- (3) *Safety* (structural) is the ability of a system not to cause human injuries or loss of lives. In these documents, safety relates mainly to protection of workers during construction and maintenance operations. The safety of the public should be covered by National Regulations.

A useful concept in deciding loading effects is that of the 'return period' of a given loading (e.g. wind speed and related pressure). Due to Gumbel, the return period is the mean time between the occurrences of a phenomenon equal to (or greater than) a specified value. As return period  $T$  is related to probability  $p$  by the expression  $Tp = 1$  it follows that a loading event with a return period  $T = 50$  years has a probability  $p$ , of 2% of being exceeded in any one year.

In order to rationalise the concept of strength, it is suggested that the value corresponding to 10% exclusion limit

Figure 30.14 Principles of risk assessment<sup>35</sup>

(hence with a 90% probability of exceeding this value) would be used as reference. In Figure 30.14, the load equal to a return period of  $T$  (years) is compared with (or made equal to) the strength at 10% exclusion limit. The area under the two overlapping curves is a measure of the annual risk  $P_f$ . The annual reliability  $P_s$  of this arrangement is:

$$P_s = 1 - P_f$$

If  $\sigma_Q$  is the standard deviation of the load,  $\sigma_R$  that of the strength, and  $\bar{Q}$  and  $\bar{R}$  are their mean values then the coefficients of variation are  $V_Q = \sigma_Q/\bar{Q}$  for the load and  $V_R = \sigma_R/\bar{R}$  for the strength.

As an order of magnitude, when  $V_Q = 0.3$  and  $V_R = 0.10$  then for a return period of load of 50 years,  $P_s = 0.98$  and for a return period of load of 150 years  $P_s = 0.993$ .

One assumption made in the probabilistic approach is that one component would be selected to be weaker than the others, hence the reliability of the line would be that of the weakest component. All the other components would have to be designed in such a way that there is a given probability that they are stronger. Figure 30.15 expresses this concept.<sup>35</sup>

Thus if the area (A1) is a measure of the risk that the load may exceed the strength of the component, the area (A2) is a measure of the probability that component R2 may be weaker than component R1.

Some typical values of the strength coordination factor  $\phi_s$  are given below, for 90% probability that the desired probability of failure will be achieved (R1 to fail before R2):

$V_{R2}$	$V_{R1}$		
	0.05	0.10	0.20
0.05	0.91	0.81	0.63
0.1	0.92	0.83	0.66
0.2	0.93	0.86	0.69

where  $V_{R1}$  is the coefficient of variation of component R1 and  $V_{R2}$  is the coefficient of variation of component R2.

**Figure 30.15** Definition of the strength coordination factor  $\phi_s$ .  $P(R2 < R1) = 1 - P(\text{sof})$  is the probability that strength  $R2$  is smaller than strength  $R1$ . It is equal to one minus the required probability for the sequence of failure. Not to scale

The basic mathematical model used for the probabilistic design of the line is given by the following general design equation:

$$\gamma_u Q_T < \phi_R R_C$$

or load effect < strength.

All documents dealing with reliability accept this design approach. Some may be more specific as to whether  $Q_T$  is a wind load, an ice load or wind on ice load. If  $Q_T$  is considered as any load due to meteorological influences, with a return period of  $T$  years, the above relationship is always valid.

In this relation, and for IEC documents:

- $\gamma_u$  is the use factor coefficient applied to load;
- $Q_T$  is the load corresponding to a return period  $T$ . This is the limit (or ultimate) load for design purposes (50, 150, and 500 years are accepted as references);
- $\phi_R$  is the global strength factor;
- $\phi_R = \phi_c \phi_N \phi_q \phi_s$ ;
- $R_C$  is the characteristic or nominal strength;
- $\phi_c$  is the correction factor referred to the exclusion limit of material strength;
- $\phi_N$  is the factor related to the number  $N$  of components subjected to the critical load;
- $\phi_q$  is the factor related to the quality level of a component during fabrication and/or construction; and
- $\phi_s$  is the strength coordination factor.

Values for these factors are given in tables<sup>34,35</sup> together with the necessary justifications, and the equations required for their evaluation. A reasonable tool is thus available to the overhead line engineer for the mechanical design of the line. No doubt a fair amount of calibration will still be needed. However comparisons of alternative designs become possible not only with regard to economics, but also with regards to relative reliabilities.

## 31.1 Introduction

The essential components of a cable are a metallic conductor of low resistivity to carry the current and insulation to provide a dielectric medium for isolating conductors from one another and from their surroundings. The conductor may consist of solid metal or of wires or segments stranded together. A single-core wiring cable for installation in conduit represents this basic construction. For other applications, two or more single-core units may be assembled together with overall protective coverings to prevent moisture ingress, and provide resistance to mechanical damage and to other external influences such as corrosion and fire.

In general, the voltage range extends from automobile cables at 6–12 V to the highest transmission voltages, which now are reaching towards 760 kV. In order to specify suitable insulation and construction for the required service performance, the design voltages are quoted in the form of  $U_0/U$ , i.e. (voltage to earth)/(voltage between phases). Cables are not manufactured, however, for every individual voltage requirement—e.g. although the most common supply voltage in the UK is 240/415 V, the cables actually used are designated as 0.6/1 kV. This is largely related to the fact that the minimum thickness of insulation which can be economically applied meets the higher voltage.

It has been traditional practice to describe cables in categories of low-voltage (l.v.), medium-voltage (m.v.), high-voltage (h.v.), supertension (s.t.), extra-high-voltage (e.h.v.) and ultra-high-voltage (u.h.v.). However, the exact demarcations have never been very precise, because they vary between different countries, among different groups of engineers and with the passing of time. Not so long ago, the conventional supply cables operating at 240/415 V were known as m.v., but now they are l.v.; 11 kV cables have also changed from h.v. to m.v. Thus, there can be confusion especially at international meetings, and it is better to refer only to the actual voltage designation.

There is also some overlap when cables are classified into the three major groups of usage: (1) wiring and general, (2) power distribution, and (3) transmission. When heavy power cables were essentially of the paper-insulated type, there was little problem, because they tended to be made in different factories from wiring cables and the type of insulation governed the usage group. When paper insulation operated with internal or external fluid or gas pressure, as required for voltages above 33 kV, the cable came into the transmission grouping. Nowadays, the basic insulation materials and constructions used for wiring cables can, with appropriate insulation thickness, be used across the three major groupings, and it is becoming more complex to define specific cable categories. For public supply there is no problem, but for ship cables, offshore supplies and large factory distribution there can be considerable overlap between the wiring and the distribution categories. At the top end of the voltage range we now have 132 kV cables for distribution rather than transmission, and polyethylene or cross-linked polyethylene is finding acceptance across the whole spectrum from 1 to 275 kV.

In this chapter, the section on power distribution cables is aimed at public supply networks together with the larger power cables used in factories, etc., from 1 to 33 kV. Where the broad wiring cable category encroaches on this field, reference is made in the text. Cables for voltages above 33 kV are covered in the section on transmission cables.

### 31.1.1 Standards

Table 31.1 lists most of the British (BS) and International (IEC) Standards applicable to cables and cable systems,

including tests. While most national standards are in accordance with IEC requirements, the IEC Standards represent a consensus of national opinion and take many years to prepare. There is, consequently, a time lag in taking account of new developments, but British Standards have been more comprehensive in requirements and in updating revisions.

However, a fundamental change affecting the British Standards arises from the activities of the European Committee for Electrotechnical Standardisation (CENELEC), of which the membership consists of the standards organisations of the European Common Market and the EFTA countries. The aim of CENELEC is to remove technical barriers to trade among the member countries, and to this end it is engaged in the harmonisation of their national standards.

The mechanism is the preparation of Harmonisation Documents and, after these are issued, the member countries are required to bring the technical requirements of their national standards into conformity with them. There must be no extra requirements or deviations, except in special circumstances and subject to general agreement, and then only on a temporary basis.

To date, the two most important harmonisation documents for cables which have come into effect are:

HD 21 Polyvinyl chloride (PVC) insulated cables and flexible cords of rated voltage up to and including 450/750 V

HD 22 Rubber insulated cables and flexible cords of rated voltage up to and including 450/750 V

and it is intended to extend harmonisation to all types of mains cables.

Among the features arising from this structure are the following:

- (1) The broad policy is to use IEC standards, if suitable and available, as a basis for harmonisation.
- (2) When CENELEC begins work on a particular type of cable (or a subject having an important bearing on cable standards), a 'standstill' or 'status quo' arrangement comes into effect. Changes in relevant national standards cannot then be made until harmonisation has been agreed or permission obtained from CENELEC, to avoid prejudicing the harmonisation.
- (3) While the number of cable designs and types will be kept to a minimum, it will still be possible to have a national standard for a type of cable not of interest to other member countries of CENELEC.
- (4) Individual customers can still obtain cables made to their own specification, but it is hoped that this will be kept to a minimum. Because they have to be produced as 'specials' they may suffer from a delivery and/or a price penalty.
- (5) Implementation for flexible cables and some wiring cables has been effected and work on the harmonisation of mains cables is at an advanced stage. PVC cables to BS 6346 will probably be the first mains cables involved, but the changes are likely to be relatively minor.

Another important facet of CENELEC activity relates to certification and associated marks. These are issued by national approval organisations (NAOs) to indicate independent assurance of manufacture to specification. A common marking scheme, utilising the 'HAR' mark, has been devised. There is a reciprocal agreement accepted by most of the CENELEC countries' national approval organisations, under which for cables to harmonised standards, each NAO will recognise the common marking as superseding its own national mark. The procedures for granting

a licence to a manufacturer to use the mark are identical in all the participating countries, based on initial approval, from inspection of manufacturing and testing facilities and testing of samples, and subsequent surveillance in the form of periodic testing of samples. In the UK the approval organisation is British Approvals Service for Cables (BASEC). Under the Low Voltage Directive, of which the requirements have to be incorporated in the national laws of the Common Market countries, it is required that electrical equipment for voltages up to 1000 V should be accepted in each country as meeting the safety requirements of the directive if it conforms with a harmonised standard. Moreover, it should be presumed to conform with the relevant harmonised standard if the manufacturer qualifies for the use of the common mark.

31.2 Cable components

31.2.1 Conductors

31.2.1.1 Conductor materials

Materials and the form in which they are used comprise normally: (a) copper in solid form up to 2.5 mm<sup>2</sup> for wiring cables and power cables, and 150 mm<sup>2</sup> for mineral insulated cables, and in stranded form up to 2000 mm<sup>2</sup>; (b) tinned copper similarly but in a narrower range for wiring cables; (c) solid aluminium up to 300 mm<sup>2</sup> and stranded aluminium up to 2000 mm<sup>2</sup>; (d) an aluminium sheath as a concentric neutral conductor; and (e) lead and aluminium sheaths and steel wire or strip as an earth conductor.

In the USA some use was made of sodium by filling it into an insulating polyethylene tube. Although technically satisfactory, handling difficulties were found to outweigh the economic advantage. Another, more novel, application, which has been proved technically but not yet brought to commercial fruition, is the use of niobium alloys with superconducting properties at very low temperatures. Further reference to this subject is made in Section 31.5.

Some typical physical and electrical properties of the metals used in cables are given in Table 31.2.

**Copper** Because of its excellent conductivity, reasonable price and ease of working into rod and wire, copper has always been the basic material of the cable industry. Until the 1950s it was virtually without any challenger. Except when tensile strength is important, notably for self-supporting overhead line cables, it is always used in the annealed condition, partly to obtain flexibility, but more because conductivity decreases significantly with degree of working. Impurities also affect conductivity and are kept to a maximum of 0.01%.

Tinned copper wires have been used for wiring and flexible cables, partly to improve solderability but mainly to prevent interaction between copper and the sulphur present to produce vulcanised rubber insulation. With the substitution of synthetic insulation for natural rubber the use of tinned conductors has diminished.

**Aluminium** Although having only 61% of the conductivity of copper and, hence, for equal conductance requiring a conductor area 1.6 times that of copper, the low density of aluminium results in the actual weight of a comparable

Table 31.2 Physical properties of metals used in cables (20°C)

Property	Copper	Aluminium	Lead

<sup>3</sup>/<sub>4</sub> H, Three-quarters hard; H, hard.

conductor being only half that required with copper; i.e. the current-carrying capacity of an aluminium conductor is 78% of that of a copper conductor of equal area, and 1 t of aluminium does the work of 2 t of copper. However, as the size is larger, the amounts of all the other materials in the cable are increased. Any economic advantage, therefore, varies with the relative metal prices and with the type of cable. When the conductor metal is a small fraction of overall volume, the use of aluminium is uneconomical.

Another difference from copper is that, whereas solid copper conductors become difficult to handle above about 16 or 25 mm<sup>2</sup>, solid aluminium conductors can be handled easily up to 240 or 300 mm<sup>2</sup>, which further keeps dimensions to a minimum. Aluminium in a soft temper is quite suitable for these solid conductors, but lacks strength in wire for stranded conductors. However, as aluminium does not suffer the same penalty as copper in loss of conductivity with work-hardening, it is satisfactory to use a broad  $\frac{3}{4}$ -hard temper for aluminium wire.

Certain impurities lower the conductivity of aluminium, but the effect is not as great as with copper. Subject to control, the basic grade of 99.5% purity produced by electrolytic refining is satisfactory and appropriately defined in cable standards.

Apart from the economic factor and its reduced weight, aluminium has no real advantage over copper for cables and it also suffers from a positive disadvantage. This relates to the protective oxide skin which is always present and which requires somewhat greater care to be taken when making soldered joints. To a large extent, compression joints have replaced soldering and have been designed to deal satisfactorily with this aspect.

### 31.2.1.2 Constructions

Metric conductor sizes, standard in the UK since 1969, are used in all countries other than the USA. Table 31.3 shows some comparisons.

Stranded conductors are available in circular form up to 2000 mm<sup>2</sup> and, for the lower voltage ranges, in sector-shaped contour up to 630 mm<sup>2</sup> in specific cases. The minimum number of wires is defined in IEC 228. Shaped conductors are normally pre-spiralled so that the cores fit easily together without applied twist in the laying-up operation. To provide a smooth surface and reduce the dimensions, it is now the practice to compact stranded conductors by a rolling process.

In the UK, aluminium conductors for cables up to 1.8/3 kV have largely been solid and of sector shape for multicore cables. Sector corner radii are fairly sharp to produce a compact construction. In Europe larger radii have been used and this form is adopted for high-voltage applications. Four 90°-sector conductors laid-up together are used for 380–960 mm<sup>2</sup> solid-sectoral circular cables to obtain increased flexibility.

The Milliken construction is frequently used for circular conductors in sizes of 960 mm<sup>2</sup> and above to reduce skin effect and improve flexibility. Four or six individual sectors are used with a layer of insulation tape over alternate sectors.

The comments above refer largely to wiring and distribution cables. Different conditions apply to conductors for transmission cables, particularly of the oil filled type. Single-conductor sizes extend to 2500 mm<sup>2</sup> and an oil duct is required in the centre. The duct may be formed by laying the conductor strands round an open metal helix or, more usually, by creating a self-supporting centre by the use of

**Table 31.3** Conductor data

1000	1.55	0.0291	0.0176

curved segmental sections. Succeeding layers may consist of wires or flat strips, the latter improving both compactness and flexibility. For 18/30 kV cables, shaped conductors are oval rather than sectoral; circular conductors only are used at all higher voltages.

## 31.2.2 Insulation

### 31.2.2.1 Thermoplastic and elastomeric materials for wiring cables

In the general wiring-type cable field and for many power cables the major insulants in general use are either thermoplastic or elastomeric materials. In making the choice, several factors have to be considered. No insulant is ideal: a compromise is sought between processability, performance and economics.

An elastomeric material is one which returns rapidly to approximately its initial dimensions and shape after deformation at room temperature by a weak stress. Under such conditions a thermoplastic material shows permanent deformation. Conventional elastomeric compounds need to be cross-linked by vulcanisation, generally by chemical methods, to provide them with the characteristics which were typified by rubber compounds.

Examples of elastomeric materials are natural rubber (NR), ethylene propylene rubber (EPR), cross-linked polyethylene (XLPE), polychloroprene (PCP), chlorosulphonated polyethylene (CSP) and silicone rubber (SR). Of these, EPR and XLPE are the most common because they combine the flexibility and electrical properties of natural rubber with a higher operating temperature limit and easier strippability.

Examples of thermoplastic materials are polyvinyl chloride (PVC), polyethylene (PE) and polypropylene (PP). Until recently, PVC was the most usual insulant because of its uncomplex processability, good general-purpose

performance and economic advantage. By adjustment of formulation, PVC compounds can meet a variety of requirements. Their robustness, relative chemical inertness, good ageing and attractive appearance in a range of colours have led to wide use not only as an insulant, but also as bedding for armour wires and for sheathing. PVC hardens at temperatures below 0°C but will recover its flexibility on returning to normal ambient temperatures. General-purpose PVC compounds are limited to a maximum conductor operating temperature of 70°C.

Where electrical properties are paramount, e.g. radio-frequency cables, polyethylene is the preferred insulant. It is also a more effective water barrier where a water-resistant property is important.

Elastomeric compounds are of advantage for long-term operation at temperatures higher than those that PVC can tolerate. EPR and XLPE can operate up to 90°C continuously, and silicone rubber at 150°C continuously. Elastomers are also the first choice where flexibility combined with mechanical ruggedness is required. Applications for this type of material range between flexible cords for domestic flat-irons, fixed wiring and power cables, and flexible trailing cables for mines and quarries.

Where light weight and high operating temperatures are of paramount importance, fluorocarbon tapes or extrusions are adopted, particularly in the aircraft industry. Among

the materials used in such high-performance cables are polytetrafluoroethylene (PTFE), fluorinated ethylene propylene (FEP), ethylene tetrafluoroethylene (ETFE) and polyimide/FEP tapes. They are characterised by low coefficient of friction, excellent electrical properties, resistance to chemical attack and stability at elevated temperatures. Besides use in aircraft applications, these materials have also been used in specialised radiofrequency cables and equipment wires.

Glass fibre in the form of lappings and braids is the insulation in a range of cables and cords for use, for example, in luminaires.

Tables 31.4 and 31.5 provide data on physical and electrical properties for a range of thermoplastic and elastomeric insulating materials.

### 31.2.2.2 Thermoplastic and elastomeric materials for power distribution cables

In the distribution field, PVC is being displaced by the thermosetting material XLPE as the most widely used insulation and, as flexibility is not important, XLPE is more favoured than the possible alternative, EPR. (It is more usual to refer to cross-linking rather than curing or vulcanising; and to thermosetting rather than to elastomeric materials.)

\* BS 6746 for PVC types and BS 6234 for polyethylene types.

† BS 6899 for GP rubber types, EPR types and cross-linked polyethylene.

‡ LSF (low smoke and fume) is a generic term and the characteristics given are typical of the material which is still under active development and improvement to meet stringent performance requirements.

Although EPR can be produced in a hard grade (known as HEPR) with properties similar to those of XLPE, it is more expensive than XLPE and, as is common with rubber compounds, it contains a large number of ingredients. XLPE comprises merely polyethylene, an antioxidant and a cross-linking agent. The cross-linking can be accomplished by a variety of methods. Until recently the most common has been to mix an organic peroxide (dicumyl peroxide) with the PE and to extrude the insulated conductor into a large catenary tube containing steam under high pressure. For high-voltage cables, where minimum moisture content of the insulation may be important, radiant electrical heating may be substituted for steam and the CCV tube filled with nitrogen.

In the CCV extrusion process there is a wastage when starting and stopping; increasing use is being made of a process by which the extrusion can be in a conventional line, as for thermoplastic materials, and the cross-linking can be accomplished by a different chemical process. A silane and an accelerator are blended with the polyethylene and cross-linking is achieved by immersion of the insulated conductor in hot water. One method requires a separate process for preparing the graft polymer (which has a limited storage life), but in the Monosil process all the ingredients are blended in the hopper of the extrusion machine.

### 31.2.2.3 Impregnated paper

Layers of paper tapes are lapped around the conductor and the cable is dried and impregnated before application of the metal sheath which is required to keep the insulation dry and undamaged in service. The paper consists of a felted matt of long cellulose fibres derived from wood pulp. Washing of the fibres, both at the pulp stage and after formation of the sheet, is an important factor in the control of the properties of paper for cables. Large quantities of water are used, and for paper intended for the highest-voltage cables this water has to be deionised to ensure minimum power factor.

Impregnants have traditionally been based on mineral oils thickened with gum rosin to limit drainage from the insulation at service operating temperatures and to provide resistance to oxidation. It is now more usual to substitute materials such as microcrystalline waxes to obtain improved non-draining performance. For high-voltage internal pressure cables of the oil filled type it is necessary to use an impregnant with very low viscosity; hence, the highly refined mineral oils formerly used have been replaced by synthetic alkylates of dodecylbenzene type.

The electrical properties of the dielectric are not critical for voltages up to about 10 kV, but, at this level, ionisation in any air spaces becomes important and the impregnation

process must ensure that butt gap spaces between paper tapes are well filled with impregnant. Impregnated paper itself, in sheet form, has a high electric strength, around 10 MV/m in short-time a.c. tests.

### 31.2.3 Armour

#### 31.2.3.1 General wiring cables

When cables are not installed in conduit or trunking, they may require armour, most commonly provided by galvanised steel wire (GSW) helically applied in a single layer and known as 'SWA' (single-wire armour).

Pliable wire armour finds application for portable cables in quarries and mines. It consists of stranded seven-wire bunches of GSW applied helically in a similar manner to SWA, but with a shorter lay length, thus providing good mechanical protection with improved flexibility, enabling the cable to be moved without affecting performance.

Braided GSW armour is mainly used in cables for ships and off-shore applications. It has the advantage of easier installation in complex cable runs. For single-core cables in a.c. circuits, where magnetic effects could cause high losses with GSW, tinned phosphor-bronze wires are normally used.

