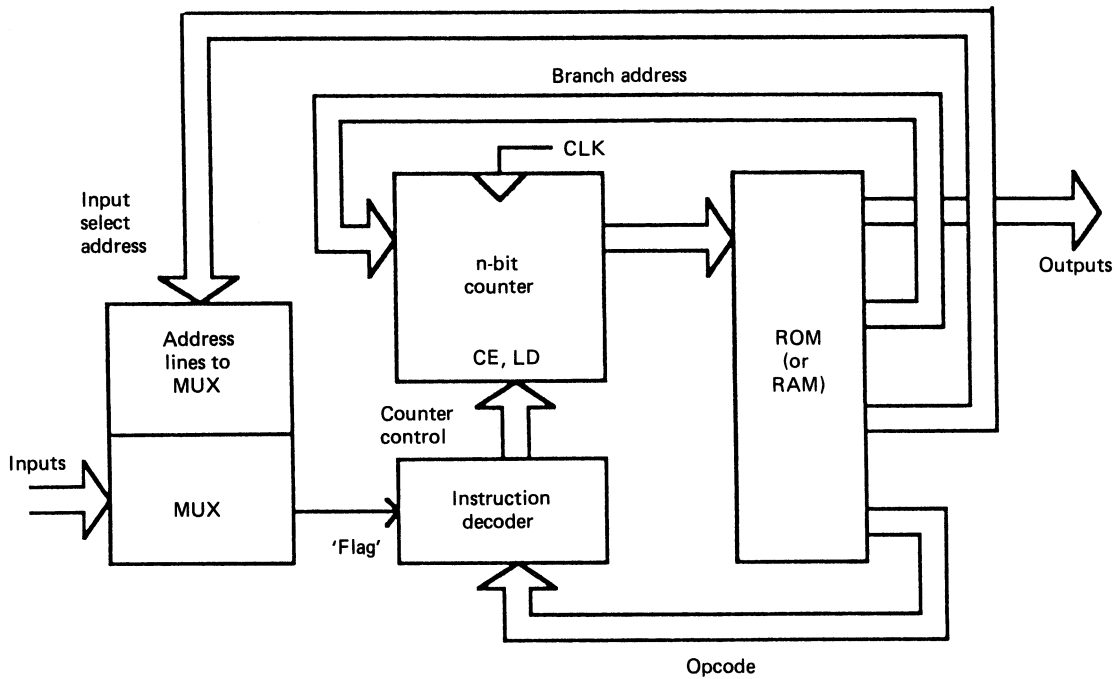

Figure 15.4 Simple microprogrammable architecture

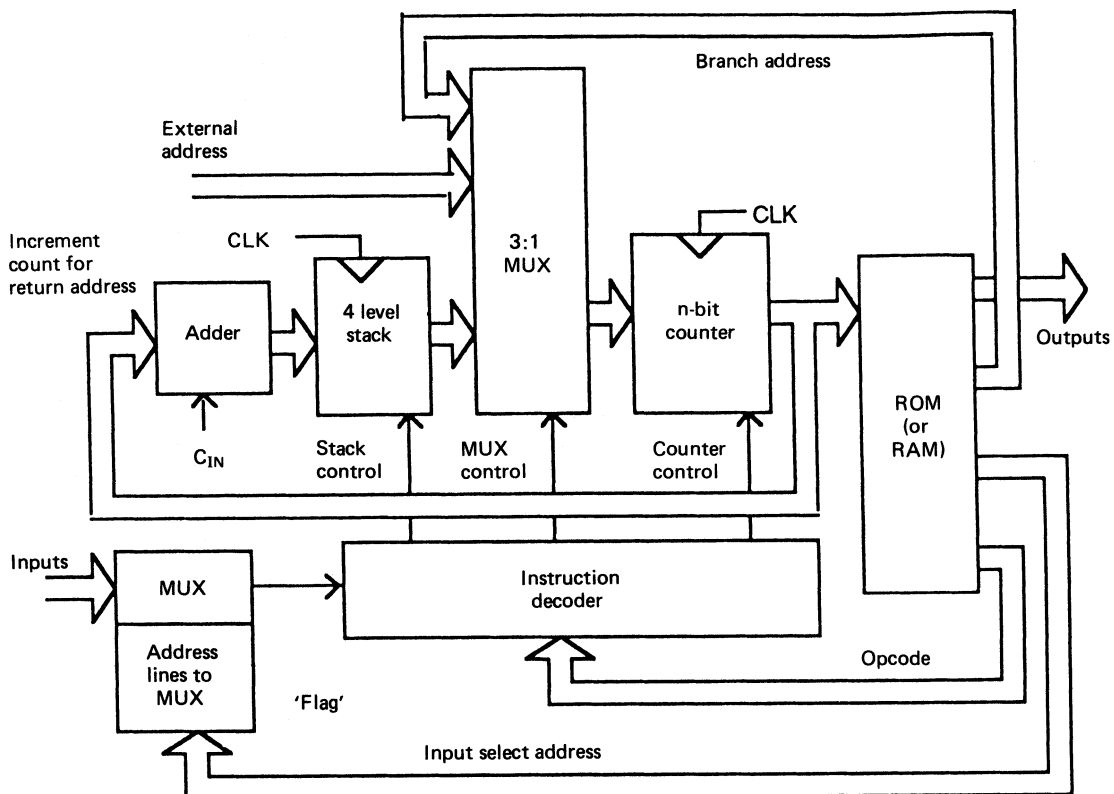

Figure 15.5 Microprogrammable controller

the counter, and to retrieve the address from the stack and load it into the counter. An external load facility for the counter may also be provided so that the controller can be used in conjunction with another processor. This gives the architecture shown in *Figure 15.5*. Such processors often have regularised instruction sets and well-developed tools for software development including simulation and emulation facilities.

Since a microprogrammed controller is a relatively simple circuit; designers have often taken the opportunity to incorporate a data processing capability into the design. Significantly, such microprogrammed 'processors' often incorporate a specialised, very high performance, arithmetic processor. Typical examples include high performance floating-point arithmetic processors, and digital signal processing devices (which include a high-speed multiplier and accumulator for implementing the repetitive add-and-multiply operations found in digital filtering algorithms). Microprogrammed controllers are readily available as stand alone devices, or as pre-prepared HDL scripts, known as 'intellectual property (IP) cores', that can be embedding within an HDL design and synthesised for an FPGA target.

## 15.4 Programmable systems

A programmable system, such as a microprocessor or computer, comprises a general-purpose processing unit which processes data or digital signals. The processing operations performed are specified by a computer program, which consists of a set of logical instructions stored in the computer memory.

A programmable system will comprise digital electronic circuits to:

- (1) *input* signals or data from external circuits or systems;
- (2) *move* or transfer the data within the system;
- (3) *store* the data before, during and after processing;
- (4) *process* the data by logic, arithmetic or bit manipulation operations;
- (5) *output* the processed data to external circuits or systems.

Each of these operations can be performed by an appropriate configuration of combinational and sequential logic circuits including memory elements. In practice, programmable systems comprise a general-purpose logic design which can be configured to perform a wide range of operations. The hardware is controlled by a program or sequence of instruction codes which define the operations necessary to implement a particular