#### 31.2.3.2 Supply distribution cables

Most types of power cable require mechanical protection and/or an earth conductor to carry fault currents. For most distribution cables this is provided by SWA. Cables with aluminium sheaths seldom require armour. Cables with lead sheaths may be armoured with steel tape, which is cheaper, but SWA is preferred in the UK for the heavier, higher voltage cables for 10 kV and upwards because it increases corrosion resistance and the longitudinal strength of the cable for installation purposes. Steel tape is normally protected against corrosion by bitumen, but if better corrosion resistance is required, the tape may be galvanised.

When additional mechanical or tensile strength is needed, as for river crossings, coal mines or long vertical runs, a double layer of steel wires may be employed. Single-core a.c. cables are rarely armoured, but if armour is necessary, it can be provided by non-magnetic tape or wire, normally of aluminium.

### 31.2.4 Oversheaths and protective finishes

#### 31.2.4.1 General wiring cables

The choice of sheathing material depends on its environmental performance. Matters for consideration are: ambient temperature; flexibility; resistance to abrasion, water, oil and other chemicals; performance under fire conditions; and compatibility with other materials with which a cable is in contact during its operational life. The sheathing material must also be chemically compatible with the other materials used in the cable both during and after processing. While insulants are chosen primarily for their electrical characteristics, sheaths are selected on their physical properties. Thus, not all insulants are suitable sheaths. However, in general, insulation and sheath materials are similar: e.g. a thermoplastic sheath protecting thermoplastic insulation.

Elastomeric sheathing materials include natural rubber, used for ordinary-duty domestic flexible cords; and synthetic rubbers such as NBR/PVC, PCP(OFR), CSP(HOFR). PCP is classed as an OFR material (oil resistant and flame retardant), and CSP as an HOFR material

(heat resistant, oil resistant and flame retardant). These materials can be specially formulated to meet special requirements, e.g. improved water resistance, extra flame retardance, improved mechanical properties. Most elastomeric materials have a wider operational temperature range than thermoplastics and their superior performance under adverse environments (as found in mines and quarries) makes them first choice for such applications. Not only are they abrasion resistant but also they are flexible over a wide range of temperatures.

In thermoplastic insulated cables, e.g. general wiring cable and radiofrequency cables, the predominant sheathing material is PVC in various formulations. Polyethylene is chosen where cables are in water or operate at subzero temperatures. For more specialised applications nylon and polyurethane are also used. Nylon has application where the cable is likely to be attacked by hydraulic fluids and is also claimed to be a termite barrier. Polyurethane is being introduced into designs which call for a cable having good flexibility, abrasion and impact properties under arduous low-temperature conditions.

Cables with high-performance insulation materials can be sheathed with conventional thermoplastic or elastomeric materials, but more commonly they have sheaths similar to the insulation composition. PTFE, FEP and a combination of PTFE and polyimide/FEP tapes are often used. These are light in weight, and are resistant to abrasion and cut-through, even when applied with small radial thicknesses.

#### 31.2.4.2 Distribution cables and transmission cables

Even when armoured cables are installed indoors above ground, it is unusual for the armour to be left bare, because (a) there are few environments where corrosion will not occur, (b) without an outer covering the armour layer may become disturbed during installation, and (c) few cables are above ground for their whole length. Nowadays, to make cables easy to handle and provide a clean finish, a polymeric sheath is usually applied overall.

Where cables are buried, the soils can be aggressive and cable life may depend on the degree of protection provided. For many years, lead sheathed cables depended on bituminised textiles as a bedding *under* the armour, and a serving of two layers of hessian or a layer of helically applied jute strings *over* the armour. Bitumen is provided over each layer, as well as to flood the armour, and use of the optimum grade of bitumen at each stage is important. Today, extruded sheathing—usually either PVC or sometimes (for toughness) polyethylene—has largely replaced bitumen finishes, even on lead sheathed cables, and all new designs of cable introduced during the last three decades have had PVC or polyethylene oversheaths. The successful introduction of aluminium for sheathing depends entirely on adequate protection with extruded plastic oversheathings.

For exposure to sunlight, plastic oversheaths should be black, but in other situations colours are sometimes used as a means of identification. To this end the sheaths are also embossed with the words 'Electric Cable', the voltage and sometimes further details of the cable construction, the manufacturer and the year of manufacture. Even though very tough, plastic oversheaths can be damaged during installation and, if they protect an aluminium sheath, it is important to carry out an inspection before backfilling. In the case of expensive transmission cables it is usual to test for damage by applying a graphite coating over the plastic and then to carry out a 10 kV d.c. test between this electrode and the metal sheath.

One of the disadvantages of PVC concerns cables in buildings or in tunnels. Although PVC is basically flame retardant, if a serious fire develops, it can transmit flame and will decompose, with evolution of noxious acidic fumes and dense smoke. Alternative synthetic compositions—sometimes known as ‘low smoke and fume’ (LSF)—are now becoming widely available to overcome this hazard.

### 31.3 General wiring cables and flexible cords

#### 31.3.1 Wiring system cables

A wiring system cable is usually regarded as the final link in the transmission network which begins in the power station and ends at the socket outlet in the home, office or factory work-bench. Although rubber was for many years the insulant for wiring cables, it has been superseded almost entirely by PVC, or for some applications by mineral insulated cables. Although several alternatives have been tried, plain annealed copper remains the sole conductor material for wiring cables up to 16 mm<sup>2</sup>.

PVC was originally developed in Germany in the 1930s. It took many years for PVC to be universally accepted for use in wiring cables. As PVC compounds improved, the thickness of insulation was progressively reduced. It now approaches half of that originally used and is acceptable for twice the operating voltage. The insulation is designed to have a higher tensile strength, resistance to deformation and a higher insulation resistance than the sheath. Sheathing compounds are usually formulated to provide good abrasion resistance and yet have easy-tear properties to facilitate stripping at terminations.

When vulcanised rubber insulation was used with copper conductors, it was necessary to tin the copper to prevent chemical reaction with the rubber. With PVC insulation, plain conductors became universally accepted. The introduction of cables to metric standards in 1969 achieved a greater degree of international alignment.

PVC wiring cables in common use in the UK are of two basic designs. One is the single-core unsheathed cable, used in conduit or trunking, the numbers of cores varying from 2 up to as many as 38. The other is the insulated and sheathed cable, available in single-core, two-core and three-core versions, the two-core and three-core cables (made in a flat formation) having the option of a bare earth continuity conductor.

In the late 1980s the need for improved fire performance wiring cables led to the introduction of an alternative insulating and sheathing material; special characteristics of these cables are the low emission of smoke and corrosive gases when affected by fire and a rapidly increasing use of these materials is foreseen.

Whilst EPR is used as the insulation for flat-twin festoon lighting cables and insulated, textile braided and compounded single-core conduit wire, another elastomeric insulation having low smoke and fume characteristics is now becoming widely available for wiring (conduit) cables (BS 7211). These cables have an upper temperature limit of 90°C, and although voltage drop may limit their advantages in some situations, it is anticipated that they will progressively replace PVC insulated cables in the next decade.

#### 31.3.2 Flexible cords

Most flexible cords are designed for and used in domestic premises as the supply lead from the socket outlet to

portable, and some fixed, appliances. The range of domestic appliances covers such items as can openers, food freezers, hairdryers, vacuum cleaners, microwave ovens, towel rails and washing machines. There is a flexible cord to suit each one.

The major cable insulants used in flexible cords are natural or synthetic rubber and PVC. Where flexibility is a prime requirement (for instance, on an electric iron), a rubber insulated type is most suitable. However, PVC is less expensive, has an attractive surface finish and is available in a larger range of colours. It is therefore the first choice for the supply lead to most domestic appliances.

Nowadays, many appliances carry the approval mark of the British Electrotechnical Approvals Board (BEAB) for House-hold Equipment, which means that in most cases the supply lead should meet the requirements of BS 6500: Insulated flexible cords. Independent auditing of flexible cords to BS 6500 by the British Approvals Service for Cables (BASEC) provides an assurance of the integrity and reliability of the cablemakers' products. This standard specifies cords having elastomeric, thermoplastic and glass-fibre insulants. These types are designed for a wide range of applications with upper temperature limits varying from 60 to 185°C. The natural rubber insulated types are rated at 60°C and cover the twin-twisted and textile braided cord in use for many years for pendant flexibles. The recommendations for this application are now 85 and 150°C rubber or glass-fibre insulated types. The UDF cord is used on electric irons and consists of rubber insulation and a thin rubber sheath, over which is applied a semi-embedded textile braid.

Currently under technical evaluation are cords employing cross-linked PVC for applications such as electric irons, where the ability to withstand contact with a hot surface is desirable combined with flexibility and abrasion resistance.

The PVC insulated and sheathed cords in BS 6500 are rated at 70°C and are available in light- and ordinary-duty versions for such applications as table lamps, television sets, washing machines and refrigerators. For areas where temperatures are likely to exceed those satisfied by standard PVC, but not in excess of 85°C conductor temperature, BS 6141 defines a range of heat resisting PVC cords. Examples of use are connections to immersion heaters and night storage heaters. For situations involving contact with oil and grease, there is an elastomeric insulated and sheathed flexible cord, rated at 85°C and having an oil resisting sheath. The glass-fibre insulated types in BS 6500 are primarily intended for use with light fittings (luminaires) and other situations where the cord is not subject to mechanical damage or continuous flexing. They can be used at temperatures up to 185°C.

Some flexibles are available in cut and trimmed form as an aid to the handyman, i.e. the cores are cut to length and the sheath and insulation are stripped. A few are also available in coiled extensible form, the most common type being for electric shavers.

There are also flexible cables designed for more harsh industrial environments. Three common types have a copper wire or galvanised steel wire braid, or a spiral steel strip, over the inner sheath, and an outer oversheath. The copper wire braided type is mainly used for portable hand lamps and where a flexible cable is required in certain flameproof installations. The steel wire braided and steel strip types are utilised where both flexibility and mechanical protection are required.

For situations where a limited degree of flexibility at low temperatures is required, special PVC formulations are available. Areas such as temporary supplies to traffic lights and portable tools on building sites are examples.

Some, but not all, designs of flexible cord used in the UK have been harmonised in accordance with the CENELEC procedure and for these the same design is standardised throughout the Common Market countries.

### 31.3.3 Control and instrumentation cables

Whereas power cables are the 'arteries' of industry, control and instrumentation cables are its 'nerves' and are used for the control of equipment and data collection. They range from single-core cables used in the wiring of control panels and switchgear, to the complex control and instrumentation cables used in power stations and petrochemical sites.

At one end of the scale are the single-core cables used within machine tools and switchgear. Where normal ambient temperatures are involved, PVC insulation is employed. At the other end of the scale is, for example, a North Sea oil terminal utilising 500 km of cable and connecting as many as 2000 instruments measuring flow rates or liquid levels in storage tanks. Control cables have copper conductors and are laid up in multicore or multipair formation, each core being separately identified.

Thermocouple cables (*Figure 31.1*) are used for connecting the thermocouple to its measuring instrument. The term 'thermocouple cable' is often used to describe both extension and compensating cables. Extension cables utilise conductors of the same alloys or metals as the thermocouple itself, while compensating cables utilise conductors of cheaper material although having similar thermoelectric characteristics. The normal conductor materials or alloys used are constantan, copper, iron, copper-nickel, nickel-chromium and nickel-aluminium.

Several national standards exist for the colour identification of insulation and sheath. Unfortunately, there is not yet a recognised international standard.

To prevent electrical interference in both control and thermocouple circuits within and between the cables, metallic screens (usually in the form of tapes) are applied over the individual pairs and/or the laid-up cores.

The finish of any type of cable to be buried in a petrochemical environment has to be given special consideration because of the presence of hydrocarbons in the soil. The steel wire armour which is normally applied as a mechanical protection on underground cables is not a barrier to the ingress of hydrocarbons into the heart of the cable: this is best achieved by applying a lead sheath. Thus, such control and instrumentation cables contain a PVC bedding, lead sheath, another PVC bedding, single wire armour and PVC oversheath. BS 5308 gives details of control cables with this type of protection. North American practice is to use an aluminium sheath.

Safety in hazardous areas has to be carefully considered. Intrinsic safety is a protective technique which ensures that any electrical sparking which may occur is incapable of causing an ignition of gas or vapour. Although a cable itself will rarely cause an explosion, it is possible for gas or vapour to percolate along the interstices of cable from a hazardous zone to a non-hazardous one. This problem can be cured by use of a stopper box or sealing gland. Reference

should be made to BS 5345 for specific details. The British Approvals Service for Electrical Equipment in Flammable Atmospheres (BASEEFA) test and certify intrinsically safe and flameproof equipment.

### 31.3.4 Cables for electronic applications

Cables for electronic applications are single-core and multicore equipment wires, and radiofrequency cables. Equipment wires are usually regarded as insulated single conductors with or without a screen and sheath. They can also be supplied in flat formation as multicores or multipairs, often with a transparent backing. The space between conductors is precisely controlled to ensure consistent electrical characteristics and to assist in termination. Multicore equipment wires generally have PVC or PTFE insulation and sheath in a range of conductor sizes and number of cores, unscreened and screened.

Radiofrequency cables transmit high-frequency signals at minimum loss. Calculation of the optimum cable design involves operating frequency, capacitance, velocity ratio, impedance and attenuation. With the exception of a few twin and special designs, radiofrequency cables are normally *coaxial*; they have an inner conductor, insulation, outer concentric conductor forming the screen, and sheath. Also used for radiofrequency applications are PE and PTFE insulated multipair cables for use in computer interfacing.

For conductors, plain annealed copper is most common but even this is available in several grades, each conferring special properties. It is possible to draw copper to extremely fine sizes because of its good ductility. By leaving copper in the hard-drawn condition, additional tensile strength may be obtained at the expense of elongation. Where d.c. conductivity is of secondary importance, composite conductors incorporating a high-tensile-steel core are employed in miniature cables.

Insulants used in electronic cables vary between PVC, PE, PPE, PVF<sub>2</sub>, PVF, ETFE, FEP and PTFE (see *Table 31.4*). The choice of insulant is an optimisation of performance and economics. In radiofrequency cables, where electrical performance is paramount, the insulation is usually either PE or PTFE. However, chemical, mechanical and thermal performance must also be considered.

Screens are applied to prevent electrical interference between circuits or to control the amount of pickup by, or leakage from, a cable. Braided and lapped wires, tapes, tubes, foils and films are among the screening materials used, depending on the application.

Sheaths are applied to act as protection. A thermoplastic or fluorocarbon material is most common. In more demanding environments it may be necessary to have additional protection over the sheath in the form of steel wire braids or armour.

Although there are many specifications covering electronic cables, manufacturers have their own standards.

In the optical fibre cable, the signals are transmitted optically rather than electrically. The conductor is made of a high-quality glass-fibre which transmits light. The main advantages of optical fibre cables compared with conventional metallic conductor cables include low weight, small volume, increased system capacity, freedom from electromagnetic interference and improved security.

**Figure 31.1** Multi-pair thermocouple cable with PVC insulation, pair screening, lead sheath and wire armour

### 31.3.5 Arc welding cables

BS 638: Part 4 Specification for welding cables, includes single-layer EPR, CSP or CPE (HOFR) 85°C rubber to

BS 6899 and a two-layer covering, EPR and CSP or CPE to BS 6899.

The conductor is made up of a large number of small copper or aluminium wires, usually with a separator between conductor and insulation to make the cable supple. Single-conductor cables meet the majority of requirements for connection to electrode holders, arc-welding guns or leads for both manual and automatically controlled metal arc-welding equipment, or to form extension or return leads. Multicore cables are sometimes required for connections to the distribution boxes of multi-operator equipment.

Because of the variable periods of operation, current ratings have to be derived specifically for arc-welding cables and are contained in BS 638: Part 4. The period during which current flows varies from periodic to continuous, according to the application. The longer the period of use, the greater the conductor heating effect, so that current ratings are reduced as the operating cycle lengthens. The operating (or duty) cycle is defined as the time a cable operates in each 5-min period expressed as a percentage: e.g. up to 1.5 min operation in the 5-min period is 30%. Duty cycles are classified as shown in the table below.

<i>Duty cycle</i>	<i>%</i>
Automatic	≤100
Semi-automatic	30–85
Manual	30–60
Intermittent or occasional	≤30

Excessive voltage drop can occur when long cable lengths are required between the set and the electrode; conductors of larger current rating must then be selected. For flexibility, the final length of cable to the electrode can revert to the area appropriate to the current rating.

### 31.3.6 Offshore and ship cables

A wide variety of installation conditions and extremes of temperature are experienced in tankers, refrigerated vessels, ferries, trawlers, tenders, passage vessels, dry cargo ships, etc. In the UK the cables used are largely standardised as ethylene propylene rubber (EPR) insulated and chlorosulphonated polyethylene (CSP) sheathed and produced to BS 6883 (Figure 31.2). The operating temperature of 85°C provided by this combination has been proved satisfactory over a number of years and has been used extensively for applications on North Sea oil platforms, although in this case braid armoured cable with an outer CSP sheath has been the main standard.

EPR has excellent electrical properties, good corona resistance and good low-temperature flexibility. The CSP sheath provides a tough outer surface which is resistant to weather, oil resistant and flame retardant.

The increasing use of higher power generation on board ship has meant that systems with voltages of 3.3 and 6.6 kV are now in operation. Again the use of suitable designs of EPR insulated CSP sheathed types have proved fully

adequate for this service. For oil rig platforms 13.8 kV cables are also in regular operation.

The conductors of ship wiring cables are of a more flexible construction than comparable land-based cables because of the problem of installing them through complex structures characteristic of shipboard installations. The reactance of a cable operating in an a.c. system depends on many factors, including, in particular, the axial spacing between conductors, and the proximity and magnetic properties of adjacent steel-work. This latter point is of crucial importance in ships and oil rigs. It is desirable to minimise the effect of magnetic induction by means of adequate spacing between cables and steel-work, minimum spacing between conductors, and the avoidance of magnetic materials between single cores in the same circuit.

There are many classification authorities that will approve cables to international and to some national standards. When a ship installation is contemplated, the local surveyor of the chosen classification authority should be consulted before a decision is taken on the particular design to be used.

### 31.3.7 Aircraft cables

Cables used for wiring aircraft are continuously under development and, as technology improves, new materials are used in this most exacting of applications. The ambient temperature variation within an aircraft is wide and provision has to be made for cables to operate down to -75°C and up to 260°C. In addition, various special fire resisting cables are needed for use in aircraft-engine fire zones.

For the lower temperature a combination of special PVC, glass braid and nylon has been used where a conductor temperature of 105°C is deemed appropriate. Since the mid-1960s, when a miniature range of cables was introduced both for multicore and screened versions, much development work has been undertaken and greater attention has been paid to the effect of cable weight on the performance of the aircraft; as a result, cables with polyimide insulation are being widely used in the aircraft industry for general airframe wiring. This material has been chosen because of its excellent mechanical and electrical properties and its resistance to the various chemical contaminants present in aircraft. Depending upon the type of conductor and coating used for colouring purposes, polyimide insulated cables are approved to operate at conductor temperatures of 150 and 210°C.

The higher temperature ranges of cable consist largely of combinations of PTFE, glass and polyimide, and when using a nickel plated conductor, are approved for operation at conductor temperatures up to 260°C.

Special fire resisting cables for engine-bay wiring are available and comprise combinations of silicone rubber, glass-fibre, quartz fibre, polyimide and PTFE to ensure that circuit integrity can be maintained for a short period during a fire.

### 31.3.8 Cables for railways

The main application for general wiring cables for railway use is for track signalling. Multicore signalling cables are laid along the trackside. The insulation is a combination of natural and synthetic rubber. A natural rubber layer is applied next to the conductor to provide electrical integrity, and the outer layer is of polychloroprene (PCP) to give each insulated conductor some oil resistant properties. The cores are collected together and covered overall with a thick

Figure 31.2 Typical ship wiring cable

**Figure 31.3** Multi-pair signalling cable with materials and construction for optimum flame retardance and freedom from smoke and fumes in a fire

sheath of heavy-duty PCP compound specially chosen for toughness, and weather and abrasion resistance.

Cables for track power feeds on electric systems at medium and low voltage are insulated with EPR and sheathed with chlorosulphonated polyethylene (CSP). Cables for traction and rolling stock are conventionally of EPR/CSP composite insulation, but recent developments have resulted in new materials having low smoke properties and greater resistance to the oils and fluids used in traction and rolling stock.

In the underground system operated by London Transport Executive particular emphasis has been placed on minimising hazards resulting from fire. Designs are now approved which, in a fire, give off fewer toxic products and far less smoke than did previous designs (*Figure 31.3*).

Two-way communication between a control centre and moving trains is now becoming common, even when the trains are in tunnels. It is accomplished by installing suitably designed electric cables near to the track, either at ground level or overhead, to act as elongated aerials. The most common cable for this purpose is the so-called 'radiating coaxial' or 'leaky feeder'.

### 31.3.9 Cables for mines and quarries

Cables for metalliferous mines and quarries have been standardised for many years. They are essentially flexible and tough, as they need to withstand all the rigours of service in a rugged and rough environment. The range of cables, given in BS 6116, incorporates ethylene propylene rubber (EPR) as insulation, a rubber undersheath, a layer of stranded galvanised steel wires applied as an armour, and a tough weather resistant outersheath of polychloroprene (PCP). Cables are available for 600/1000 V, 3.3 kV and 6.6 kV systems. Some higher voltage installations have been made using cables with individually screened cores and a thick overall PCP sheath, but their use is subject to permission from the relevant authorities.

Cables for use by equipment connection in underground coal mines are manufactured to specifications issued by British Coal and use an EPR compound insulation specially formulated to give good impact strength and crush resistance. Individual core screening is the norm as part of the safety measures necessary for operation at the coal face. The sheath is of PCP, which has excellent mechanical properties and is flame retardant. Low-voltage pliable armoured

cables similar to those in quarries are also used for portable supply cables to conveyor loaders, etc., and similar cables suitable for 3.3 kV and 6.6 kV systems are used for connection to transformers.

Thermoplastic insulated cables are also widely used for power, lighting and signalling purposes, and British Coal has now standardised power cables insulated with XLPE and EPR.

An increasing demand for improved communication services in mines and quarries is reflected in the expanding use of two-way mobile radio, radio paging and radio control systems. However, mines and quarries often present situations where free-space propagation is not possible: for instance, propagation in tunnels can be restricted to only a few hundred metres. One solution is the radiating cable or leaky feeder in which signals radiate from the cable rather than from a conventional aerial. Radiating cables have special screens which provide and control the electromagnetic field around the cable so that signals can be picked up by nearby mobile receivers, with communication in the reverse direction also possible. These cables use low-permittivity dielectrics, which, with the special screens, ensure good radiation and transmission characteristics unaffected by the arduous external environmental conditions encountered in mines.

### 31.3.10 Mineral insulated metal sheathed cables

Mineral insulated metal sheathed cables generally consist of copper conductors insulated with compressed mineral powder, typically magnesium oxide (MgO), and enclosed in a copper sheath.

The traditional method of manufacture is to position the required conductors within a large-diameter tube and fill them with powder using a ramming process, the filled cable then being drawn to the required final diameter by cold drawing through numerous dies with inter-stage and final furnace annealing. More recently, continuous manufacturing methods have been developed in which the sheath is produced from rolled and welded strip into which powder and conductors are introduced, the assembly being reduced to its final diameter by rolling or a combination of rolling and die drawing with inter-stage and final annealing by induction. The annealing of the copper is carried out to restore ductility and conductivity, lost due to work hardening. Moisture ingress into the dielectric is inhibited by control of the chemical activity of the powder, or by additives.

Normally, mineral insulated cables need no further protection over the copper sheath, will withstand high service temperatures, and are impervious to oil and water. Being composed of inert inorganic materials they are incombustible and non-ageing. However, for aesthetic appeal, identification or corrosion protection of cables buried underground or in aggressive industrial environments a thermoplastic outer covering may be applied, which may be typically PVC, but more recently low smoke and fume sheathing materials have been introduced.

Mineral insulated cables are made with 1, 2, 3, 4, 7, 12 or 19 conductors in light-duty (500 V) or heavy-duty (750 V) grades, with conductor areas ranging from 1 to 400 mm<sup>2</sup>, and current ratings of 11 A to over 1000 A depending on the cable size and installed conditions.

The current rating of mineral insulated cables, unlike other types of cable, is not determined by the temperature withstand of the insulation, but by the temperature attained by the copper sheath. For normal applications and where the cable has an outer covering, the limiting temperature is

70°C. As for other types of cable installed in buildings, the published ratings are based on an ambient temperature of 30°C with adjustments being needed for other ambient temperatures and grouping as detailed in Section 31.6.

However, bare mineral insulated cable with a copper sheath can operate continuously at sheath temperatures up to 250°C, depending on the type of end seal applied, and when so rated the current rating capacity is greatly increased. At temperatures above 250°C, progressive oxidation of the copper sheath occurs, although the cable can function for limited periods with sheath temperatures in the region of 1000°C.

To make connections the copper sheath is removed at each end and seals provided by the cable's manufacturer are used to seal the face of the insulant and to insulate the exposed conductor tails. The copper sheath provides an excellent low resistance circuit protective conductor, connection to which is achieved by use of compression glands or by use of special end seals with integral earth tails.

For specialised applications such as thermoelectric cables, heating cables, down-well and other transducer cables or for continuous operation at temperatures higher than 250°C, stainless steel or alloy sheaths are also used with nickel, steel, alloy and many other special conductors.

### 31.3.11 Cables in fire hazard

An area of electric cable technology where much research and development work has been concentrated in recent years is that of the behaviour of cables in fires. Although they may overheat when subject to current overloads or mechanical damage, electric cables in themselves do not present a primary fire hazard. However, cables are frequently involved in outbreaks of fire from other causes which can eventually ignite the cables. The result can be the propagation of flames and production of noxious fumes and smoke. This result, added to the fact that cables can be carrying power control circuits which it is essential to protect during a fire to ensure an orderly shutdown of plant and equipment, has led to a large amount of development work by cablemakers. This work has included investigations on a wide range of materials and cable designs, together with the establishment of new test and assessment techniques.

Although PVC is essentially flame retardant, it has been found that, where groups of cables occupy long vertical shafts and there is a substantial airflow, fire can be propagated along the cables. Besides delaying the spread of fire by sealing ducts at spaced intervals, an additional safeguard is the use of cables with reduced flame propagating properties. Attention has also been focused on potential hazards in underground railways, where smoke and toxic fumes could distress passengers and hinder their rescue. Initially, compounds with reduced acidic products of combustion were incorporated in cables which have barrier layers to significantly reduce the smoke generated. In the meantime, other cablemaking materials have been developed which contain no halogens and which also produce low levels of smoke and toxic fumes as well as having reduced flame propagating properties. These are now incorporated in British Standards such as BS 6724 and BS 7211.

A different requirement in many installations, such as in ships, aircraft, nuclear plant and the petrochemical industry (both on and off-shore), is that critical circuits should continue to function during and after a fire. Amongst the cables with excellent fire withstand performance, mineral insulated metal sheathed cables are particularly suited for use in

Figure 31.4 Heat sensor cable

emergency lighting systems and industrial installations where 'fire survival' is required. As fire survival requirements on oil rigs and petrochemical plants become more severe, new control cable designs have been developed to meet fire tests at 1000°C for 3 h with impact and water spray also applied, and also to have low smoke and low toxic properties.

Another novel approach to fire protection in power stations and warehouses is the use of fire detector cables (Figure 31.4). These are used in a system which both detects and initiates the extinction of a fire in the relatively early stages of its growth. These cables have also been installed in shops, offices and public buildings, where the cables can be used to operate warning lights or alarms.

The present position in relation to materials is that problems due to smoke and objectionable fumes are dealt with in the case of insulation by heavy additions of aluminium trihydrate in EPR and EVA. For beddings and oversheaths similar addition may be made to ethylene acrylic elastomer, but such compounds do not have the toughness and oil resistance of CSP and PCP compounds.

For aircraft engine components, where cable weight is important, the cable construction is based on silicone rubber plus quartz with PTFE coverings.

For ships' cables, silicone rubber is also used, and where a glass braid is also included, the silica ash enables the IEC 331 test at 750°C to be met. By use of special EPR compounds, the withstand temperature may be increased to 1000°C. The use of mica/glass tapes on conductors provides good high-temperature insulation which is cost effective in comparison with silicone/glass and mineral insulated designs.

## 31.4 Supply distribution cables

For underground public supply systems and mains distribution in factories, paper insulation has given way to synthetic insulation, except for certain sectors of the public supply.

Since the early 1960s, PVC has been the major insulant for industrial cables up to 3 kV, but this is now changing and XLPE is increasingly finding favour because of its potentially higher operating temperature (90°C). Similarly, for higher voltage industrial applications, XLPE is now the preferred dielectric.

In Europe and elsewhere, consumers are supplied at around 240 V single-phase and 240/415 V three-phase, as required. From the outset, the system for urban areas has been underground with direct burial of multicore cables, and three-phase transformers feeding large groups of consumers through cables along the whole length of every road. The step-down from the transmission grid has moved towards voltages of 19/33 kV and 6.35/11 kV, but international standardisation for cable specifications caters for a full range of 0.6/1, 1.8/3, 3.6/6, 6/10, 8.7/15, 12/20 and 18/30 kV r.m.s. The rounding off of voltages to whole numbers allows for the fact that the designs cater for 20% variation of voltage.

In the USA, and other countries following American practice, cable designs and voltage standards are the same, but the types favoured and the practical utilisation tend to be very different. The supply to the consumer caters for

both 110 and 220 V or thereabouts, and except for the innermost areas of cities the distribution is largely by overhead lines. Instead of three-phase transformers, the local supply is from single-phase units at 10–15 kV or higher, using appropriate transformers to obtain the dual consumer voltages. Conventionally, such transformers are pole mounted, and small, as they feed only a few consumers.

Undergrounding on the American system tends to be a replica of the overhead practice by continuation of the use of similar small transformers and merely adding insulation to the overhead line conductors. Extruded polyethylene or XLPE is convenient for this purpose for both low-voltage and high-voltage requirements, and this is why the interest first developed on the American continent. Very simple single-core cable constructions meet the requirement and much high-voltage cable has been installed in which the neutral conductor comprises copper wires applied over the insulation with no outer sheath. In recent years a concerted effort has been made to get away from the unsightly poles and overhead distribution lines with emphasis on 'underground residential distribution' (URD). This embraces the concept of small single-phase transformers outlined above but more emphasis is now being placed on direct burial of cables instead of installation in ducts. With the dual voltage requirement for consumers, the URD concept, together with the use of single-core cables, provides a way of undergrounding overhead networks at minimum cost. It seems unlikely that it will be adopted in countries where systems have long been geared to other practices.

### 31.4.1 Paper insulated cables

From its introduction at the end of the last century, impregnated paper has given excellent service to the cable industry. Under normal conditions, users have been able to install the cables and then forget about them. Ultimate lives of 50–60 years are common, and the majority of cables have been replaced only because they became too small for the load. The UK supply industry depreciates paper cables over a 40-year life—surely towards the maximum for any industrial plant.

While the basic dielectrics have changed little throughout this century, there have been considerable improvements in quality of materials and manufacturing techniques, and these have led to successive reductions in thickness over the years.

#### 31.4.1.1 Belted and screened constructions

In multicore cables a greater insulation thickness is required between conductors than from conductor to metal sheath. The most economic construction, therefore, is to apply part over the individual conductors and then a small thickness as a 'belt' over the laid-up cores (*Figure 31.5*). The spaces between the cable cores under the belt are filled with jute or paper, but whereas the main insulation consists of paper tapes applied in a controlled manner, the filler insulation has to be softer and less dense to be compressed into the space available. It is therefore weaker electrically, and it will be seen from the pattern of flux distribution in *Figure 31.6* that significant stresses arise in the filler spaces. An even more important effect, to be seen in *Figure 31.6* is that, in addition to the radial stresses through the layers of paper, there is also a tangential stress component along the paper surface. In the tangential direction the electric strength of impregnated paper is only one-tenth of that radially.

**Figure 31.5** Four-core, 1 kv, paper insulated, lead sheathed cable

**Figure 31.6** Flux distribution in paper insulated belted cable with top conductor at peak potential

When supply voltages were increased to 22 kV and 33 kV in the 1920s, many cable failures occurred due to lack of appreciation of this fact. Hochstädter identified the need for an earthed metallic layer over the insulation to create a purely radial field, a construction subsequently known as 'H'-type or screened. Very little metal is required for the purpose, and while thin copper tapes have been used, the most common form nowadays for multicore cables is a layer of thin aluminium tape or of metallised paper, consisting of aluminium foil on a paper backing. The latter is usually pinpricked to facilitate passage of oil during impregnation. The cores and fillers are held together by a binder of 'copper woven fabric tape' (CWF) containing a few thin wires woven into the web. This gives protection against scuffing and provides electrical contact between the screen and the metallic sheath. Another construction, used mainly in continental Europe, is the 'HSL' or 'HSA' type, which denotes three lead or aluminium sheathed single cores laid up together and then armoured overall.

The screened construction is optional at 11 kV, but mandatory for higher voltages. Because the dielectric has much better electric field distribution the operating temperature can be increased and higher current ratings obtained. Some 11 kV users find that these factors justify the somewhat greater expense and the extra skill required in jointing.

#### 31.4.1.2 Insulation

The insulation comprises layers of paper tapes, of thickness in the range 0.7–1.9 mm, carefully applied to maintain controlled butt gap spacings and optimum registration between layers. The stress is highest at the conductor surface and may be increased locally, owing to the conductor profile or lack of smoothness. To improve this situation at voltages of 6.35/11 kV and above, a layer of semiconducting carbon paper is applied over the conductor to exclude from the field the small spaces between the wires of the outer layer which otherwise could be sites for discharge.

The thickness of insulation has to be determined by both mechanical and electrical requirements, the former being dominant at the lower voltages, e.g. to withstand bending and to resist damage due to impact. Similarly, at 11 kV, while impregnated paper itself has an a.c. breakdown strength of the order of 10 MV/m, the actual cable design stress is only 2 MV/m, the effects in butt gap spaces being one of the most important factors.

The impregnation of the paper is carried out before application of the metallic sheath by the 'mass-impregnation' process. The cores, on drums or rewound into trays, are inserted into large tanks. These are first evacuated to remove all the moisture in the paper. Hot impregnating compound is then admitted, and the tank is maintained under pressure for a period which depends on voltage, and then cooled slowly to ensure that contraction voids are not present within the insulation.

To obtain good impregnation, the compound viscosity at 120°C should be low, but in the operating temperature range of the cable it needs to be as high as practicable, so that no drainage occurs into the inevitable space under the metallic sheath and into joints. Traditionally, the compound consisted of mineral oil thickened with gum rosin. A problem with such compounds was that the viscosity at maximum operating temperature was not high enough to prevent drainage when cables were installed vertically or on hilly routes, thus leaving the already relatively weak butt gap spaces devoid of impregnant. In the 1950s, BICC developed the 'mass-impregnated non-draining compounds' (MIND) which subsequently became standardised in the UK. In these compounds the viscosity control is obtained by the addition of such materials as microcrystalline waxes and polyethylene to mineral oil.

When single- or three-core cables are operated at 11 kV or higher, some discharge may occur in the space between the insulation and the inside of the metallic sheath. Although this is not unduly detrimental, it is eliminated by the inclusion of a carbon paper over the insulation.

#### 31.4.1.3 Lead sheath

Unalloyed lead is suitable for the majority of armoured cables but is prone to fatigue cracking if subjected to vibration or to high expansion and contraction, as when cables are suspended on hangers or are in manholes. In the UK, when moderate improvement of fatigue strength is required, it is usual to adopt alloy 'E' to BS 801 (0.4% tin, 0.2% antimony). Alloy 'B' (0.85% antimony) has higher fatigue strength and is desirable for conditions involving severe flexing, such as aerial cable installations and cables on bridges. Other alloys are available and are preferred in some countries.

The use of very high-purity lead is detrimental because it can give rise to large grain size and low fatigue strength. Hence, it is always preferable to use lead with impurities up to the limit of 0.1% as permitted by BS 801. Tin and antimony are frequently added for this reason.

#### 31.4.1.4 Armour

The use of armour fulfils a variety of functions, primarily to supply mechanical protection during cable handling and installation, and subsequently in service. Steel taping is the most common, but in the UK a layer of galvanised steel wire is often applied for 11 kV and higher to increase the longitudinal strength of the cable. Galvanised steel tape is popular in tropical countries to provide greater resistance

to corrosion; narrow steel strips are often preferred in continental Europe. In general, the resistance to damage is proportional to the armour thickness, and steel strips or tapes are less effective than steel wire.

#### 31.4.1.5 11 kV aluminium sheathed cables

The replacement of a lead sheath by an aluminium sheath with good corrosion protection, such as an extruded plastics oversheath, provides a very economic cable construction eliminating armour. For cables of a type offering other advantages, e.g. to provide a concentric conductor as in the Consac CNE type cable described later, and h.v. cables operating under internal pressure, aluminium sheaths have been widely used since the mid-1960s.

For other types of paper insulated cables, however, aluminium sheaths have not found favour, one factor being the somewhat greater skill required for sheath plumbing when joints other than the cast resin type are used. An exception is that in the UK, the public supply authorities did standardise almost universally in the mid-1970s on 11 kV aluminium sheathed cables and, until recently, XLPE insulated cables were unable to compete on price. There are now clear signs that XLPE will be increasingly used on electricity company networks at 11 kV. However, whilst they were using aluminium sheathed cables, there was a variation of design, some preferring a smooth sheath, whilst others favoured the corrugated form. With a weight reduction of 50% compared to lead sheathed and armoured cables, both types were easy to handle, although there was a problem with pulling 240 and 300 mm<sup>2</sup> cables with smooth sheaths into ducts. Subsequently the preference was for corrugated sheaths.

A significant factor is the effect of thermomechanical forces at straight joints. With the flexible corrugated sheath the position does not greatly differ from that with lead sheathed cables. However, if full load is to be carried regularly, it is desirable with smooth aluminium sheathed cable to employ joints filled with cast resin to overcome possible problems at the plumbs and buckling of cores within the joint sleeve. Most of the 11 kV cable installed by the public supply authority in the UK operates at less than maximum rating because of factors of which the most pertinent is that the cable network is in open rings and is only required to carry full load when the ring is closed because of a fault near to the transformer.

Typical 11 kV aluminium sheathed constructions as used by some authorities are shown in *Figure 31.7*; the design

**Figure 31.7** Smooth (a) and corrugated (b) aluminium sheathed, 11 kV, paper insulated cables

which was finally standardised was a belted version with corrugated aluminium sheath. In this construction there is a large space between the outside of the insulation and the inside of the sheath. It is important that this should be partially (but not completely) filled with impregnating compound.

### 31.4.2 CNE cables for PME systems

In this heading CNE denotes a 'combined neutral and earth' conductor in cable construction and PME signifies 'protective multiple earth' applied to a network.

#### 31.4.2.1 PME systems

Traditional practice in UK buried systems involved earthing of the neutral conductor at one point only, at the substation. This meant that the supply cables along the streets required five conductors, three phases, one neutral and one earth (the lead sheath). Consumers normally obtained a satisfactory earth by connection to buried lead water pipes, but when conditions were difficult, as with overhead line sections in rural areas, a practice of multiple earthing of the neutral (MEN) was introduced in the 1940s by burying suitable metal adjacent to poles. This gradually extended to the PME concept, which basically implies that consumers are provided with an earth terminal connected to the supply neutral conductor.

In the 1950s further problems arose when lead water pipes began to be replaced by plastic pipes. One solution was to earth consumers' plant to the lead sheath of the supply cable, but this was only satisfactory if across all straight and branch joints the lead sheaths were plumbed to the jointing sleeves. In many cases, however, the joints were of the mechanical grip type in cast-iron boxes, and these had such a high resistance that the earth path to the substation was inadequate. By additional earthing of the neutral conductor, nowadays usually only at the remote end of the run, and by using this conductor also as the protective earthing conductor, the consumer earthing problems were overcome. Moreover, the supply cable required one fewer conductor and by developing a new range of cables very considerable savings were obtained. *Figure 31.8* shows the much lower material utilisation achieved with one form of CNE cable.

Initially, PME systems with CNE cables were kept separate from the existing networks, but by appropriate and simple bonding between neutral conductors and lead sheaths, all existing systems can be converted to PME. The UK network has largely been modified in this way. CNE cables can, therefore, be installed indiscriminately for

replacements and additions. A point requiring attention is that, if consumers are given a PME earthing facility, all exposed earthed metal within the installation which may be touched must be suitably bonded to provide an equipotential background.

#### 31.4.2.2 CNE cable types

The Consac cable (BS 5593), first introduced in the mid-1960s and shown in *Figure 31.9*, maintains the use of paper insulation. Aluminium sheathing provides the neutral. The use of solid aluminium conductors with 1 kV paper insulation had already become established with four-core PILS cables before the development of Consac. Because of the total use of aluminium as conductor metal and the small amount of other material, Consac has a very economic construction, but in the early days some of the cost advantage was lost by the extra difficulty of plumbing the aluminium sheath. This was later overcome by the simple techniques involving the use of mechanical fittings and cast resin filling.

One of the important features in the design of any CNE cable is that, in the event of cable failure, there should be no loss of the important protective neutral conductor. It has also to be recognised that, with the growing use of mechanical excavating equipment, the main source of cable failures is now third-party damage. If the PVC oversheath on Consac is damaged, local corrosion of the aluminium sheath will follow and water entering the insulation will produce detectable cable failure before there is any severe reduction in conductance of the neutral.

The Waveform cable type (*Figure 31.10*) is also known as Waveconal and Alpex. Although introduced some years after Consac, and a little more expensive, it has become more extensively used than Consac, because of its simple jointing techniques. The XLPE insulation represented the first departure by the UK regional electricity companies from paper insulation for mains cables. In Waveform cable the neutral conductor comprises aluminium wires applied with a sinusoidal lay, and, as with all modern cable designs, there is an outer PVC oversheath. For making service joints, no cutting of the neutral is involved and the wires can readily be formed into two bunches for mechanical jointing. A key point in the design is that the wires are spaced and encapsulated between two layers of unvulcanised rubber so that each wire is separately embedded in the rubber. In the event of local damage to the oversheath, the entry of groundwater is thus limited; again an important factor in preventing loss of the neutral conductor. In Germany this form of sinusoidal lay neutral construction is

**Figure 31.8** Comparative dimensions of four-core PILS/STA and Consac CNE cables of equal rating

**Figure 31.9** Consac cable

**Figure 31.10** Waveconal cable

known as 'Ceander', but has only been employed with copper wires and without the rubber bedding. The use of copper wires as the neutral together with a single layer of unvulcanised rubber has recently found favour with the distribution companies in the UK, and many of those currently using Waveconal and Consac have now indicated their intention to adopt the cable having a copper wire neutral.

In Scotland some use has been made of 'Dstricable', a type which is also found in France. This is a four-core construction, again with XLPE insulation on the phase cores, but the neutral/earth circular or shaped conductor has a lead sheath to protect it from corrosion. Two thin galvanised steel tapes are applied as a binder and to provide a metal screen in contact with the neutral/earth conductor. A PVC sheath is applied overall.

Ultimate simplicity in CNE cable design and ease of jointing can be achieved by the use of four shaped aluminium conductors, insulated with XLPE and then provided with a PVC or polyethylene oversheath with no outer metallic protection. This type has already replaced all other public supply mains cable types in Germany. In the UK it has been rejected, however, even though a metallic envelope is not mandatory below 650 V and spiking tests have shown that danger from flash or shock is little greater than with the Waveconal, Consac, Dstricable or lead sheathed paper cables. The reason is that, in the event of mechanical damage, there could be exposure of the aluminium in the neutral to groundwater, with the possibility of undetected loss of this conductor. Damage to phase conductor insulation could also give rise to currents in the ground, flowing through other buried metalwork.