processing function. The instruction codes are normally stored in the memory part of the system and the function of the system can be changed simply by altering the stored program. This type of system can be considered to be composed of two parts: the hardware which is basically independent of the application and the software which defines the application function. Since the hardware part of such a system is invariant, it can be produced economically as a standard design or device.

There are basically two types of general-purpose programmable system. The fixed function programmable machine is a limited form of programmable system which is constrained to perform a prescribed and fixed sequence of instructions. This type of system does not have the capability under software control to select between two alternative sequences of instruction. A fixed function programmable machine is therefore forced to execute a

fixed sequence of instructions in all circumstances and is properly regarded as a programmed machine rather than a computer. The application function of such a system can be altered only by reprogramming the system. These systems can be used in any applications in which the processing function does not depend on the nature or value of the data being processed.

The digital computer is the most powerful and flexible form of programmable system. A program of instructions which are executed in sequence again defines its function, but in the case of the computer the program may specify alternative sequences of instructions and the conditions under which they can be executed. For example, conditional expressions and alternative sequences are implicit in high-level programming constructs such as 'if condition-true then...', 'repeat...until condition-true', and 'while condition-true do...'. Special hardware is required to carry out this type of operation and a computer is equipped with a logic circuit, known as a status register, which is used to store information about the status of the processor after it has executed an instruction. When a program is executed, each conditional expression is evaluated (using the actual values of the data variables) and the resulting values of the bits or flags in the status register are used to identify which alternative sequence of instructions is to be executed next. Thus, the order of processing may be modified according to the result of the instruction. It is this mechanism which allows a program to take into account the nature of the information being processed.