### 31.4.3 Service cable

Prior to the introduction of CNE mains cables, the service cables were of the three-conductor split-concentric type. This design is still used for consumers where it is not practicable to provide a PME earth terminal connected to the supply neutral/earth. The single-core (or multicore for three-phase supply) phase conductors are insulated with PVC or XLPE. In a helically applied concentric layer around the phase core or cores, some of the copper wires are bare to form the earth conductor and some have a thin layer of PVC coating to comprise the neutral conductor, the two portions being separated by PVC strings.

For a PME system, the construction is further simplified to a two-conductor design, the concentric layer consisting of bare copper wires.

As an alternative design of service cable, some users of Waveform mains cable prefer to adopt the same construction, i.e. sinusoidal lay aluminium wires embedded in rubber, as the neutral/earth conductor.

In addition to use for house service, all these cables find applications for such requirements as street lighting, traffic signs and complete individual routes for motorway lighting.

### 31.4.4 PVC insulated power cables

Although used for public supply cables in some overseas countries, PVC insulation has never been adopted in the UK for this purpose, other than for the service cables described above. The reason is associated with its thermoplastic nature and resultant softening at elevated temperatures. Thus, at 1 kV, ratings are restricted by a maximum temperature of 70°C, whereas paper can be operated to 80°C and XLPE to 90°C. More important, however, is

that, in the event of a short overload, severe thinning may occur due to deformation by conductor thrust at bends, whereas paper or XLPE insulation would be relatively unaffected.

Close fusing to give cable protection is usually impracticable in public supply systems, but presents no great problem in industrial applications. From the late 1950s, therefore, PVC insulated cables were almost universally applied in this sector for voltages up to 3.3 kV. More recently, XLPE, with its superior overload characteristics has become increasingly more popular. Close fusing was defined by the 14th edition of IEE Wiring Regulations as an excess-current operating device which operates within 4 h at 30% excess rated value for cables direct in the ground, or 50% excess for cables in ducts or in air. In the 15th and recent 16th editions the whole concept has been changed (see Section 31.6.7).

Figure 31.11 shows typical 1 kV cable and 6 kV cable, the latter as used in coal mines.

As PVC insulated cables are little affected by moisture, no metal sheath is required, and this contributes greatly to ease of handling as well as simplifying jointing and terminating procedures. No precautions have to be taken to prevent entry of moisture.

BS 6346 caters for conductors of stranded copper or solid aluminium, but not stranded aluminium. The solid form was chosen because it provides the most economic cable construction and is particularly suitable for manufacture with PVC insulation. Solid conductors are also very much better for either soldering or mechanical jointing techniques. Stranded aluminium conductors are often preferred by overseas users and are also used for power supply cables in coal mines, as they facilitate coiling for taking the cables down the mine shafts.

Except for the smallest sizes, the conductors are shaped, and uniform thickness of insulation is obtained by extruding the PVC as a slightly oversize tube which is made a snug fit on the conductor by a combination of conductor feed speed control and internal vacuum. For multicore cables, the cores fit tightly together, leaving few gaps, but when these are of larger size, non-hygroscopic fillers are included so that the laid-up cores are reasonably circular.

For the armour bedding, there is a choice between PVC tapes and a layer of extruded PVC. The latter is more expensive but provides a robust cable which is preferred for cables with circular conductors, for cables laid

**Figure 31.11** Pvc insulated cables: (a) three-core, 1 kV, SWA for industrial use; (b) British Coal three-core, 6.6 kV DWA

underground, and when it is desirable for terminating glands to provide a seal on to the bedding.

While any form of armour can be supplied (e.g. steel tape or strip, aluminium strip or galvanised wire (GSW)), BS 6346 covers only GSW or aluminium strip. GSW is normally preferred, as it gives optimum mechanical protection and adequate earth conductivity. Aluminium strip armour is now usual only when extra earth conductance is required and it is then important that suitably designed aluminium terminating glands be used. Aluminium armour is also necessary for single-core cables, because steel armour, being magnetic, increases losses, with an adverse effect on ratings.

A PVC sheath is usually applied overall and no bitumen is normally included over the armour. When this was done in the early years, following conventional practice with textile servings, it was found that the bitumen extracted plasticisers from the PVC, creating a mobile black liquid which would bleed from the cables at terminations below vertical runs.

The early choice of PVC by British Coal for mining cables operating at 3.3, 6.6 and, to some extent, at 11 kV was associated with the fact that the resilience of the insulation was found to provide better resistance than paper insulation to damage by rock falls. Although PVC is also satisfactory for higher voltages and has been used extensively in Germany at 20 kV, the electrical losses tend to be high. Better materials such as XLPE are now available when polymeric insulation is preferred.

Although the relative hardness of PVC at ambient temperature can be modified considerably by the choice and proportion of the plasticisers used, these cannot exert a significant effect on deformation at maximum operating temperatures. Heat resisting grades are defined in BS 6746, and such grades can even be formulated to allow PVC to operate for limited periods up to around 100°C without serious degradation due to chemical factors. However, they do little to improve deformation resistance and not much use has been made of them for power cables.

### 31.4.5 XLPE insulated cables up to 3.3 kV

Polyethylene has never found much application outside the USA for power cables, largely because PVC became established and polyethylene suffered from the same disadvantage of thermal deformation. XLPE completely overcomes this problem, and in the voltage range up to 3.3 kV it provides an advantageous alternative with cable constructions which are essentially identical. The main difference is that, as it is a much tougher material, the insulation thickness can be reduced, in the case of 1 kV cables to the minimum which can be extruded satisfactorily.

XLPE has now firmly established itself as an attractive alternative (both technically and economically) to PVC for industrial cables in the UK. XLPE has positive advantages because it is a better insulating material with much lower dielectric loss factor; more particularly, it can be operated satisfactorily to 90°C, with corresponding improvement in cable ratings. These factors have clearly provided an incentive for XLPE to be considered as a competitive material throughout the whole range of power cables up to the highest voltages and it is now being used in all spheres of application. There are competitors, such as ethylene propylene rubber, which may have advantages for specific cable types, but are unlikely to be economic over the whole range.

Up to 3.3 kV, therefore, XLPE is now superseding both paper and PVC insulation. In comparison with PVC,

the continuous current rating advantage is usually more apparent than real, because cable size is dictated by voltage drop rather than current rating. The short-circuit rating based on 250°C instead of 160°C is likewise a bonus only infrequently required. Where XLPE does gain is in that, when ambient temperature is high, such as in tropical countries, the benefit from a smaller derating factor can be substantial. XLPE is not flame retardant, as is PVC, but as flame retardancy is governed more by the oversheath than the insulation, this is not normally significant.

In comparison with paper insulation, XLPE also has a small continuous rating benefit, but the main advantage is the absence of a metallic sheath and the availability of cable which is much cleaner and easier to handle in laying and jointing, together with lower permissible bending radii. The simpler jointing techniques, without any need for plumbing, provide strong attraction for developing countries where such skills are not readily available, and, to date, this is probably the area where XLPE has made the greatest impact.

Another field for XLPE is for self-supporting 240/415 V cables for overhead distribution, as a replacement for bare conductors. Four insulated circular stranded aluminium conductors are twisted together with a long lay and used with special fittings. Following widespread use in Europe, this application has now proved to be an economic alternative in the UK.

Some European countries have extended this application for higher voltages (up to 15 kV), but so far the only use in the UK has been in pilot schemes at 11 kV.

### 31.4.6 PE and XLPE cables for 11 kV to 45 kV

The excellent dielectric properties of PE and XLPE brought these materials into prominence in the early 1960s for higher voltage applications and an increasing scale of effort has been devoted to them ever since. In some countries, particularly the USA, they came into regular use at 10–20 kV at an early stage, and, in spite of a very poor initial service performance in comparison with paper insulation, they have since virtually replaced it for many years at voltages up to 45 kV.

The most important single factor which has caused problems is that, as with paper insulation, internal partial discharges occur at voltages of 5 kV upwards at any irregularities within or at the surface of the insulation. However, whereas paper insulation has fairly good resistance to such discharges and the effects in butt gap spaces can be minimised by oil or gas pressure, polyolefines such as PE and XLPE are particularly weak. Both PVC and EPR are rather better, but have other limitations.

While it was recognised that the insulation must be extremely clean and free from voids, and that screening at both surfaces of the insulation was necessary, many cables were put into service without adequate testing to ensure freedom from discharge. It was also not until the mid-1970s that ideal forms of screening were developed which could be readily removed for jointing and adequately deal with thermal expansion and contraction. Then, in the succeeding years, the final problem was to identify and find solutions to problems caused by effects of water in contact with the insulation. Water has minute solubility in PE and XLPE, but 'tree-like' structures were found in the insulation and it was eventually established that these could lead to electrical breakdown.

Although UK manufacturers supplied some of the first cables used in the early 1960s, the acceptance of XLPE at

home has been slow to come. Three main reasons account for this. First, for the types of cable used, there was, until recently, no clear economic incentive in comparison with paper insulation. Second, in the countries where polymeric materials were quickly adopted, one of the prime reasons was to enable jointing to be carried out with less-skilled resources. In the UK this was not necessary. Third, the higher operating temperature of cross-linked insulation has particular benefit in reducing the derating penalty in countries having high ambient temperatures. Nevertheless, cable manufacturers export a large proportion of their production and so have been obliged to produce competitively.

In the problems that have arisen, polyethylene has no advantages over XLPE and, because it is a thermoplastic material, has great disadvantages in current ratings. Even in the USA, where the use of PE was substantial, it has now given way to XLPE. The remainder of this section refers to XLPE only.

For many years, IEC Specification 502 formed the basis for cable construction for UK manufacturers. However, the issue of BS 6622, which generally follows IEC 502 but is somewhat more demanding, covers the voltage range from 6.6 kV up to and including 33 kV. Above this voltage there is no international specification, but for cables above 30 kV and up to 150 kV, IEC Specification 840 gives detailed requirements for their test performance.

#### 31.4.6.1 Conductors

Up to the present the vast majority of XLPE insulated cables have employed circular conductors in either solid or stranded form. However, extrusion techniques will now allow the use of shaped conductors and they are permitted for use up to 11 kV in BS 6622. At the moment there is limited demand for shaped conductors. Because of the importance of the screen between conductor and insulation, a smooth conductor surface is desirable and stranded conductors need to be well compacted.

#### 31.4.6.2 Conductor screens

Many of the early cable failures were due to imperfections resulting from the use of semiconducting fabric tapes as conductor screens. A thin layer of extruded semiconducting polymeric material is now mandatory, and to ensure a clean interface it is normally extruded in tandem with the main insulation and cured with it. In the case of stranded conductors, a semiconducting tape may be applied between the conductor and extruded screen to prevent penetration between the wires and facilitate removal for jointing.

#### 31.4.6.3 Insulation

Extrusion and curing can be carried out by a variety of processes, but a cardinal feature of all of them is that good material handling to avoid dirt and contamination is vital. The most common method of extrusion for cables up to 20 kV is the Monosil (or similar) process, whilst for 30 kV and above it is the continuous catenary vulcanising (CCV) method in which the curing is carried out by radiant heating and nitrogen under pressure (although it has limitations, curing is sometimes carried out by the application of steam pressure and cooling in water).

As explained earlier, the Monosil type process involves curing the cores in hot water; despite this the insulation performance and subsequent dielectric moisture content is equivalent to that of a 'dry-cured cable'.

#### 31.4.6.4 Insulation screen

One of the main factors concerning the dielectric screen is that it should be easily removed for jointing. A layer of semiconducting polymeric material, compatible with the insulation, can readily be extruded and cured in the same operation and techniques and materials are now readily available to enable the manufacturer to produce either a firmly bonded screen or a 'strippable' screen, which—although in intimate contact with the insulation—can readily be removed without recourse to special tools. Up to 33 kV the majority of cables use strippable screens, whilst bonded screens are occasionally used for 33 kV and almost always for higher voltages.

The older, taped, form of insulation comprising a layer of semiconducting varnish followed by an easily removed semiconducting tape is now used less often.

Both forms of semiconducting screen are usually followed by either a copper tape, applied helically, or a concentric layer of copper wires. The amount of metal in these screens must be related to what is required for earth fault current-carrying capacity; if tapes are used for three-core cables the metal tapes can be supplemented by copper wires in the filler spaces.

#### 31.4.6.5 Finish

A typical three-core cable is shown in *Figure 31.12*, in which the copper taped cores are laid-up, then provided with a PVC extruded bedding, galvanised steel wire armour and PVC or PE oversheath.

**Figure 31.12** Three-core 8.7/15 kV XLPE insulated steel wire armoured cable

PVC or PE bedding over the concentric copper earth wires, then aluminium wire armour and PVC or PE oversheath.

Bearing in mind the faults that can be experienced due to contact between groundwater and insulation, and acknowledging the fact that plastic oversheaths may be damaged during installation or subsequently, new designs with components or special layers to restrict movement of water within cables are being produced. These will utilise some form of conductor blocking, usually in conjunction with blocking (swelling) tapes applied radially under the outer layers. Other designs use a powder which swells on contact with moisture.

#### 31.4.6.6 Dielectric deterioration by treeing phenomena

No discussion on polymeric insulation at high voltage would be complete without some reference to deterioration caused by treeing mechanisms. These are related to a pre-breakdown characteristic which gradually spreads through the dielectric under electrical stress through paths which, when visible or made visible, resemble the branch structure of trees. Trees are of two basic types:

(1) *Electrical trees* These are trees in a dielectric consisting of permanent channels having dendritic or branching patterns due to partial discharges during application of a.c., d.c. or impulse electrical stresses. The channels originate at sites of high stress due to non-uniform electrical fields from imperfections such as protrusions at an insulation interface, a void or a contaminant.

(2) *Electrochemical trees* This is a class of tree generated in a dielectric during application of electrical stress in the presence of liquid water or water vapour—hence, often known as ‘water trees’. They consist of fine water channels which can be seen under a microscope after staining. They disappear if the sample is dried, but reappear after boiling in water. Electrochemical trees are formed at stresses which are much lower than those required to produce electrical trees, and the rate of growth may be very slow. The tree patterns appear generally at opaque areas in the translucent polyethylene. If the dielectric or screen is in contact with soil water containing such minerals as sulphides, the water may have a characteristically coloured stain. The initiation of electrochemical trees is at the same types of site as indicated above for electrical trees. Characteristic names are often given to them according to origin, e.g. ‘bow-tie’ trees from contaminants (*Figure 31.13(a)*) and ‘bush’ or ‘broccoli’ from surface imperfections. *Figure 31.13(b)* shows an electrical tree which is developing in an area where electrochemical treeing has become extensive.

It is this treeing phenomenon which is the important reason for the insulation to be free from all irregularities and for the surfaces to be smooth and in good contact with the screens. Cables may operate for many years before a tree size is generated which will contribute to ultimate breakdown. The presence of water is a requisite for treeing to be initiated, but a very small amount suffices, and for the highest voltages it is desirable to ensure that all moisture is excluded, e.g. by provision of a metallic sheath.

#### 31.4.7 Cable tests

Full details of the tests and procedures required are given in the cable standards listed at the beginning of the section. IEC 55, IEC 502 and IEC 840 are the most relevant documents and values quoted below are taken from these standards. A complete summary would be lengthy and it is

(a)

(b)

**Figure 31.13** (a) Bow-tie tree at an inclusion; (b) Electrical tree in an area of extensive water tree development

only possible to give a brief outline to illustrate the general basis for the more important tests.

#### 31.4.7.1 Manufacturing tests

Tests during manufacture are restricted to those which are not possible on finished cables and comprise a.c. spark tests on polymeric insulation and sheaths.

#### 31.4.7.2 Tests of completed cables at works

Tests of completed cables at works comprise the following:

- (1) Measurement of the thickness of insulation and other prescribed components.
- (2) Conductor resistance test.
- (3) An a.c. test for 5 min (30 min for cables above 30 kV) at a voltage which is usually  $2.5 U_0 + 2$  kV for cables rated up to 3.6/6 kV, and  $2.5 U_0$  for cables of 6/10 kV and above. For multicore non-screened cables the test is required between conductors and also between any conductor and sheath. For cables with individually screened cores it is from conductor to sheath only.
- (4) For paper insulated cables with rated voltage  $U_0$  of 8.7 kV and above, a dielectric power factor/voltage test is required to determine compliance with prescribed limits for maximum power factor at 0.5 times  $U_0$  and maximum difference in power factor from 0.5 to 1.25 times  $U_0$  and from 1.5 to 2.0 times  $U_0$ .
- (5) A partial discharge test is required for cables insulated with PE and XLPE of rated voltages above 1.8/3 kV and on cables insulated with EPR and PVC of rated voltages above 3.6/6 kV. The magnitude of discharge at  $1.5 U_0$  must not exceed (a) 20 picocoulombs (pC) for EPR, PE and XLPE for cable up to 30 kV, (b) 10 pC for PE, EPR and XLPE above 30 kV and up to 150 kV, and (c) 40 pC for PVC.

#### 31.4.7.3 Tests after installation

- (a) Paper cables: a 15 min d.c. test at a voltage of 70% of the values given in (3) above.
- (b) Polymeric cables: a 15 min d.c. test at a voltage of approximately  $4 U_0$  for cables up to 30 kV and  $3 U_0$  for cables above 30 kV up to 150 kV.

#### 31.4.7.4 Special and type tests

- (1) A bending test at a radius much more severe than stipulated for installation, followed by a voltage test. For paper cables the diameter of the test cylinder varies, according to the cable rated voltage and type, from 12 to 25 times the diameter of the cable plus the diameter of the conductor ( $D + d$ ). Three cycles of bending are required and maximum limits are stipulated for tearing of individual paper tapes. For polymeric cables up to 30 kV two cycles of bending are required over a test cylinder of  $20(D + d)$  for single-core cables and  $15(D + d)$  for multicore cables. For polymeric cables above 30 kV and up to 150 kV three cycles are required over a test cylinder of  $25(d + D) + 5\%$  for cables with metal sheaths and  $20(d + D) + 5\%$  for others.
- (2) A drainage test for non-draining paper cables at the maximum continuous operating temperature for the cable. The maximum permissible drainage is 2.5–3% of the internal volume of the metal sheath.
- (3) A dielectric security test for paper cables comprising sequential bending, impulse and a.c. tests. The impulse withstand requirement is 95 kV for  $U_0 = 8.7$  kV, 125 kV

for  $U_0 = 42$  kV and 170 kV for  $U_0 = 48$  kV. The a.c. application is  $4 U_0$  for oil/resin impregnation and  $3 U_0$  for non-draining impregnants.

- (4) A power factor/temperature test for paper cables of  $U_0 = 8.7$  kV and above to a temperature  $10^\circ\text{C}$  above rated temperature. Limits are  $20\text{--}60^\circ\text{C}$ , 0.0060;  $70^\circ\text{C}$ , 0.0130;  $75^\circ\text{C}$ , 0.160;  $80^\circ\text{C}$ , 0.0190;  $85^\circ\text{C}$ , 0.0230.
- (5) An electrical test for PE and XLPE cables above 1.8/3 kV and PVC or EPR cables above 3.6/6 kV. This requires sequential application and/or measurement of partial discharge, bending, power factor/voltage, power factor/temperature, load cycles, partial discharge, impulse withstand and a.c. high voltage. For synthetic insulated cables above 30 kV and up to 150 kV the sequential application and/or measurement is bending, partial discharge, power factor/temperature, load cycles, partial discharge, impulse withstand and a.c. high voltage. The impulse requirement is  $U_0 = 3.6$  kV, 60 kV;  $U_0 = 6$  kV, 75 kV;  $U_0 = 8.7$  kV, 95 kV;  $U_0 = 42$  kV, 125 kV;  $U_0 = 48$  kV, 170 kV;  $U_0 = 26$  kV, 250 kV;  $U_0 = 36$  kV, 325 kV;  $U_0 = 64$  kV, 550 kV;  $U_0 = 76$  kV, 650 kV; and  $U_0 = 87$  kV, 750 kV. The a.c. test comprises 4 h at  $3 U_0$  for cables up to 30 kV and 15 min at  $2.5 U_0$  for cables above 30 kV up to and including 150 kV.
- (6) Tests on the component materials before and after ageing and, in the case of polymeric cables, on the complete cables after ageing.

## 31.5 Transmission cables

### 31.5.1 Historical development sequences for a.c. transmission

#### 31.5.1.1 Problems due to partial discharges within paper insulation

Reference has already been made to the work by Hochstädter which led to the 'H' type or 'screened' radial field design. Such constructions were quite satisfactory at 33 kV and to a limited extent at 66 kV. Failures at 66 kV and higher voltage were found to be due to discharges in minute vacuous voids formed by expansion of the impregnating compound with insufficient subsequent contraction to fill all the space available. Emanuel in the late 1920s pioneered the first solution, which was the oil filled cable. The basic requirement was either to eliminate completely the possibility of voids being created, as in the pressurised oil filled cable, or to ensure that they were always under a high gas pressure. Gas may be admitted directly into the insulation or exerted externally on a flexible sheath over the insulation, in which case the void suppression principle is more akin to that of the OF cable.

As the void formation mechanism was also clearly related to the temperature excursions of the insulation, the operating temperature limit of the solid (i.e. non-pressure) insulation could be raised from 65 to  $85^\circ\text{C}$  for gas filled cables and  $90^\circ\text{C}$  for oil filled cables, with consequently much improved cable ratings. Even more important was the fact that the a.c. operating electrical stress of impregnated paper insulation could be increased from 4 MV/m to about 16 MV/m and reductions in dielectric power factor were achieved.

#### 31.5.1.2 Types of paper-insulated pressurised cables

Many different types of pressuring are possible and may be classified into the two basic constructions indicated in Table 31.6 which lists those currently in service.

**Table 31.6** Pressure cables and voltage in commercial service

<i>Design</i>	<i>Voltage range (kV)</i>
<i>Fully oil impregnated</i>	
Lead or aluminium sheath	
Low-pressure OF	30–525
Steel pipe	
High-pressure OF	30–500
External gas pressure with diaphragm sheath	30–275
<i>Internal gas pressure</i>	
Lead or aluminium sheath	30–275
Steel pipe	30–132

OF, oil filled.

A fact which emerges from *Table 31.6* is that oil pressure can be used up to the highest voltages at present required (525 kV). Gas pressure has a limitation primarily related to a lower electrical breakdown strength. Although gas pressure cables have some advantages in terms of the associated accessories and equipment, the oil pressure cables are usually more economic.

#### 31.5.1.3 Transmission system requirements

When Emanuelli first developed the pressure cable technique, he was fulfilling a need for the requirement of the early 1930s to transmit in the range of 30–132 kV with conductor sizes of around 200 mm<sup>2</sup>. With the growth in the usage of electricity during the next 30 years, cable voltages and ratings had to keep pace with and match the overhead-line circuits. Developments quickly proceeded to find solutions for the higher voltages with conductors up to 2500 mm<sup>2</sup>.

Bulk transmission in the UK began in the 1930s with a circuit requirement of 110 MVA at 132 kV; 275 kV followed in the late 1950s with a winter circuit rating of 760 MVA; and by the late 1960s the circuit demand had increased to 2600 MVA at 400 kV. To obtain this from a single cable circuit meant that design had to be pushed towards the limit for paper insulation in relation to electrical features, diameter and coiling on drums. To match the increases in overhead-line ratings, it has become necessary for the heat generated in cables to be removed by more sophisticated engineering means involving cooling pipes.

#### 31.5.1.4 Alternatives to impregnated paper insulation

The oil filled cable has been most successful in meeting all requirements up to 525 kV. At some future date (possibly not until the next century in the UK, but earlier in some other countries) there will be a need for undergrounding parts of transmission lines operating at 800–1000 kV. To produce cables within a diameter (say 160 mm) which is practicable for manufacture and handling, and to keep losses within an economic limit, it seems essential to use higher stresses (possibly 25 MV/m) and dielectrics with lower power factor and permittivity than can be achieved at present with impregnated paper. Possibilities are discussed later.

There has been much recent interest in materials such as polyethylene and XLPE, which have good potentialities for very high voltages and other advantages for the lower voltage range. To date, the enthusiasm has stemmed not

primarily from low losses, but from the possibility of a much simpler cable construction, the promise of less complicated jointing requirements and, above all, the elimination of pipework and pressurising equipment. In some overseas countries, where installation and maintenance skills are not readily available, this is an important factor which could well justify a higher intrinsic cable cost. Location and repair of oil leaks can be troublesome. However, some of the problems with polymeric insulation for distribution cables have been discussed, and for voltages greater than 132 kV the usage so far of PE and XLPE cables has been relatively small.

### 31.5.2 Types of cable

#### 31.5.2.1 Basic requirements

Apart from absolute consistency and freedom from defects, the essential requirements of high-voltage dielectrics are:

- (1) High impulse strength, because this is the ultimate design stress requirement and determines dimensions.
- (2) Low dielectric power factor in order to keep the heat generation to a minimum. When conductor size is at the maximum possible, much expense may have to be devoted to means of cooling the cable to obtain an economic circuit.
- (3) Low permittivity to reduce both the electrical losses and charging current.
- (4) Ease of bending during installation without sustaining damage which could affect service life.

Impregnated paper under oil pressure is the only dielectric which so far has met all these requirements up to about 525 kV. In relation to electrical losses, however, it is reaching its limit at this voltage without forced cooling. Impregnated paper with gas pressure is technically satisfactory up to 275 kV but is not generally economically competitive with oil filled cables.

Low-pressure oil filled cable (*Figure 31.14*) is used almost universally in the UK throughout the voltage range and it is predominant throughout the world. High-pressure OF cable is favoured in the USA.

The influence of the impulse strength requirement on design stress can be seen from *Table 31.7*.

Conventional oil filled cable has a safe impulse stress of around 100 MV/m and a.c. stress of 30 MV/m, a ratio of about 3/1. This has to be compared with the service performance requirement of between 10.2/1 and 6.2/1 according to voltage, i.e. cables must be designed on an impulse breakdown stress basis and then they will have a large safety margin for a.c. performance. The reverse would soon lead to breakdown. *Table 31.7* also illustrates that, because the impulse/a.c. ratio reduces with increasing voltage, higher design stresses can be adopted as voltage increases: typical

**Table 31.7** Working and impulse voltages

<i>System voltage (kV)</i>	<i>Working voltage (kV)</i>	<i>Impulse-test voltage (kV)</i>	<i>Impulse/working ratio</i>
33	19	194	10.2
66	38	342	9.1
132	76	640	8.4
275	160	1050	6.6
400	230	1425	6.2

**Figure 31.14** A 400 kV single-core oil filled cable

values are 7.5 MV/m at 33 kV; 12 MV/m at 132 kV; and 15 MV/m at 275–400 kV.

### 31.5.2.2 Low-pressure oil filled

Right from the beginning the low-pressure oil filled cable has been well to the fore and has been the only type of cable widely used in the UK at 275 and 400 kV. Single- and three-core designs are available from 33 to 132 kV but, because of diameter limitations, only single-core cables can be produced for the higher voltages. *Figure 31.15* illustrates how oil channels are provided within the cable. In single-core cables the oil flow is normally through a duct in the centre of the conductor, but for short lengths used to terminate three-core cables the design may incorporate an annulus formed by the provision of longitudinal ribs on the inside of the lead sheath. In triple-core lead sheathed cables and aluminium sheathed cables with circular conductors, a duct is

**Figure 31.15** Cross-sections of typical oil filled cables

placed in the fillers between the cores. Alternatively, with a corrugated aluminium sheath (CSA) it is possible to omit the ducts and fillers. At 33 kV the conductors may be of oval shape and the construction is known as ductless shaped oil filled, whereas for higher voltages with circular conductors it becomes ductless circular oil.

As the cable heats, the oil expands and is forced out of the cable through pipes at joints or terminations into a tank reservoir having internal pressurised capsules so designed that, on cooling, there is a feedback of oil into the cable. *Figure 31.16* illustrates the system. Tanks are of sizes to suit the route length and volume of oil in the cable. They are pressurised to take into account variations in height along the cable route. By the inclusion of stop joints between lengths of cable the circuit may be split into several oil sections. The designed static pressure within the cable is 5.25 bar, but transient pressures up to 8 bar can occur during periods of rapid heating due to increasing load. Optimum planning of the oil feed and sectionalising arrangements is a very important part of the economic design of a cable system.

From the time the cable is filled with oil during manufacture, the oil pressure must be continually maintained. A small tank is fitted on the cable drum; it remains connected during cable laying and even during jointing a flow of oil is maintained. When cables are installed in vertical shafts, e.g. for pumped storage stations, special arrangements are necessary. The Cruachan 275 kV pumped storage scheme in Scotland has a vertical head of 325 m with a consequent hydrostatic pressure of approximately 30 bar. The cable had to be partially drained under vacuum to limit the oil flow while making the lower stop joint, and reimpregnated before making the upper sealing end.

Lead sheaths will not withstand significant internal pressures, and are reinforced to withstand a continuous pressure of 5.25 bar for normal installations by the helical application of bronze tapes. In spite of the reinforcement, the lead sheath is subject to some expansion under creep stress. British practice favours the use of  $\frac{1}{2}$ C alloy (0.2% tin, 0.075% cadmium). Aluminium sheaths have technical and economic advantages and nowadays they are of corrugated design. This enables the thickness to be reduced and also provides greater flexibility for handling.

To maximise the efficiency of oil flow and the length of individual oil sections, the viscosity of the oil needs to be as

**Figure 31.16** Diagrammatic layout of a typical three-core OF cable system

low as possible, consistent with low power factor and electrical strength. Until recently, mineral oils were used with a viscosity of about 12 centistokes maximum at 20°C. However, current practice is to use synthetic alkylates of dodecylbenzene type which have better gas absorbing properties under electric stress. Such impregnants are intermediates in detergent manufacture.

Apart from the impregnant, the insulation for oil filled cables also differs significantly from that for lower-voltage paper cables. To keep the power factor as low as possible, the paper needs to be more thoroughly treated to remove impurities. For example, the water used in papermaking and washing for very-high-voltage cables may be deionised. For electrical stress reasons, and to obtain good bending performance without disturbance of the dielectric by wrinkling, etc., the papers tapes are graded from thin adjacent to the conductor (where the electrical stress is highest) towards much thicker and wider on the outside (to withstand the higher mechanical stress). With the large insulation thickness (up to 30 mm) required for the highest-voltage cables it is necessary to control the design and paper lapping parameters to allow individual paper layers to slide over one another on bending. This is done by shrinking the papers by predrying before lapping, and carrying out the lapping in a low-humidity atmosphere with careful control of tension.

### 31.5.2.3 High-pressure oil filled cable

The high-pressure oil filled cable is a type of cable (*Figure 31.17*) developed in the USA and used extensively only in a few countries. It evolved from the predominant American practice of installing cables in buried ducts, the steel pipe being essentially a duct which can be installed a short length at a time without need for long trenches to be kept open. Either the cable cores have a temporary lead sheath which is stripped off as the cable is pulled into the pipe, or the unsheathed cable is delivered to site on a specially sealed and protected drum. So that the cores are not damaged during the pulling operation, D-shaped skid wires are applied helically over the insulation. After jointing, the pipe is evacuated and filled with oil to a pressure of 14 bar and the pressure is maintained by automatic pumping stations. The relatively large volume of oil and the high pressure enable a viscous impregnant to be used.

Pipe type high-pressure oil filled cables tend to be more expensive than self-contained oil filled cables laid directly in the ground, but in built-up inner city areas, or where robustness is desirable, they can be advantageous. Except

**Figure 31.17** Pipe type 230 kV high-pressure OF cable

for terminations, they always consist of three single-core cables pulled into a single pipe. The proximity of the cores and the high electrical losses in the pipe impose lower ratings than for self-contained cables.

### 31.5.2.4 Gas pressure cables

During the 1930s–1940s, many designs became established to utilise the principle of gas pressure to suppress partial discharge in voids.

In the 'internal gas pressure' cable and in one form of pipe type cable the gas was admitted directly into the cable insulation and held by the metal sheath or steel pipe. The 'gas compression' cable worked on a different principle. Insulated oval conductors were sheathed with either lead or polyethylene and the individual cores or the three laid-up cores were then covered with a pressure retaining metallic

sheath or pulled into a steel pipe. The space between the inner sheath and the outer pressure retaining member was filled with high-pressure gas, usually nitrogen. Expansion and contraction of the relatively viscous impregnating compound was compensated for by the inner sheath acting as a diaphragm.

With one exception, gas pressure designs are obsolete mainly because they cannot match the technical performance of oil filled cables through the voltage range. At 275 kV and above, low power factor and high breakdown strength (a.c. and impulse) become increasingly important, and oil filled cables can be operated to higher design stresses.

The exception is the 'pre-impregnated gas filled cable', useful for applications where problems exist in creating practicable oil sections, e.g. on hilly and undersea routes. Other advantages are: (a) there is no need for specialised oil equipment and (b) long continuous lengths suitable for submarine use can be manufactured. The total length for installation is determined by what can be coiled down in a ship, as joints between lengths can be made either in the factory or on the ship. In this gas filled cable system the paper is impregnated with a special greasy compound before being lapped on to the conductor. With modern designs the impregnated cores are covered by a smooth aluminium sheath and gas is admitted directly into the insulation after installation. There is a minimum of impregnating compound, and although voids do exist from the outset, the high nitrogen pressure provides good electrical strength. As with other forms of gas cable, however, operating voltages are usually limited to 132 kV.

#### 31.5.2.5 Cables with polymeric insulation

Mention has already been made of the increasing use of polymeric insulation, largely XLPE, for distribution cables up to 33 kV. The low power factor of around 0.0005 which is attainable with such cables is also clearly attractive in comparison with the minimum of about 0.002 which is possible with the best oil filled cables. It seems likely that a new phase of cable transmission is emerging. Incentives are simpler jointing techniques, and reduced maintenance as pressurising equipment and oil leaks are avoided. An economic consideration relates to the voltage limit above which it is desirable to have a metal sheath over the insulation to prevent contact with water.

It was reported in 1988 that 230 km of lead sheathed 225 kV cable with thermoplastic polyethylene insulation was in satisfactory service in France, the first lengths having been installed in 1969. Electricité de France also claimed that the overall economics were favourable. This is despite the use of a lead sheath and limitation with straight polyethylene of the operating temperature to 70°C compared with 90°C with paper insulation.

Following consolidation of satisfactory experience at 33 kV, it is at around 132 kV that large-scale experience will first be obtained and it is now generally accepted that for voltages of 66 kV and above, a metallic sheath is required. XLPE is now well established as a dielectric at 132 kV and long length installations at 275 kV are just beginning. Many small installations at 132 kV are in service with a design stress of 7–9 MN/m. The problems have been enumerated in Section 31.4.6 and are primarily concerned with the production of clean insulation and screen interfaces plus possible incidence of water treeing in service. The French experience with straight polyethylene indicates that the former can be overcome, and only time will prove whether a metal sheath is necessary to prevent degradation by water tree mechanisms.

Much development work is proceeding on the optimum method of curing XLPE. Although dry-cured material has a lower content of microvoids than steam-cured material, there is little difference between the two levels in water tree growth if water is in contact with the insulation. If kept dry, treeing ceases to be a problem and the improved short-term breakdown strength of the dry-cured material enables it to be operated at a higher stress.

### 31.5.3 Submarine power cables

The engineering of submarine cable links is complex. Apart from the choice between a.c. and d.c. transmission, cable design has to take account of the maximum depth on the projected route, the potential hazards caused by shipping, corrosion and possibly marine borers. There are many submarine power cable installations giving satisfactory service at voltages up to  $\pm 400$  kV d.c. and 420 kV a.c.

The choice of cable for a submarine crossing is influenced by the system voltage, the maximum depth and the length of the crossing. Solid type paper insulated cables are suitable for voltages up to 400 kV d.c. and 33 kV a.c. For deep-water installations special design features are necessary to enable this type of cable to resist the external water pressure. Solid type cable has been used successfully at 550 m depth on a d.c. link between Norway and Denmark. For higher voltages self-contained pressure assisted cables (oil filled and gas filled) are used, the internal pressure being maintained above the external water pressure at the deepest part of the route. Although not so far used for major submarine transmission schemes, polymeric insulated cables may be attractive for future a.c. links.

It is preferable that the cable be manufactured in continuous lengths without joints. As this is not always possible, proven techniques have been developed for the construction of flexible joints in all types of power cable, to facilitate laying in a continuous operation. Manufacture has to be arranged so that the cable can be coiled down on land and then reloaded directly into the cable laying vessel.

Experience on the  $\pm 100$  kV d.c. cable circuit between England and France (1961) and on the Sweden–Denmark ('Konti-Skan')  $\pm 250$  kV d.c. link (1965), indicates that cables laid directly on the sea-bed across busy shipping lanes or fishing zones are liable to suffer frequent impact damage caused by dragging anchors and trawls. A significant increase in circuit security can then be obtained by embedding the cables. Techniques have been developed for cutting trenches in the sea-bed and for accurate positioning of the cables within the trenches. On many cable routes adequate security can be obtained by burying the cable at the shore approaches only.

### 31.5.4 D.c. transmission

Table 31.8 indicates the main d.c. schemes in operation, all of them being submarine. There are advantages in cable cost, but expensive terminal conversion stations may make such schemes uneconomic unless there are other overriding considerations. These arise when large national systems need to be interconnected and occasionally when large blocks of power have to be transmitted within a network. Most of the existing schemes are for submarine links where the charging currents for a.c. cable systems would be excessive.

D.c. cables can be operated at much higher design stresses than a.c. cables. For example, a typical 250 kV oil filled cable could have a maximum design stress of 33 MV/m, whereas a comparable 275 kV a.c. cable would have

**Table 31.8** D.c. cable schemes

Link	Voltage (kV)	Approximate installation date	Type of cable	Approximate route length (km)

a design stress of 15 MV/m. Although the partial discharge in voids mechanism does not apply in d.c. operation, there are other factors, such as stress distribution and transient voltages arising from rectifier malfunction, which have to be taken into account.

In a.c. cables the stress distribution in the insulation is determined by the geometry and the permittivity of the dielectric. It is usual to assume a uniform permittivity, as this property is affected only to a minor degree by changes in cable temperature and voltage. In d.c. cables, however, the steady state stress distribution is dependent on the geometry and resistivity of the dielectric. If the latter remains uniform, the stress distribution is the same as that for a.c. However, the resistivity of the dielectric is highly dependent on the dielectric temperature and to a lesser degree on the applied stress. When the cable is carrying load, there is a temperature gradient across the dielectric, the effect of which is to reduce the stress adjacent to the conductor and to increase it at the outside. It is possible to arrive at the conditions where the stress at the outside exceeds that at the conductor and the insulation must be designed to cater for these changing stress conditions. *Figure 31.18* illustrates the principles involved.

Nevertheless, as pressurising of the insulation is not so necessary and does not give much advantage in direct voltage and impulse breakdown strength, it is possible to use mass impregnated solid type cables for much higher equivalent direct voltages. This assumes that the dielectric is not weakened by migration of impregnating compound, i.e. the

insulation is ‘non-draining’. For the highest voltage levels, oil filled cables are used and, as with a.c. but for a different reason, clean paper obtained by the use of deionised water is desirable. Excessive conductivity due to ionic impurities can lead to thermal instability and breakdown.

A power of 500 MW can be transmitted by *three* single-core a.c. cables with 1000 mm<sup>2</sup> conductors at 275 kV. The same power can be conveyed by *two* single-core 800 mm<sup>2</sup> d.c. cables at ±250 kV. To transmit 1500 MW would require a double circuit comprising *six* naturally cooled 2000 mm<sup>2</sup> a.c. cables, but still only *two* d.c. cables, reducing by two-thirds the number of substantially identical cables required.

### 31.5.5 Cable ratings and forced cooling

The considerations in the general section on current carrying capacity are applicable also to transmission cables, but because of the much greater power carried, the effects of heat dissipation in the ground are of particular importance. First, it is necessary to inspect the soil to determine its thermal resistivity: 1.2°C m/W is taken as a representative value, but it may be much higher in sand, shingle or made-up ground, or if the soil is likely to be permanently dry. The moisture content is a significant factor in ground thermal resistivity; this became apparent when cables were loaded continuously so that moisture could not seep back during reduced load periods. If the ground surrounding the cable reaches a temperature of around 50°C, there is a considerable danger, with certain types of soil, of reaching a ‘runaway’ condition: complete drying out, high thermal resistivity, excessive temperature rise in the cable and breakdown.

When there is doubt about the thermal properties of the backfill, it is safer to surround the cable with imported material having known thermal resistivity in the dry condition. This means creating a dense mass with little air space by a controlled mixture of sand and gravel, particle sizes being blended to obtain good packing. Laboratory control of composition and compaction is important. An alternative is to use a mixture of selected sand and cement in the proportion of 14:1.

During the early 1960s, following the first failure due to ground drying out, several installations were completed in the UK with cooling pipes laid adjacent to each cable, water being circulated through a closed heat exchanger. The latter was air cooled or in some locations water cooled by supplies from bore-holes. Initially, aluminium was used for the pipe but this was later changed to high-density polyethylene.

**Figure 31.18** Stress distribution in d.c. and a.c. cables

In these later installations four pipes were used with an internal bore of approximately 66 mm. Specially selected sand was used around the cables and pipes. Some 160 circuit km of 275 kV with a winter rating of 760 MVA was installed in this way. It was later found that this rating, together with 1100 MVA at 400 kV, could be achieved by naturally cooled cables with a stabilised backfill and more realistic assumption of ambient ground parameters.

Separate pipe cooling came back into prominence in 1977 when overhead line ratings were further increased by raising the operating temperature to 65°C. This required a winter rating of 2038 A, equivalent to 970 MVA at 275 kV and 1410 MVA at 400 kV, which could not be achieved with the 2500 mm<sup>2</sup> maximum conductor size and stabilised backfill. A similar need for additional cooling also arose with the 400 kV cables in the Dinorwic pumped storage scheme in North Wales. Improved water pipe systems were adopted, the emphasis being on the use of larger pipe diameters and special arrangements for water cooling of the joints (Figure 31.19).

A rating factor which is particularly important with high-voltage single-core cables is to prevent the very high losses in metallic sheaths and reinforcement if these were solidly bonded at both ends of a feeder. The losses accrue from currents induced in the low-impedance sheath circuit and are related to the conductor current and separation between phases. Without elimination of such losses the use of aluminium sheaths would not generally be economic. In some cases it may be possible to bond earth at one end only, but modern practice is to employ a transposition method (Figure 31.20) in which the metallic sheaths are interrupted every few hundred metres with cross-connection at jointing positions. Voltages are then balanced at every third joint and usually kept below 65 V under full-load conditions. High transient voltages can occur; and to check that the sheath insulation is satisfactory, a 10 kV d.c. test is carried out after laying.

When two circuits are laid on a common route, the current rating will be reduced by mutual heating unless thermal independence can be obtained by a separation of about 2 m at 132 kV, with progressive increases for higher voltages. To obtain the most economic solution, it is necessary to examine the cost of larger conductor cable, extra trenching and external cooling. In the case of a single-core circuit the mutual heating effects between the phase cables must also be taken into account. With single-point bonding and cross-bonding to eliminate sheath circulating currents,

Figure 31.19 Typical layout of cables and water cooling pipes in a trench

Figure 31.20 Cross-bonding of cable sheaths to provide transposition for reducing sheath losses

a flat formation with spacing between cables of 150–300 mm is usually beneficial to avoid unduly high sheath voltages. If single-core cables are bonded and earthed at both ends, it is necessary to install the cables in trefoil formation, because with wide spacing the increase in sheath losses would more than offset the reduction in mutual heating.