In effect, the computer can be programmed to take a decision about the future courses of action that it may take, based on the actual value of the data being processed. It is this facility which characterises a proper computing system and which makes the computer such a powerful data processing system. Such systems are providing economic solutions to digital signal and data processing problems in an increasingly wide range of applications.

### 15.4.1 The logic design of a digital computer system

A digital computer system can be considered to be composed of two logic structures. The first is associated with the flow, storage and processing of data and consists of the data input and output subsystems, the data highways used to move or transfer data within the system, the memory which is used to store the data, and the arithmetic logic unit which is used to process the data. The function of the processor is prescribed by a program of instructions held in memory. The second structure is responsible for controlling the fetching of instructions from memory and for ensuring that they are executed in the correct sequence. It also governs the detailed execution of each instruction and controls the data-flow and data-processing elements so that they perform the required processing operation.

The control structure consists of the memory which is used to store the program code and mechanisms for identifying the location of the next instruction, for fetching and decoding the instruction, and for identifying the location of any inputs or stored data which form the operands in a processing operation. It controls all aspects of the execution of the instruction including fetching operand data and, when necessary, taking into account the status of the previous programming operation. It also identifies the destination location of any resultand data generated by the processing operation and stores the resultand or generates an output.

The data-processing and program-control structures are heavily interconnected and often share common hardware.

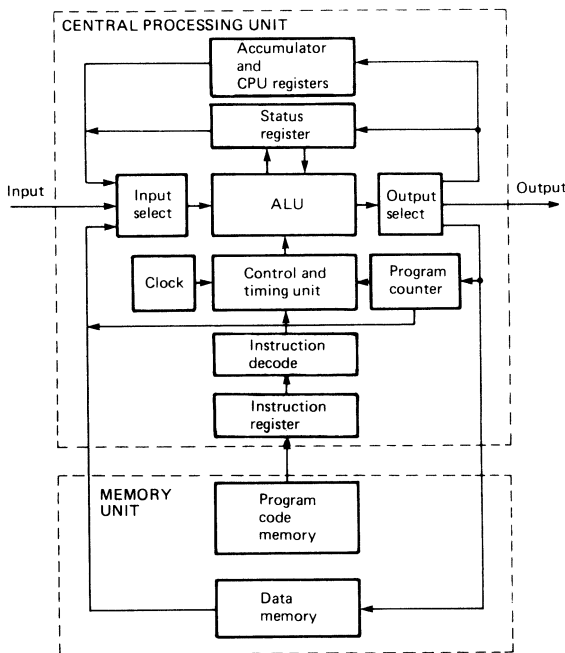

Figure 15.6 Processor architecture

In particular, the program code and the data being processed are usually stored in an identical binary format. It is usual for code and data to be stored in separate areas or segments within a common memory unit.

## 15.4.2 Processor architecture

Computers and microprocessors are general-purpose programmable systems which perform sequential processing operations. Classically, they are constructed using general-purpose functional units such as a central processing unit or CPU, a memory unit, and an input/output subsystem, as shown in Figure 15.6.

The CPU is the heart of the computer, it contains the control and timing unit (CTU) which controls the programmed operation of the system and the arithmetic logic unit (ALU) which processes the data. An external clock

provides the timing pulses or reference signals required by the CTU. The CPU also contains a number of important registers such as the *program-counter* which points to the next instruction, the *instruction register* which holds the current instruction, and the *status register* or *flag register* which stores the status information about the result of the previous instruction executed by the CPU.

The memory unit provides storage for program code and data. The code and data are always considered to be separate entities although they may share physical memory. (Some processor designs enforce the conceptual separation of code and data by providing separate memories for code and data.) The memory is arranged into words which consist of several binary digits, typically 8, 16 or 32 bits. Each word can be individually addressed and operated on by the computer.

The input/output subsystem of a computer provides the interface to external circuits or systems. Data may be passed in and out of the computer via serial or parallel interfaces. The input/output system is used to input program code, to input data for processing, and to output results. It also provides the means of communication with the operator via a man-machine or human-computer interface (MMI or HCI). The processing power of the computer can only be used if the input/output subsystems allow efficient communication between the user or application and the processing system.

Many computer systems are configured around one or more general-purpose data highways. They typically consists of a common bus structure of address, data and control lines and are used to communicate to all devices external to the CPU including memory, input/output systems and backing stores. The simple bus-orientated architecture illustrated in Figure 15.7 provides ease of access to the control, address and data highways which are used to interface any logical system to the CPU. Bus-oriented architectures are used in many designs to provide a flexible and easily expanded computer system.

## 15.4.3 Central processing unit

The CPU contains the CTU which coordinates, synchronises and controls the fetching of instructions from memory and the execution of the instructions. The execution of an instruction will typically involve fetching operand data from memory, processing the data in the ALU, and storing the result in memory. The CPU also contains at least the minimum set of internal registers necessary for the execution of a program. These include the program-counter

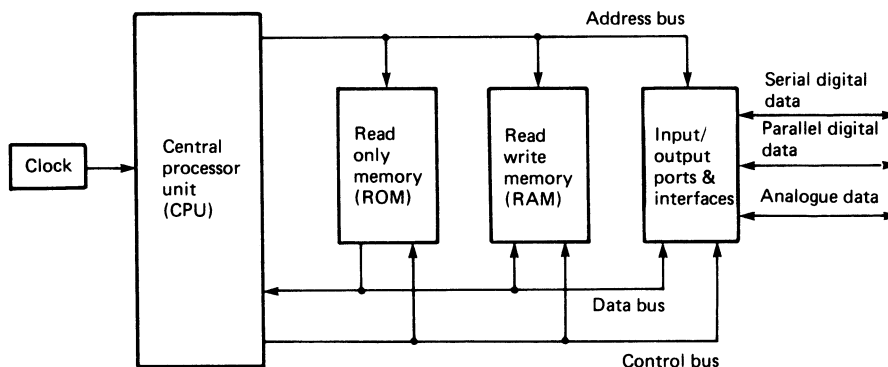

Figure 15.7 Bus-orientated system architecture

register, the instruction register, the data memory reference registers, and the CPU data registers.

15.4.3.1 Program-counter register

This holds the address of the memory location containing the next instruction to be executed. It is the programmer's responsibility to initialise the program-counter correctly, so that it points to the first instruction in the program. During program execution, the program-counter is automatically incremented by the CTU to point to the next instruction. In this way the CPU is forced to execute instructions in strict sequence. However, some instructions are provided which modify the contents of the program-counter. For example, unconditional jump, branch, or 'go-to' instructions simply overwrite or modify the contents of the program-counter to effect a branch to another instruction. Similarly, conditional jump or branch instructions modify the contents of the program-counter if a particular condition is satisfied. This feature allows the program sequence to be modified if a specified condition is detected in the data being processed e.g. if the result of the previous instruction was negative.

15.4.3.2 Instruction register

This register holds the current instruction so that it can be decoded and input to the control and timing unit. Specifically, the instruction register holds the opcode which defines the type of instruction. Depending on the type of instruction, it may also hold immediate operand data or the addresses of operands and the address of the resultand. Since operand data and addresses comprise many bits, they are commonly held in temporary registers which can be considered as extensions to the instruction register. The contents of the instruction register can not be overwritten by the ALU, nor can they be accessed by a programmer.

15.4.3.3 Status register

This comprises a number of discrete status bits or flags and holds status data about the result of the previous instruction executed by the ALU. The data are used when computing 'decisions', such as selecting one of two possible future courses of action. Processors actually compute decisions of this type in two stages. In the first stage the ALU computes the condition which governs the decision; the Boolean result (yes/no or true/false) is held in the status register. In the second stage, this result is used as a qualifier in a conditional operation, such as a conditional branch or jump, such that the value of the qualifier is used to choose the appropriate future sequence of instructions. It is the responsibility of the programmer (or compiler writer) to ensure the correct and consistent use of the status register throughout the two-stage process of computing a decision.

15.4.3.4 Data memory reference pointers

These registers hold the addresses of the operands and resultand and are loaded during the instruction 'fetch'. They are used to access data objects during the execution phase of the instruction cycle and should be capable of accommodating the various addressing modes associated with the complex data types used in high-level programming languages. Therefore, it is perhaps more accurate to think of a data memory reference pointer as a mechanism which generates the address of a data object. The number of

address registers available in a CPU is an important feature of computer architecture. Ideally, separate pointers or mechanisms are required for each operand and the resultand.

15.4.3.5 CPU data registers

These hold operands and resultand data during the execution of a program. Again, microprocessors differ, particularly in the internal storage provided in the form of CPU data registers. However, most processors have an accumulator register into which the ALU will automatically load the resultand of a processing operation. Many modern microprocessors have a larger number of CPU data registers which can operate as accumulators in complex arithmetic and logic operations.

Those parts of a processor which are of direct interest to a programmer are shown in the *programmer's model* which describes only those registers within the CPU which can be accessed by the programmer. Figure 15.8 shows the programmer's model of a typical microprocessor system.

15.5.4 Control and timing unit