### 31.5.6 Future development

It was mentioned earlier that the low-pressure OF cable was nearing its limit of performance at the present maximum service voltage of 525 kV. However, overhead lines will soon be in operation at around 1000 kV, and at some future date there will be a need for cables to match them.

A major factor in the development of such cables is the need to keep the diameter of the cables down to a size that will enable drums of completed cable to be transported on existing road systems. As 525 kV cables are already approaching this limit, only a small increase in insulation thickness can be permitted. This will result in the insulation of the higher voltage cables operating at a much higher electrical stress. Experimental work has shown that this should be feasible provided the minimum oil pressure is substantially increased.

While higher design stresses are possible with impregnated paper insulation, they create problems insofar as dielectric losses are concerned. The dielectric loss of a cable which occurs whenever the cable is energised can be expressed as follows:

$$\text{Dielectric loss} = 27.7 V f d s \epsilon \delta \times 10^{-4} (\text{W/m}) \leftarrow$$

where  $V$  is the phase voltage (kV),  $f$  is the frequency (Hz),  $d$  is the conductor screen diameter (mm),  $s$  is the maximum design stress (kV/mm),  $\epsilon$  is the relative permittivity of the insulation, and  $\delta$  is the dielectric loss angle.

For a given conductor size, frequency of supply and insulation characteristics, the dielectric losses are proportional to the product of the operating voltage and design stress. The increase in the dielectric loss means that the current dependent losses, i.e. the current rating, must be reduced to prevent the maximum design temperature being exceeded. At a voltage of approximately 850 kV, the cable reaches its maximum design temperature purely by voltage energisation and, therefore, has no current rating.

To overcome these problems, designers have been looking for alternative materials which have lower dielectric

losses than paper but which have the required mechanical and physical characteristics. Although much research work has been devoted to insulation consisting of all-plastic films, the material now being introduced into commercial service is a laminate consisting of a film of polypropylene between two layers of paper (PPL). The proportion of paper to polypropylene is approximately 50:50. It has been found that this type of laminate overcomes many of the problems associated with all-plastic films.

The use of PPL reduces the dielectric loss to about 25% that of conventional paper insulation and extends the useful operating voltage range above 1000 kV. It is also beginning to find use in low- and high-pressure oil filled cables with voltage ratings down to 345 kV.

Polymeric insulation such as XLPE also has very low dielectric losses and, therefore, is attractive for the higher operating voltages. Until recently these insulations operated at much lower electrical stresses than paper insulation and therefore were not suitable for use in cables at voltages in excess of 275 kV. However, much development work has been undertaken with the object of increasing the operating stress. This has been mainly directed at reducing the contaminant level in the insulation and providing extremely smooth conductor and dielectric screens. Short lengths of 500 kV cable are now in service to obtain operating experience.

A completely different approach is to make use of superconduction: very large currents can be carried by small conductors without the generation of much heat. Until recently, it was necessary to use liquid helium to cool the conductor to the required temperature.

The engineering problems are not inconsiderable, but experimental cables have been made and trials undertaken to demonstrate the practicability of such schemes. It has, nevertheless, been established that the economics are such that this form of transmission can only be justified for

ratings of the order of 5–10 GVA. In the UK such requirements are several times what can immediately be envisaged.

The subject has attracted renewed interest with the recent discovery of high temperature superconduction. At the time of writing discoveries are still taking place and, therefore, it is not possible to assess its full impact on underground transmission. It would appear that with these new superconductors, liquid nitrogen is a possible coolant which is considerably cheaper than liquid helium. However, the materials so far discovered are of a brittle nature and will require special designs of conductors.

### 31.6 Current-carrying capacity

The continuous current rating of a cable is dependent on the way heat generated in the conductor, insulation and metallic components is transmitted through the cable and then dissipated from its external surface. For convenience the conductor temperature is taken as the reference datum for the cable. A notional maximum cable rating can then be calculated from the permissible temperature rise from a standard base ambient or ground temperature to the maximum temperature that the particular type of insulation will withstand with a reasonable margin of safety. Adjustments to this notional rating have to be applied to cover many factors, which include a different base temperature and variations in heat dissipation from the cable surface: e.g. dissipation from a cable in a duct is lower than from a cable in free air.

The difference between conductor temperature and external or ambient temperature is directly related to the total heat losses and the law of heat flow, using a conduction current analogue. This analogy may be extended into the type of circuit diagram in *Figure 31.21*, which shows how the heat input at several positions has to flow through

Figure 31.21 Equivalent circuit diagram for the heat flow in a three-phase belted cable

various layers of different thermal resistance. To make calculations, values of thermal resistivity have to be measured for all the materials involved. Thermal resistivity is defined as the difference in degrees Kelvin between opposite faces of a metre cube caused by the transference of 1 J/s of heat; the SI unit is kelvin-metres per watt (K-m/W).

### 31.6.1 Availability of continuous ratings

Cable users frequently need to ascertain the rating for a particular type of cable at a given voltage and with a range of copper or aluminium conductor sizes. The most common sources of reference are:

- (1) The IEE Regulations for the Electrical Equipment of Buildings. This source covers cables of all standard types (up to 1 kV). A difference from the others listed below is that the ratings quoted are lower, as they are calculated from a base ambient temperature of 30°C (compared with 25°C) and, hence, a lower permissible temperature rise. Only 'in air' ratings are included.
- (2) Report ERA 69-30 (8 parts), published by ERA Technology Ltd, provides ratings for paper cables up to 33 kV, PVC cables up to 3.3 kV and thermosetting insulated cables up to 3.3 kV. Guidance is also provided for cyclic and emergency ratings, together with further information relating to cables in typical specific installation conditions.
- (3) Manufacturers' catalogues.
- (4) Lower ratings may be selected for specialised installations because of particular environmental conditions. For example, the IEE Regulations for the Electrical and Electronic Equipment of Ships stipulate an ambient temperature of 45°C and somewhat lower maximum temperatures for continuous operation (80°C for thermosetting insulation).
- (5) The above cover installations based on British cable practice. When USA types of cable and system are applicable, reference may be made to ICEA publications.
- (6) IEC Publications 364-5-523 and 287 (*Table 31.1*): 364-5-523 provides ratings for unarmoured cables and 287 gives the basic methods for calculating ratings using the standard data included. Values prepared by all other bodies are almost always derived in accordance with this specification.

In general, these documents provide tabulated figures for copper and aluminium conductor cables installed in air, in ducts and buried directly in the ground. The data quoted are for standard conditions, and multiplying factors are given for variations in the conditions.

A feature of USA practice is that data provision is made for limited periods of operation with emergency overload for a specified number of hours per year to a higher temperature. While it is recognised that such operation could affect the life of the cable, the conditions are chosen to ensure that only limited ageing is likely to occur. British practice has not yet included this feature in published recommendations.

Another important aspect relates to the fact that the published ratings are quoted for 'continuous' or 'sustained' operation. Few cables are loaded for the whole of their life to full rating, and allowance is made for this. Nevertheless, the derivation of ratings is a most complex subject and many large users, such as the UK distribution companies, have developed ratings which allow for their own circumstances, such as cyclic operation and the emergency

conditions which can arise with 11 and 33 kV cables normally installed as open rings (Electricity Council Engineering Recommendation P 17—Current Rating Guide for Distribution Cables).

A standard rating for the particular cable and specified installation conditions having been determined, factors have then to be applied to obtain the actual rating for the individual conditions. The references quoted provide these factors for variations such as ambient or ground temperature, depth of laying, thermal resistivity of soil and mutual heating due to cables being installed close together.

### 31.6.2 Factors in cable ratings

#### 31.6.2.1 Temperature

As previously mentioned, ratings are governed primarily by the permissible temperature rise from a declared base temperature to a maximum for the particular cable design. The base temperature is normally 15°C for buried cables and either 25 or 30°C for cables in air. At the maximum continuous temperature the heat generated in the cable equates with the heat dissipation from it, which is dependent on the thermal resistance of the cable components and the surroundings.

The internationally recognised limits for conductor temperatures with the common types of insulation and cable design are shown in *Tables 31.9* and *31.10*.

In the case of the insulation materials, it is not usually chemical degradation which is the main aspect. With paper insulation the permissible temperature is reduced with increasing voltage and this ensures that there is not undue expulsion of impregnating compound for the duty required.

**Table 31.9** Paper cables: conductor temperature limits

Rated voltage, $U_0/U$ (kV)	Design	Temperature* (°C)
0.6/1, 1.8/3 and 3.6/6	Belted	80
6/10	Belted	65
6/10	Screened	70
8.7/15	Screened	70
12/20 and 18/30 MIND	Screened	65

\* For continuous operation. Temperature for short-circuit conditions is 160°C, except for 0.6/1 kV cable, for which the limit is 250°C, subject to the accessories being suitable.

**Table 31.10** Polymeric cables: conductor temperature limits

Insulating compound	Temperature* (°C)	
	Continuous	Short-circuit
Polyvinyl chloride	70	160†
Polyethylene	70	130
Butyl rubber	85	220
Ethylene propylene rubber	90	250
Cross-linked polyethylene	90	250

\* Temperature limits are based on intrinsic properties and do not take account of variations in cable and accessory design. Short-circuit ratings are affected by (a) reduction of thickness of PVC and PE by thermomechanical forces; (b) conductor and core screens; (c) design of accessories (e.g. soldered conductor joints are unsuitable).

† 140°C for conductors above 300 mm<sup>2</sup>.

Similarly, screened paper cables are more independent of compound effects in the filler spaces and can be operated to a higher temperature. Thermoplastic insulation softens significantly with increasing temperature and the limit is governed by deformation. Thermosetting materials can withstand much higher temperatures without undue deformation. Limitation by ageing effects is a factor with natural rubber compounds.

### 31.6.2.2 Conductor losses

With the exception of some higher voltage transmission cables, the  $I^2R$  conductor losses represent the major source of heat produced. These also have to be dissipated through the longest radial path in the cable. When the conductors are large, the effective resistance may also be increased because of skin effect. The increase is negligible for sizes up to about 185 mm<sup>2</sup> and can be reduced by the use of the Milliken construction described earlier.

Proximity effects may be caused by the interaction of magnetic fields associated with adjacent current-carrying conductors and these, too, can cause further redistribution, as with skin effect. The proximity effect occurs with small spacing and so is most significant for low-voltage cables of large conductor size.

### 31.6.2.3 Dielectric losses

Dielectric losses are reasonably negligible for paper and XLPE cables up to about 60 kV and for PVC cables up to 6 kV. They are mainly of importance for high-voltage transmission cables. One reason that PVC has not found much application in the 10–20 kV field is that the losses are high in comparison with paper and XLPE. Even so, they represent only around 6–8% of the conductor losses in 11 kV cables. With XLPE the figure is around 0.1%.

### 31.6.2.4 Sheath and armour losses

Losses in metallic sheaths are of great importance for large conductor single-core cables bonded and earthed at both ends. As explained in Section 31.5.5, they can be avoided by cross-bonding. Although they make some contribution to total losses, the effect is not very significant for multicore cables. Similar remarks apply to armour, but losses due to magnetic effects are dominant for single-core cables and it is usually necessary to use non-magnetic armour material.

### 31.6.2.5 Internal thermal resistance

Thermal resistance within the cable is related to: (a) cable design and construction, e.g. the number of separate layers and the volume; and (b) the thermal resistivities and thicknesses of the individual materials. Values (in Km/W) included in IEC 287 are:

Impregnated paper, solid cables	6.0
Oil filled cables	5.0
Polyethylene, XLPE	3.5
Polyvinyl chloride	5.0/6.0
Ethylene propylene rubber	3.5/5.0
Bituminous textiles	6.0

### 31.6.2.6 External thermal resistance

For cables in free air the heat dissipation is related to the degree of exposure and to the surface emissivity, which

depends on surface condition. Published ratings assume shading from the sun, and if this is not provided, derating may be necessary.

## 31.6.3 Sustained ratings

Table 31.11 indicates a typical example of published ratings for one type of cable installed in air, in ducts and buried directly in the ground. When cables are installed in ducts two other thermal resistances are introduced—namely, an air space between the cable and the duct, and the duct itself. As can be seen from Table 31.11, these cause a heavy rating penalty. Table 31.11 also illustrates that while ratings for cables in air and buried direct in the ground are broadly similar, in air they are lower for small conductor sizes and higher for larger sizes. These differences are related to heat dissipation as a function of surface area.

Cables installed under water have the lowest external thermal resistance and highest ratings. However, there is always a danger that in time a layer of silt may build up, and investigations in canals have shown that such layers can have high thermal resistivity.

## 31.6.4 Short-time and cyclic ratings

A cable on load will show an exponential temperature rise/time relationship and, if starting from a low temperature, may take many hours to reach stable condition at maximum temperature. It can, therefore, carry more than maximum continuous rating for a limited time, the factor for overload depending on the extent of initial loading.

For cyclic loadings some increase of rating, compared with continuous, may be applied to an extent which will vary with the shape of the load curves. Calculations to take advantage of this possibility are rather tedious, but guidance may be obtained from ERA 69–30: Part IV (published by ERA Technology Ltd).

## 31.6.5 Short-circuit ratings

Often the conductor size necessary is related to short-circuit current rather than continuous current requirements. The

**Table 31.11** Sustained current ratings and volt drop for triple-core copper, 0.6/1 kV, XLPE insulated, armoured cables

Conductor area (mm <sup>2</sup> )	Rating, dg (A)	Rating, sd (A)	Rating, air (A)	Volt drop (mV/A/m)
16	119	96	107	2.5
25	152	124	134	1.7
35	182	149	165	1.2
50	217	177	201	0.87
70	266	218	256	0.60
95	319	263	316	0.45
120	363	300	369	0.37
150	406	338	423	0.30
180	458	382	489	0.26
240	529	442	582	0.21
300	592	496	672	0.19

Depth of laying, 0.5 m.

Soil thermal resistivity, 1.2 Km/W.

Ground temperature, 15°C.

Ambient air temperature, 25°C.

Maximum conductor temperature, 90°C.

Rating: dg, direct in ground; sd, in single-way ducts; air, in free air.

short-circuit current, which may be 20 or more times normal, produces thermal and electromagnetic effects proportional to the square of the current. So far as the cable insulation itself is concerned, much higher conductor temperatures can be allowed because the heating and cooling are very rapid and the full temperature will not be sustained for significant time by the insulation. Figures are included in *Tables 31.9* and *31.10*.

Short-circuit ratings are not published for individual cables in any official documents, because of the large number of the cable types and sizes involved and the fact that they have to be related to the duration of short circuit which applies to the particular circuit. *Figure 31.22* illustrates a typical example of the graphs available from manufacturers to provide information on a basis of a maximum conductor temperature with a range of durations.

Other factors may dictate a lower rating for a particular design of cable or installation condition. A short circuit in a cable produces electromagnetic forces which could burst the cable if the cores are not adequately bound together (single-core cables are a special case of this). The accessories must also be designed to withstand both electromagnetic and thermomechanical forces; and accessories must be compatible with the cable in this respect. Soldered joints impose limitation of the short-circuit temperatures to 160°C.

The method of installation may also limit permissible short-circuit current. Local pressure due to clamping may lead to high forces, with deformation of cable components. Longitudinal expansion can also be considerable and has to be absorbed uniformly. When cables are buried, the cable is restrained and these forces must be accommodated by joints and terminations.

### 31.6.6 Voltage drop

Voltage drop may be of great significance for 0.6/1 kV cables but is not usually important at higher voltages. A typical

requirement in the IEE Regulations is that the voltage drop in a cable run should be such that the total drop in the circuit, of which the cable forms a part, does not exceed 4% of the nominal voltage.

As the actual power factor of the load is seldom known, a practical approach is to assume the worst condition, i.e. where the phase angle of the load is equal to that of the cable. Cable manufacturers issue tabulated figures for volt drop, as in *Table 31.11*, based on this assumption. If the actual current differs greatly from the tabulated current the figure may be approximate only. From a table such as this, a suitable cable size may be selected but it must also be able to carry the current.

### 31.6.7 Protection against overload current

For some types of cable, particularly wiring cables, the required current rating of the cable must be determined by the overload protective device rather than the circuit current. The rating of the device must not be less than the circuit current and, of course, such ratings are in discrete steps. In the 16th edition of the IEE Wiring Regulations the protective device must satisfy the requirements of:

$$I_B \leq I_n \leq I_z$$

$$I_2 \leq 1.45 I_z$$

where (a) the nominal or current setting  $I_n$  shall not be less than the design current  $I_B$  of the circuit; (b)  $I_n$  does not exceed the lowest of the current-carrying capacities  $I_z$  of any of the conductors in the circuit; (c) the current causing effective operation of the protective device  $I_2$  does not exceed 1.45 times the lowest of the current-carrying capacities  $I_z$  of any of the conductors of the circuit.

## 31.7 Jointing and accessories

### 31.7.1 Aluminium conductor jointing

The technique involving a flux for soldering with aluminium is essentially the same as for copper, but more care is required and strict observance of temperature limits is important. A special flux is necessary to remove the oxide skin and its composition should be without dermatitic risk. Solid conductors have an advantage in that a tinned layer can more readily be produced by the abrasion tinning procedure.

Problems with aluminium conductors, however, have largely been overcome by development of improved and simple compression methods suitable for both solid and stranded conductors. Probably the only remaining difficulty is that, when making straight joints on multicore cables, the larger separation necessary between cores for inserting the tool head makes the joints more bulky. Test requirements are given in BS 4579: Part 3.

Reference has been made to the problems with aluminium conductors in the tunnel type terminations of house-wiring fittings and these emphasise the care necessary in designing any mechanical fittings for aluminium. Suitable approved fittings are available for specific requirements such as the concentric neutral conductor in Waveform distribution cable, and for aluminium conductors in house-service cut-outs. Alternatively, for terminations, fittings are available for connecting a short piece of copper to an aluminium conductor.

**Figure 31.22** Short-circuit ratings for copper conductor XLPE insulated cables (temperature rise 90 to 250°C)

(a)

(b)

**Figure 31.23** Cast resin type joints before resin filling: (a) service joint on Waveconal cable; (b) straight joint on paper insulated cable

Where maximum strength and minimum volume of joint are essential, welding techniques have been developed, but they have only achieved widespread use for oil filled cables. There are doubts about the creep strength of soldered joints and jointing is made more difficult by the oil flow which must be maintained. The metal inert gas (MIG) welding procedure, which is essentially a casting process, proved to be practical and reliable.

### 31.7.2 Joints for distribution cables

The traditional practices of the past, which required highly skilled jointers for soldering and plumbing and involved materials which were sometimes, heavy, bulky and cumbersome, have now been largely dispensed with. By the use of mechanical joints and cast resin filling into simple shell type plastics moulds, all the components can be packed as a convenient complete kit and only simple tools are needed on site. The resin is poured while cold, and when mechanical fittings are used, no heating of any kind is required. At the time of mixing on site, the resin is fluid and penetrates well to fill all cavities, but it subsequently sets quickly to a hard solid mass. Most joints can be completed in 1–1½ h and can be energised immediately. The basic principles of cast resin jointing apply to all types of cable for all voltages up to and including 10 kV. *Figure 31.23* shows two typical examples. Where ‘live’ jointing is practicable, e.g. for 240/415 V services, it can equally well be carried out with these designs. The main advantages, however, accrue from the lower skill demanded and the short time required for jointer training.

*Figure 31.24* shows a cross-section of a service joint on CNE cable taken through one of the phase connectors. With this type of connector it is not necessary to remove

**Figure 31.24** Section of cast resin service joint on Waveconal cable, showing the insulation piercing phase conductor connector

the insulation from the phase conductor, even if it consists of XLPE, because knife edges on the connector pierce the insulation and establish firm contact with the conductor.

### 31.7.3 Joints for transmission cables

Special fittings are required to joint and terminate transmission cables, the detailed design of which depends on the type of cable system employed. The following description of those used for low-pressure oil filled cables gives an indication of the important categories.

**Straight joints** The main requirements for joints connecting adjacent lengths of cables are: (a) to provide electrical continuity for the cable conductors; (b) to maintain the electrical insulation; (c) to provide an oil-tight connection between the sheaths; (d) in the case of cross-bonded single-core installations, to provide an insulating barrier between adjacent cable sheaths with facilities for cross connection; and (e) to maintain the insulation of the sheaths in the case of cross-bonded cable installations.

The electrical connection between conductors is usually provided by a compression ferrule for copper conductors and MIG welding for aluminium. As the factory-applied insulation has had to be removed to permit access to the conductors, it has to be replaced by hand-applied impregnated paper tapes and rolls. These are not electrically as strong as the factory-applied insulation and must be built up to a greater diameter. The different diameters for the cable and hand-applied insulation introduce longitudinal electric stresses in the joint. The stresses (and, hence, the shape of the boundaries) must be carefully controlled, as the electric strength of paper insulation along the laminations is only about 1/15 of that normal to the surface of the paper. *Figure 31.25* illustrates a typical straight joint for 33 kV triple-core cable.

**Trifurcating joint** This type of joint resembles a straight joint but is used to connect a three-core cable to three single-core cables, usually for terminating purposes.

**Stop joint** A stop joint provides all the functions of a straight joint but, in addition, separates the two adjacent cables hydraulically. It is used to limit the hydraulic pressure in a cable system installed when there are significant changes in elevation. This requirement has a major effect on the design, as it is necessary to introduce a different material in the electrical insulation to be capable of withstanding the hydraulic pressure difference. In modern designs of stop joint, this function is carried out by a moulded barrier of epoxy resin with a mineral filler. A

**Figure 31.25** Straight joint for a 33 kV, three-core, OF cable

stop joint for 132 kV single-core cable is shown in *Figure 31.26*.

**Outdoor termination** The termination is enclosed in a porcelain housing, which retains the oil pressure and provides protection against climatic conditions. The porcelain has a long creepage path to allow for contamination by dirt, rain, fog and snow. As for straight joints, care must be taken to control the longitudinal stresses in the paper insulation. In very-high-voltage cable systems this is usually provided by means of a 'capacitor cone' similar to that used in high-voltage bushing.

**Oil immersed termination** This is similar to an outdoor termination but is used to make connection to oil immersed equipment. As there is no surface contamination from the atmosphere the length of the termination is appreciably shorter than the equivalent outdoor form.

**SF<sub>6</sub> immersed termination** Increasing use is now being made of SF<sub>6</sub> gas instead of oil for insulation. *Figure 31.27* shows a cable termination into SF<sub>6</sub> insulated metal-clad equipment. The cable is of the single-core 132 kV oil filled type with a copper conductor. The insulator is of the plug-in connector type, which employs a solid cast-in electrode, unpierced by the need for seals. The electrical stress control is of the capacitor cone type and is composed of cylinders of aluminium foil embedded in oil impregnated paper rolls.

## 31.8 Cable fault location

Irrespective of the type of cable, fault location demands a systematic approach if time and cost are to be minimised. Current practice is to adopt the four-step approach of diagnosis, preconditioning, prelocation and pinpointing.

### 31.8.1 Diagnosis

Diagnosis is used to confirm the existence of a fault and to determine its character. The dividing line between low- and high-resistance faults is based on the assumption that prelocation will be by a modern technique such as the

**Figure 31.26** Single-core, 132 kV, OF cable stop joint

Figure 31.27 SF<sub>6</sub> plug-in sealing end for 132 kV OF cable

pulse-echo method, rather than by any of the classical bridge methods. It is essential that the fault resistance be measured using an ohmmeter and not an insulation tester such as a 'megger'. Cable continuity may be checked using a pulse-echo set, rather than an ohmmeter, with the advantage that breaks in the cable sheath as well as in the cable cores will be detected.

### 31.8.2 Preconditioning

Preconditioning (often referred to as 'fault burning') is used to change high-resistance faults to low-resistance ones which can then be prelocated using the pulse-echo method. Fault burners are usually designed to give various combinations of voltage and current output at ratings of up to 5 kVA. While reasonably successful on paper insulated cables (except on flashing and intermittent faults), fault burning has not proved to be effective on cables employing polymeric insulation, particularly XLPE. Prelocation techniques, such as the impulse current method, described below, have eliminated the need to precondition faults.

### 31.8.3 Prelocation methods

Prelocation is the application of a test at the terminals of a cable to give an indication of the distance of the fault from

the test point. While the measurement should be as accurate as conditions allow, the primary purpose of the terminal tests is to give an indication, as quickly as possible, of the vicinity in which to commence the final pinpointing tests.

For many years cable fault prelocation methods were based on d.c. or low-frequency measurements of conductor resistance or capacitance. Most of these tests were performed using some form of bridge circuit which, when balanced, would indicate the ratio of the resistance, or capacitance, of the faulty conductor to that of a healthy one in the same cable. Versions of these 'classical' methods are still in use today but they have been largely replaced by 'modern' methods which are based on travelling-wave phenomena—the first to appear being the pulse-echo or radar method.

#### 31.8.3.1 Pulse-echo method

Pulse-echo fault locators generate a short-duration pulse which is injected into the cable and which travels to the fault point at  $D$  (metres) and back in a time  $t$  (microseconds):

$$t = \frac{2D}{v} (\mu\text{s}) \Leftarrow$$

where  $v$  (m/ $\mu\text{s}$ ) is the speed at which the pulse travels along the cable and is determined almost totally by the permittivity of the cable dielectric  $\epsilon$ , according to the formula:

$$v = \frac{300}{\sqrt{\epsilon_r}} (\text{m}/\mu\text{s}) \Leftarrow$$

where 300 m/ $\mu\text{s}$  is the velocity of light in vacuo.

The advantages of the pulse-echo method, compared with bridge methods, are that it requires access to only one end of the cable and it is not necessary to perform any 'equivalent length conversions', provided the cable insulation is the same throughout the whole cable route. It is thus far less dependent on accurate cable records than are the bridge methods.

In the earliest instruments, the injected pulse and its reflection(s) were displayed on a cathode-ray tube but modern versions now use dot-matrix liquid crystal display (LCD) panels. Simplified instruments, for cable-length checking as opposed to cable fault location, may not provide a graphical display of the 'echogram', but only give an (automatic) readout of the time/distance to the reflection from the end of the cable.

Pulse-echo fault locators do, however, have one serious limitation in that the amplitude of the reflection produced by a fault depends on the ratio of the fault resistance  $R_f$  to the surge impedance of the cable  $Z_0$ , as shown in Figure 31.28. Series faults, i.e. faults affecting the continuity of one or more conductors of a cable, generally present no difficulty as they are generally complete open circuits producing 100% reflections (of the same polarity as the injected pulse). Shunt faults, i.e. faults affecting the cable insulation, produce (reversed polarity) reflections with amplitudes of less than 5% if the fault resistance is greater than 10 times the surge impedance of the cable. A reflection amplitude of 5% is about the smallest which can be easily identified from amongst the other 'background' reflections which arise on a jointed cable route. Comparison of the trace obtained from the faulty phase with that from a healthy phase in the same cable can simplify the interpretation and

**Figure 31.28** Relative amplitude of reflective pulse as a function of the ratio of fault resistance ( $R_f$ ) to surge impedance ( $Z_0$ ) for both series and shunt faults

extend the sensitivity to possibly 1%. With typical power cable surge impedances lying in the range 15–50  $\Omega$ , it is frequently impossible to locate shunt faults without the use of ‘fault burning’ or ‘fault re-energisation’.

### 31.8.4 Cable fault characteristics

Representing cable faults simply as resistors is misleading, and a more realistic equivalent circuit, where the fault resistance is paralleled by both a spark gap and a capacitor, is shown in Figure 31.29. The values of all the elements of the equivalent circuit can vary widely and are completely independent of each other. The breakdown voltage  $V_b$  of the spark gap is determined by the distance between the two metallic boundaries of the fault which may be bridged by carbonised insulation in the case of a shunt fault or air spaced for an open circuit series fault. The value of the resistance is directly related to the degree of carbonisation of the insulation, whilst the value of the capacitance varies with the amount of moisture present. Based on the equivalent circuit shown in Figure 31.29, and the ‘5% reflection’ limit for the pulse-echo method, cable faults can be conveniently classified as shown in Table 31.12.

The existence of the fault ‘spark gap’ has been well known for many years, and it has been extensively exploited

**Figure 31.29** Equivalent circuit of a cable fault. SG, spark gap

**Table 31.12** Classification of cable fault types

Fault type	$R_f$	Spark gap
Series	$\rightarrow \infty \leftarrow$	Breakdown under impulse or d.c.
Low resistance	$< 10 \times Z_0$	Breakdown under impulse, provided $R_f$ is not too low
High resistance	$> 10 \times Z_0$	Breakdown under impulse
Flashing	$\infty \leftarrow$	Breakdown under impulse or d.c.
Intermittent	$\infty \leftarrow$	Breakdown under prolonged d.c.

in the acoustic method of pinpointing—based on applying a high-voltage impulse to the cable to create an audible flashover at the fault point.

#### 31.8.4.1 Impulse-current method

The impulse-current method of fault location also exploits the existence of the spark gap, but in this case it is the electrical transient created by the breakdown, rather than the acoustic transient, which is of interest. This method overcomes the limitation of the pulse-echo method since it is applicable to every type of fault. Faults are located by detecting and recording the current signals flowing in the impulse generator circuit using a high speed digital transient recorder.

Low resistance shunt faults and open circuit series faults are located by identifying the direct reflections of the applied impulse in much the same way as with a standard pulse-echo instrument—albeit with reversed reflection polarities. Most faults, however, are located from the transients created by the flashover of the spark gap at the fault point which always occurs some time after the arrival of the voltage impulse due to a phenomenon known as ‘ionisation delay’.

Figure 31.30(a) shows how a typical current transient is created under the application of an impulse voltage from a capacitor discharge generator where the impulse reflects from the open circuit end producing ‘voltage doubling’ which (eventually) results in breakdown of the fault spark gap. An actual recorded transient, produced under the conditions illustrated in Figure 31.30(a), is shown in Figure 31.31. The transient can sometimes be simplified by increasing the applied voltage sufficiently to reduce the ionisation delay so that the fault breaks down before the reflection from the open-circuit end arrives back at the fault point—this is shown in Figure 31.30(b). On flashing or intermittent faults, an even simpler transient can be produced by closing the impulse generator contactor and raising the voltage on the cable and the generator capacitor at the same time until flashover occurs, thereby producing the transient shown in Figure 31.30(c).

The impulse-current method has now been adopted by every cable fault location equipment manufacturer in Europe, and is in widespread use throughout the world. As a method, it can accommodate a far wider range of fault and cable types than the pulse-echo method and requires only a simple and inexpensive ‘linear coupler’ to connect the recording instrument to the impulse generator. In one respect, however, it is inferior to the pulse-echo method, since the transient phenomena are far more complex and

**Figure 31.30** Current transients created by the application of an impulse voltage from a charged capacitor: (a) voltage doubling induced breakdown; (b) fault breakdown before reflected pulse; (c) simpler transient produced by closing the generator contactor

**Figure 31.31** Recorded transient corresponding to the condition shown in Figure 31.30(a)

**Figure 31.32** Cable fault analyser

require more experience to interpret. One solution to this problem has been the introduction of computer-aided equipment such as the cable fault analyser shown in Figure 31.32.

#### 31.8.4.2 Secondary-impulse method

An alternative solution to the problem of the complexity of impulse current waveforms has been the development of the secondary-impulse method. Here the high voltage impulse generator is used to create a flashover of the fault spark gap and then, whilst current is still flowing through the ionised fault, a (second) low-voltage signal from a digital pulse echo instrument (Figure 31.33) is applied to the cable via a special high-voltage isolation and filter unit.

The secondary-impulse method cannot cope with as wide a range of cable and fault types as the impulse-current method, but interpretation of the waveforms is much simpler—a very important aspect when locating faults on the multi-branched networks frequently used in low-voltage distribution systems. A further complication of fault location on low voltage cables is that consumers' loads must often be assumed to be still connected to the cable, thereby precluding the application of any abnormal voltage

**Figure 31.33** Digital pulse echo instrument

Figure 31.34 Test lead connected to the cable termination

to 'condition' faults—many of which may only be 'active,' and therefore detectable, when the cable is energised.

Connecting a pulse-echo set to an energised low-voltage power cable requires careful attention to safety, e.g. the provision of suitably fused test leads, and to methods of reducing the complexity of the waveforms—particularly the unavoidable mismatch which exists where the test lead is connected to the cable termination (Figure 31.34). A second test lead is connected to a 'balancing network' which is adjusted to present a complex impedance as close as possible to that created by the stray inductance of the main test lead connections onto the cable tails in combination with the surge impedance of the cable under test. The signals produced on the test lead connected to the cable are subtracted from those produced on the test lead connected to the balancing network by a hybrid transformer. With an effective method of removing the outgoing pulse, and its associated 'ringing' within the test lead connections, it is possible to increase the width of transmitted pulse without any loss of short-range discrimination. Wide pulses propagate further than narrow pulses as they not only contain more energy but also the spectral distribution of the energy is shifted towards lower frequencies where the cable attenuation is also less.

When using the secondary-impulse method to locate unstable faults on low-voltage power cables, it is necessary that the pulse echo set injects its signal into the faulty cable after the fault arc has been established. During the arc the effective resistance of the fault will be almost zero, producing a reflection amplitude approaching 100%. Before the arc is struck, or after it has extinguished, there is no reflection from the fault, but the reflections from all the other points of mismatch along the cable remain the same. One method of detecting when the fault arc exists is to use a clip-on current transformer, as shown in Figure 31.34. For convenience, and safety, the cable should be re-energised via a switching device which must include a series 'wavetrapp' to prevent the injected pulse from reaching the substation busbar, and thereby all the other cables connected to it. When the re-energising device closes, there is usually a delay before the fault responds and the cable termination triggers the pulse-echo set. As can be seen from Figure 31.35, the

Figure 31.35 Typical secondary impulse method result

operator's task is simply to compare the waveform recorded during the time when fault current is flowing with a waveform obtained when fault current is not flowing.

### 31.8.5 Pinpointing

Pinpointing is essential on direct buried cables if the location and repair of a fault is to be accomplished with a

Figure 31.36 The AF induction method

**Figure 31.37** Pool of potential method for serving fault location

single excavation. The majority of faults on high-voltage power cables are pinpointed by detecting the acoustic signal generated when the fault spark gap breaks down either from the application of a voltage impulse from a surge generator or a high direct voltage from a pressure test set. In some cases the acoustic signal can be detected without any special equipment but, in general, it is an advantage to use a 'ground microphone' and amplifier to pick up the mechanical shock wave. The importance of the pinpointing stage cannot be overemphasised, and anything which might jeopardise the generation of the acoustic signal, such as prolonged preconditioning, should be avoided.

Once a fault develops into a very low-resistance 'welded' condition, it will 'short out' the spark-gap, making it impossible to generate an acoustic signal. Multiple excavations may then be unavoidable unless the fault is between two conductors or both conductors are welded to the cable sheath. If a low-resistance path exists between one conductor and another, it is possible to pinpoint the fault using the 'AF induction' or 'Bimec' method (Figure 31.36). Between the signal generator and the fault the signal induced in the search coil exhibits a characteristic rise and fall owing to the lay of the cable cores, while beyond the fault the signal either disappears completely or, more likely, becomes constant. The lay effect is the only positive means of identifying that the received signal is emanating from the faulty cable and is not caused by re-radiation from other adjacent buried metallic services. The induction method of pinpointing can be applied, subject to the necessary fault conditions, without any prior knowledge of the cable route and without prelocating the fault. As the appropriate fault conditions for the 'induction' method occur relatively infrequently, the main use of the technique is in cable route tracing when an artificial core-to-core fault is applied at the far end of the cable.

Both the acoustic and the induction pinpointing techniques require a complete metallic path in which the signal currents can flow. An alternative approach, used in pinpointing serving faults on insulated sheath transmission cables, is to apply a signal between the metallic sheath and the general mass of ground so that a voltage gradient is established in the earth in the vicinity of the fault. The voltage gradient or pool of potential is detected using a sensitive voltmeter connected to a pair of probes and the fault position is pinpointed accurately (Figure 31.37). Probing over the complete length of a long transmission cable is time consuming, and many serving faults are sectional-

ised, using a magnetometer to trace the current flowing in the sheath up to the fault point.

When cables are accessible, being installed above ground or still on the drum prior to installation, it is often possible to pinpoint faults by exploiting their 'microphonic' characteristics. A high-gain amplifier, a.c. coupled to a faulty cable, will pick up the small 'noise' voltages generated when the fault is subjected to mechanical vibration. Partially broken conductors can be detected and pinpointed by circulating constant d.c. through the cable; insulation faults can be detected using a high-voltage source to pass a small polarising current through the fault resistance.

## Acknowledgements

The author is grateful to his past colleagues at BICC for their assistance in the preparation of this chapter, and in particular to Tony Arkell for his help in updating the section on transmission cables.

## 32.1 Introduction

The first commercial generators were direct current (d.c.) and therefore so were the early distribution systems. As distribution was at relatively low voltages, transmission distances were by necessity very short. The potential benefits of electrical energy were fully recognised and work to improve existing transmission systems was undertaken both in Europe and in the USA.

In 1883, Nikola Tesla was granted patents for the inventions on which he had worked during the previous 10 years relating to polyphase alternating current (a.c.) systems. In May of that year he delivered his classic lecture to the American Institute of Electrical Engineers: 'A New System of Alternating Current Motors and Transformers'. Although, today we cannot visualise life without a.c. electrical systems, they were not immediately or universally accepted. Edison, who was working on a comprehensive d.c. distribution system, wrote in 1889 in the *Scientific American*: 'My personal desire would be to prohibit entirely the use of alternating currents. They are as unnecessary as they are dangerous. I can therefore see no justification for the introduction of a system which has no element of permanency and every element of danger to life and property'.

Elimination of commutators made generators simpler and transformers allowed voltage to be changed easily; the use of higher voltages became practical and transmission over longer distances feasible. Widespread use of a.c. generation and transmission followed the exploitation of the Niagara Falls energy in 1895. Yet engineers continued to seek means of transmitting d.c. at high voltages, because they realised that the cost of overhead lines and cables for high voltage direct current (h.v.d.c.) could be considerably lower than for a.c. at the same power. An a.c. line has three conductors each insulated for the crest value of the

alternating phase voltage, but the power transmitted is related to the r.m.s. value; the design of a.c. lines has also to take into account the flow of reactive current. HVDC transmission lines require only two conductors and the normal working voltage equals the rated voltage of the line. However, it was necessary to develop an adequate a.c./d.c./a.c. converter in order to benefit from lower cost of d.c. lines and cables in an a.c. system environment.

The first commercial h.v.d.c. scheme connecting two a.c. systems was a submarine cable link between the Swedish mainland and the island of Gotland. The scheme, rated for 20 MW at 100 kV was commissioned in 1953. Mercury arc valves each rated at 50 kV, 200 A were used as the converting device. Eleven mercury arc valve schemes totalling 6400 MW have since been commissioned. The last scheme to use mercury arc valves was Nelson River Bipole 1 in Canada, rated for 1620/1800 MW at  $\pm 450$  kV. It uses the world's largest mercury arc valves, made in the UK, each rated at 155 kV, 1800/2000 A (Figure 32.1).

In the late 1960s experiments using thyristor valves in mercury arc schemes were carried out in Sweden and in England. In 1970 the Gotland scheme was upgraded to 30 MW at 150 kV by the addition of a 50 kV, 200 A thyristor valve bridge. In 1972 the first thyristor scheme, 320 MW back-to-back, was commissioned at Eel River in New Brunswick, Canada. At present there are some 70 schemes totalling over 60 000 MW of installed capacity in service or under construction. The recent increase in the utilisation of h.v.d.c. can be explained partly by its technical attributes and partly by the advantages gained from the interconnection of power systems which it facilitates.

The largest long distance overhead line transmission h.v.d.c. system is the 6300 MW Itaipu scheme in Brazil consisting of two bipoles each rated at  $\pm 600$  kV. The largest h.v.d.c. submarine cable scheme is the 2000 MW link

**Figure 32.1** Dorsey Converter Station of the Nelson River h.v.d.c. scheme. The photograph shows valve halls and outdoor equipment of Bipole I rated for 1800 A at  $\pm 465$  kV and Bipole II rated for 1800 A at  $\pm 500$  kV. In an emergency the two bipoles can be paralleled on one bipolar line transmitting 3600 A at  $\pm 465$  kV. (Courtesy of Manitoba Hydro)

between France and England, consisting of two bipoles, each rated for 1000 MW at  $\pm 270$  kV. The largest zero distance or 'back-to-back' schemes are rated for 1000 MW, Chateauguay in Canada and Chandrapur in India.

## 32.2 Applications of HVDC

### 32.2.1 Introduction

The answer to the question 'Why h.v.d.c.?' was, historically, that h.v.d.c. lines and cables are cheaper than those for a.c. for the same power transmission capability and, provided the transmission distance is more than a critical value (the 'break-even distance'), the savings from using h.v.d.c. lines or cables would more than pay for the a.c. to d.c. converters. The length of submarine cable made a.c. impracticable for some schemes due to the large charging current.

Today, only a few h.v.d.c. links are justified by such simple economics. They are not relevant to back-to-back schemes in which the distance between adjacent a.c. systems is zero, and in most other transmission schemes other attributes of h.v.d.c., its asynchronous nature or its ability to control power, play an equally important part in the choice of transmission.

### 32.2.2 Types of d.c. interconnection

An h.v.d.c. link is itself asynchronous but it may connect two asynchronous or synchronous a.c. systems and can be further sub-classified by distance according to whether or not there is a h.v.d.c. line or cable between the two converter terminals, as follows.

*Asynchronous:* where h.v.d.c. is the only interconnection between two systems with different frequencies, e.g. 50 and 60 Hz, or two systems at nominally the same frequency but with uncontrolled phase relationships.

*Synchronous:* where h.v.d.c. link is used within an a.c. system or in parallel with an a.c. interconnection.

*Long distance point-to-point interconnections by:* (a) overhead line, (b) undersea cable, (c) underground cable, or (d) combination of overhead lines and cables.

*Zero distance back-to-back interconnections.*

### 32.2.3 Purposes of transmission interconnections

A.c. or d.c. interconnections can be classified as follows.

- (1) Power transfer exclusively or largely in one direction, normally characteristic of point-to-point applications:
  - (a) from remote hydro, thermal or nuclear generation to load areas; or
  - (b) from a strong to a weak a.c. system.
- (2) Power transfer in either direction, normally characteristic of interconnections between neighbouring a.c. systems, typically of similar strength. Such system interconnections, where a.c. or d.c., offer one or more of the following benefits:
  - (a) include the link's capacity in the spinning reserve for each system, minimising the generating capacity allocated in each system for such duties,
  - (b) increase the security of supply by offering mutual support,
  - (c) take advantage of seasonal generation and load pattern differences between the two systems,

- (d) take advantage of timing differences between daily load peaks of the two systems, and
- (e) take advantage of different types of generating plant with different base to peak cost ratios in the two systems.

### 32.2.4 Reasons for choosing HVDC

Of the many reasons which may contribute to the choice of the h.v.d.c. as a means of interconnecting two power systems (or elements of power systems), two stand out as being the most important, namely:

- (1) Frequency or phase angle variation between the two terminals of the interconnection may render an a.c. link impractical. In an extreme case, the a.c. bus-bars at the terminals of the link may operate at different frequencies. Even if they are synchronised, it does not follow that reliable a.c. transmission can be established, because variations in relative phase angle between the two bus-bars, caused either by variation in load or by network disturbances, may result in unacceptable power flow severe enough to cause frequent tripping. Thus, it may prove economic to use h.v.d.c. for a zero length (back-to-back) transmission, or in parallel with an existing a.c. transmission path.
- (2) The transmission distance may be so long that the cost savings arising from the use of relatively cheaper h.v.d.c. conductor systems is more than sufficient to outweigh the costs of the extra terminal equipment required for h.v.d.c.

Combinations of these two factors constitute more powerful economic pressures than either by itself.

Benefits which h.v.d.c. may provide beyond those provided by an a.c. interconnection can be summarised as follows:

- (i) Provide the facility to interconnect two systems which have different operational procedures for frequency or voltage control.
- (ii) Provide predetermined and controlled power transfer. Power flow in an a.c. interconnection is controlled by phase relationships which, being relatively uncontrolled, can cause inadvertent overloading or under-utilisation during normal or disturbed operation. In the case of h.v.d.c., two utilities can pre-set the limits of power by which at any time they can assist each other and power will change automatically up to those limits in response to predetermined conditions, such as a frequency change.
- (iii) Improve transient stability of the interconnected systems by modulating synchronising or damping power to reduce intermachine swings.
- (iv) Avoid excitation of subsynchronous resonance as might occur in the case of series capacitor applications in an equivalent a.c. interconnection.
- (v) Distribute the available power more effectively and thus delay the introduction of new power stations and major transmission reinforcements.
- (vi) Permit staged development of a country's overall power system in a more controlled and hence less expensive manner by providing the means to utilise generation in geographically separate systems, compared to what could be done by a purely a.c. transmission development.
- (vii) HVDC does not contribute to the a.c. system fault current. The contribution to the system fault current

by an a.c. interconnection may necessitate the replacement of the existing switchgear.

Therefore, in addition to the use of h.v.d.c. to connect two systems which cannot be synchronised, it should also be considered as one of the possible alternatives whenever enhancements are needed to make an a.c. interconnection attractive: the use of series compensation, variable shunt reactive compensation, phase shift boosters, etc.

### 32.2.5 Application of HVDC to developing systems

In developing countries or regions experiencing load growth the integration of h.v.d.c. should be considered at every stage of system development, not merely as an appendage to an otherwise fully designed system.

Two kinds of interconnection are often required: long distance links for bulk power transfer from remote generation, and shorter links (perhaps even of the back-to-back type) to interconnect adjoining relatively large regional systems. For both kinds of interconnection, but particularly in the latter case, to provide a sufficiently secure link using a.c. may require a large installation, typically of multiple e.h.v. lines, which may not be justifiable economically until a much later stage of load growth. The immunity of an h.v.d.c. link from problems arising from variations in the relative phase of the two networks may permit the benefits of interconnection to be realised economically at a much earlier stage of system and load growth than that at which a.c. becomes justifiable. If at some future date the natural system growth justifies an e.h.v. or u.h.v. overlay of a.c. transmission lines, the d.c. interconnection would readily become an integrated part of the combined a.c./d.c. system and, by virtue of its rapid controllability, improve the overall system stability and dynamic performance. Thus the economic and technical advantages of both d.c. and a.c. interconnections can contribute both to the intermediate and to the long-term transmission planning.

## 32.3 Principles of HVDC converters

### 32.3.1 Converter operation: simplified case of zero commutating inductance

The standard 'building-block' for h.v.d.c. converters is the three-phase full-wave bridge using six controlled (thyristor)

Figure 32.2 Basic six-pulse converter bridge

Figure 32.3 Idealised waveform for a six-pulse converter, neglecting commutation inductance

valves, as shown in Figure 32.2. This is known as a 'six-pulse' converter group or bridge, because there are six valve firing pulses, and six pulses per power frequency cycle in the output, at the d.c. terminals. Figure 32.3 shows the 'idealised' current and voltage waveforms, neglecting commutation inductance  $L$  in Figure 32.2 and assuming acceptably smooth direct current output  $I_d$ , achieved by the action of the relatively large d.c. smoothing reactor  $L_d$ . For this case valve current pulses are  $120^\circ$  long, and their flat-tops have a magnitude equal to  $I_d$ . The time at which uncontrolled (diode) valves would commence conduction is used as a reference, and the 'firing delay angle' is defined to be zero at this point on the wave. Figure 32.3 is drawn for the case where the firing time for each valve is delayed by the 'firing delay angle'  $\alpha$  relative to diode operation, i.e.  $\alpha \leq 90^\circ$ .

All conventional treatments of converter theory make the assumption that the e.m.f.  $E_1$  in Figure 32.2 is sinusoidal; an assumption which is substantially true in practice because of the a.c. harmonic filters which are usually connected at the a.c. terminals of converter stations, preventing the non-sinusoidal converter current from appreciably disturbing the shape of the power frequency voltage. The analysis which follows neglects the effects of the current-dependent losses of converters. This is because they are both small and non-linear, making it unreasonably laborious to take them into account unless digital computers are used to carry out the calculations.

Some numerical relationships for this simplified case are

$$U_d = E_1(3\sqrt{2}/\pi) \cos \alpha = 1.35 E_1 \cos \alpha \quad (32.1) \Leftarrow$$

$$I_1 = (\sqrt{2}/\sqrt{3}) I_d = 0.816 I_d \quad (32.2) \Leftarrow$$

$$I = (\sqrt{6}/\pi) I_d = 0.780 I_d \quad (32.3) \Leftarrow$$

where  $U_d$  is the d.c. voltage of the six-pulse bridge,  $E_1$  is the commutation e.m.f. (r.m.s. line-line),  $I_d$  is the d.c. current,  $I_1$  is the r.m.s. a.c. current per phase, and  $I$  is the fundamental component of the a.c. current.

Equation (32.1) describes the principal control action of a converter, i.e. by change of firing angle  $\alpha$  the d.c. voltage can be changed from maximum positive (rectification) at  $\alpha = 0^\circ$ , through zero at  $\alpha = 90^\circ$  to negative (inversion) for  $\alpha$  approaching  $180^\circ$ . The d.c. voltage  $U_d$ , at  $\alpha = 0$  and  $I_d = 0$  is termed ideal no-load voltage,  $U_{dio}$ ; this is a fictitious quantity but it is often used as the basis for further calculations.

$$U_{dio} = 1.35 E_1 \quad (32.4) \Leftarrow$$

In practice the a.c. connection is via a transformer (not shown in Figure 32.2). The transformer rating is defined as  $E_1 I_1 \sqrt{3}$ . Although the choice of this definition is arbitrary from the viewpoint of converter operation, it offers the convenience that it would be equally applicable if the transformer were to be utilised for a.c. transmission. With the combined simplifications of zero commutation (leakage) reactance and assuming diode operation ( $\alpha = 0$ ) from equations (32.1) and (32.2) this exhibits its minimum value of 1.047 times d.c. power.

### 32.3.2 Converter operation: practical case of finite commutating inductance

In a six-pulse bridge circuit (Figure 32.2) the valves 1, 3 and 5 commute the outgoing direct current  $I_d$  between themselves, while the valves 2, 4 and 6 commute the incoming direct current  $I_d$ ; the two three-pulse conversion processes form the six-pulse bridge conversion. For clarity the Figure 32.4 is drawn for one-half of the six-pulse bridge, i.e. the commutations between valves 1, 3 and 5 only are shown.

In practice, the converter transformer will have a finite leakage inductance ( $L$  in Figure 32.2). This causes current

Figure 32.4 Rectifier operation with finite commutating reactance

waveforms to exhibit more gradual transitions as shown in Figure 32.4, i.e. the current requires a finite time to commute from one valve to the next valve in sequence in that particular row of three valves of the 6-pulse bridge. This is known as commutation overlap time, usually expressed as an angle  $u$  in electrical degrees. The value of  $u$  increases with increasing d.c. current, reaching typically  $25^\circ$  at rated current.

The d.c. voltage  $U_d$  is reduced by the value  $dx$  due to the commutation notch  $C_n$  on Figure 32.4. (The derivation of the equations used is well documented in text books given as the general references at the end of the chapter.)

Equation (32.1) becomes

$$U_d = 1.35 E_1 \cos \alpha - dx \quad (32.5) \Leftarrow$$

where

$$dx = \frac{3}{\pi} I_d X_c \quad (32.6) \Leftarrow$$

where  $X_c$  is the commutating reactance. Usually the commutating (i.e. converter transformer) reactance is expressed in per unit of the converter transformer rating. The equation (32.5) becomes

$$U_d = 1.35 E \left( \cos \alpha - 0.5 \frac{I_d}{I_{dl}} x_c \right) \quad (32.7) \Leftarrow$$

or using equation (32.4)

$$U_d = U_{dio} \left( \cos \alpha - 0.5 \frac{I_d}{I_{dl}} x_c \right) \quad (32.8) \Leftarrow$$

where  $I_{dl}$  is rated direct current.

### 32.3.3 Converter operation: converter acting as an inverter

This occurs when the firing angle  $\alpha$  exceeds  $90^\circ$ . If current flow is to continue, this can only occur as a result of an external power source supporting the direct voltage. An inverter connected to an external circuit composed only of passive components does not conduct, being essentially a provider of back-e.m.f., to be overcome by the d.c. line voltage. The waveforms are generally similar to those above, but d.c. voltage  $U_d$  is negative. Thus to reverse power flow in a converter, although d.c. current cannot be reversed, d.c. voltage can be reversed by control action.

Figure 32.5 shows the inversion process for valves 1, 2 and 3 of Figure 32.2. When valve 3 fires, its current rises to  $I_d$ , and valve 1 current falls to zero, in a time  $u$  degrees, similarly as for rectifier operation. However, the current is now flowing due to d.c. line voltage and against the (negative) inverter transformer voltage, which acts as 'back-e.m.f.'. The commutation process must be completed before phase A voltage becomes more positive than phase B voltage, point D on Figure 32.5. If valve 1 is still conducting at that point it will continue to conduct driven by the sum of d.c. line and the phase A voltages. The inverter is operated so that the commutation process is completed well before point D. The quantity  $\gamma$  is the 'extinction angle' and is the time available for the valve to turn off, i.e. become capable of withstanding the subsequent forward voltage. Valve performance is discussed in Section 32.7.

Small working values of  $\gamma$  (i.e. values of  $\alpha$  approaching  $180^\circ$ ) lead to low capital cost of valves and transformers,

Figure 32.5 Inverter operation

low harmonic generation, low reactive power consumption and low station losses. However, too small a value of  $\gamma$  causes commutation failure. This is usually initiated by disturbances arriving from the a.c. system which distort the waveform at the a.c. terminals of the converter station, resulting in temporarily reduced  $\gamma$  for one or more commutations. A reduction of  $\gamma$  to less than  $10^\circ$  ( $12^\circ$ ) at 50 Hz (60 Hz) is usually needed before commutation failure becomes likely, but once it has occurred, it may temporarily collapse inverter operation, requiring 100 ms or so before the control system succeeds in restoring normal operation.

A typical running value of  $\gamma$ , which gives reasonable immunity to commutation failure, is  $15^\circ$  to  $18^\circ$  (for a 50 Hz system). The corresponding value of  $\alpha$  to produce this is typically about  $140^\circ$ . It is important that inverters are provided with constant-extinction angle ( $\gamma$ ) control to prevent commutation failures in normal steady-state operation, as discussed in Section 32.10.

For constant  $\gamma$  operation, equation (32.8) becomes

$$U_d = E_{dio} \left( \cos \gamma - 0.5 \frac{I_d}{I_{dl}} x_c \right) \quad (32.9) \Leftarrow$$

### 32.3.4 Twelve-pulse converters

The harmonics produced by a six-pulse converter are large, requiring expensive filters. They can be reduced by use of a 12-pulse converter as discussed in Section 32.8. The usual arrangement of this for h.v.d.c. uses two six-pulse bridges connected in series on the d.c. side, with their transformers respectively star-star and star-delta, connected in parallel to the a.c. bus-bar. As the cancellation of harmonics takes place at the a.c. side of the converter/transformers, the conversion process takes place independently in each six-pulse bridge.

### 32.3.5 Basic d.c. voltage/d.c. current characteristics

Figure 32.6 shows these for a converter operating on a zero-impedance a.c. system. Natural boundaries to this occur at zero d.c. current (because d.c. current cannot reverse) and at  $\alpha = 0^\circ$  (firing cannot occur for  $\alpha$  negative because this would mean attempting to fire valves when their anode-cathode voltage is negative). Other boundaries are applied by control action:

Figure 32.6 Basic firing angle control characteristics (a.c. voltage constant)

- (1) a minimum limit of  $\alpha = 2^\circ$  is applied in practice to ensure reliable firing of each valve;
- (2) a minimum  $\gamma$  limit (say at  $\gamma_1 = 45^\circ$ ) prevents commutation failure in normal operation as described above; or
- (3) a d.c. current limit is applied at the thermal current limit of valves and other components.

Within these boundaries, any desired shape of d.c. voltage/d.c. current characteristics can be obtained by control action, i.e. by change of  $\alpha$ , as described later.

### 32.3.6 Basic principles of control of HVDC transmission

Figure 32.7 shows a simplified diagram for a two-terminal h.v.d.c. link, with elementary controls.

At the rectifier a closed-loop current control is provided, which adjusts firing angle  $\alpha$  in response to the difference between measured d.c. current  $I_d$ , measured by means of a d.c. current transformer, and a current order signal  $I_o$ , assumed fixed for the present.

At the inverter, closed-loop  $\gamma$  control is provided, operating similarly but from measured  $\gamma$ , with a fixed reference demanding  $\gamma_1$  of typically  $15^\circ$  to  $18^\circ$ . A current control loop is also provided, similar to that at the rectifier, supplied with the same current order, but with a 'current margin' signal  $I_m$  subtracted from it.  $I_m$  is typically 0.1 of rated d.c. current,  $I_{dl}$ .

Figure 32.8 shows the resulting d.c. voltage/d.c. current characteristics. The rectifier current loop generates the constant-current characteristic BCD. This has a natural transition at B to the  $\alpha = 0^\circ$  line AB. The inverter has a constant- $\gamma$  characteristic FCE, with a transition at F to a constant-current characteristic FG at  $I_m$  below BCD.

the converter group circuit breaker is tripped. Zero a.c. side current usually occurs in less than 10 ms, except for some types of flashover within the station, which the circuit breakers will clear in, say, three cycles.

### 32.3.8 Power reversal

As described earlier, in h.v.d.c. schemes, due to the unidirectional property of the thyristors, the current cannot reverse. Power reversal is achieved by reversing d.c. voltage. This is carried out by changing over the operation characteristics of the converters in the two stations. The effect of this is to change the phase angle of the current at the a.c. bus-bars by reversing its power component; its reactive component always remains negative.

As for start and stop, power reversal can be done rapidly if desired, within typically 200 ms. However, reversal is normally carried out by reducing power order slowly to zero or a low value, and then reversing the power flow at low current. The power order is then increased to the new desired value.

### 32.3.9 Isolating a valve group

In some schemes, several valve groups at a converter station are connected in series and it may be desirable to be able to block or deblock, or isolate, one group whilst another remains in service. In such cases it is necessary to provide a bypass path for the current and means to transfer the current between the bypass path and the path through the converters.

The ultimate bypass path is normally a metallic switch in a substantially conventional form, and transfer of current from the converter valves to the bypass switch presents no difficulty as the volt drop in conducting valves will be greater than in the switch. The converter can first either be controlled just into the inverter region, or put into its bypass mode. When the contacts of the switch close, current will transfer and valve firing pulses can be blocked. The valve group may then be isolated if desired.

To transfer current from the bypass switch to the converter valves a special technique is necessary to extinguish the current in the switch. One alternative is to provide a means to increase the voltage drop in the switch to exceed that in the valve bypass path, to force current to transfer.

### 32.3.10 Numerical example

Calculations performed for the purpose of equipment steady state ratings are normally carried out by means of computer programs using equations similar to those described previously but taking into account the losses of the converters. For nominal conditions, simplified equations can provide reasonably accurate results. The following takes as an example a 1500 MW bipolar h.v.d.c. scheme with a rated voltage of  $\pm 500$  kV at the rectifier d.c. line terminals. The nominal d.c. resistance of the overhead line is 10.0 ohm. The d.c. voltage ( $U_{di}$ ) at the inverter d.c. line terminal, for rated d.c. current  $I_d = 1500$  A, is

$$U_{di} = 500 - 0.5 \times 1500 \times 10 = 492.5 \text{ kV/pole}$$

and the bipolar powers at the rectifier and inverter d.c. line terminals are

$$P_{dr} = 2 \times U_{dr} \times I_d = 2 \times 500 \times 1500 = 1500 \text{ MW}$$

$$P_{di} = 2 \times U_{di} \times I_d = 2 \times 492.5 \times 1500 = 1477.5 \text{ MW}$$

Each pole consists of two series connected six-pulse valve groups.

Therefore,  $U_{dr}$  and  $U_{di}$  of each six-pulse bridge is

$$\frac{1}{2} U_{dr} \text{ pole} = 500/2 = 250 \text{ kV d.c.}$$

$$\frac{1}{2} U_{di} \text{ pole} = 492.5/2 = 246.52 \text{ kV d.c.}$$

To limit the fault surge current in the thyristor valves to an acceptable level a transformer reactance of 15% is specified. Rated  $\alpha$  is specified as  $12^\circ$  and rated  $\gamma$  as  $15^\circ$ .

The value winding e.m.f. required at the nominal operating point can be calculated using equation (32.7) for the rectifier and equation (32.9) for the converter.

$$\begin{aligned} E_{lr} &= \frac{U_{dr}/2}{1.35 \times \left[ \cos \alpha - 0.5 \frac{I_d}{I_{dl}} x_{cr} \right]} \\ &= \frac{250}{1.35 \times (\cos 12^\circ - 0.5 \times 0.15)} = 205 \text{ kV r.m.s.} \end{aligned}$$

$$\begin{aligned} E_{li} &= \frac{U_{di}/2}{1.35 \times \left[ \cos \gamma - 0.5 \frac{I_d}{I_{dl}} x_{ci} \right]} \\ &= \frac{246.25}{1.35 \times (\cos 15^\circ - 0.5 \times 0.15)} = 204.7 \text{ kV r.m.s.} \end{aligned}$$

The transformer rating can be calculated as

$$\begin{aligned} \text{Rectifier: } \sqrt{2} \times E_{lr} \times I_{dl} &= 1.41 \times 205 \times 1.5 \\ &= 433.6 \text{ MVA} \end{aligned}$$

$$\begin{aligned} \text{Inverter: } \sqrt{2} \times E_{li} \times I_{dl} &= 1.41 \times 204.7 \times 1.5 \\ &= 432.9 \text{ MVA} \end{aligned}$$

The reactive power absorbed by the six-pulse group can be calculated as

$$\begin{aligned} Q_r &= U_{dr} \times I_{dr} \sqrt{\left[ \left( \frac{1.35 E_{lr}}{U_{dr}} \right)^2 - 1 \right]} \\ &= 250 \times 1.5 \times \sqrt{\left[ \left( \frac{1.35 \times 205}{250} \right)^2 - 1 \right]} \\ &= 178 \text{ MV-Ar for the rectifier} \end{aligned}$$

and

$$\begin{aligned} Q_i &= U_{di} \times I_{di} \sqrt{\left[ \left( \frac{1.35 E_{li}}{U_{di}} \right)^2 - 1 \right]} \\ &= 246.25 \times 1.5 \sqrt{\left[ \left( \frac{1.35 \times 204.7}{246.25} \right)^2 - 1 \right]} \\ &= 188 \text{ MV-Ar for the inverter} \end{aligned}$$

## 32.4 Transmission arrangements

### 32.4.1 Bipolar lines

The bipole is the most commonly used arrangement. It consists of one line at positive potential with respect to

**Figure 32.9** Transmission arrangements: (a) bipolar transmission line; (b) two monopolar transmission lines; (c) cable monopolar transmission with sea return; (d) back-to-back connection

earth and the other of negative potential, the neutral being solidly grounded in the converter station. *Figure 32.9(a)* indicates an overhead line, but the same arrangement is used for bipolar cable schemes.

Control is so arranged that during normal operation the currents in the two poles are balanced so that the current flowing out from the positive pole returns via the negative line, and the current flowing in the earth is negligible. For a fault on one pole controls will reduce direct current and voltage of the affected pole to zero in an attempt to clear the fault. In the meantime transmission by the unfaulted pole continues using earth as the temporary return path. Clearly this technique offers the prospect of increased reliability of h.v.d.c. transmission compares with three-phase a.c. transmission, in which phase faults may cause loss of the complete circuit.

### 32.4.2 Two monopolar lines

In circumstances where the probability of line failure arising from environmental conditions is high, two monopolar towers (*Figure 32.9(b)*) have been used on separate rights-of-way although the system operates as a bipole.

A monopolar line can be operated using earth return with the connection to earth made via a ground electrode. However, ground electrodes have so far only been constructed for use in emergency conditions, being designed to

operate only for a matter of hours, or in some cases for a few months.

### 32.4.3 Cable schemes with sea return

Sea electrodes have been used successfully (*Figure 32.9(c)*) on several schemes for continuous monopolar operation, low resistivity sea water providing a permanent return path. The resistivity of sea water is in the order of  $0.2 \Omega\text{-m}$  compared with  $10 \Omega\text{-m}$  for earth at an ideal land site or  $100 \Omega\text{-m}$  for fresh water.

### 32.4.4 Back-to-back arrangement

If there is a need to connect two nearby systems by h.v.d.c., economies can be achieved by combining two converter stations in a back-to-back arrangement (*Figure 32.9(d)*)

### 32.4.5 Ground electrodes

The earth provides a readily available medium for the return of direct current. While in certain countries permanent use of the ground in a power circuit is not permitted, its use under emergency conditions such as a line or terminal outage is accepted. A bipolar circuit with ground return thus provides two independent transmission paths.

A typical design of a ground electrode consists of a 3 m annular trench, 250–400 m in diameter, containing coke (*Figure 32.10*). A steel conductor embedded in the coke is connected to the electrode line by four or more radial insulated conductors. The coke acts as the electrode and the ring diameter is chosen so that the maximum voltage gradient at the ground surface does not exceed  $(5 + 0.03\rho) \text{ V/m}$ , where  $\rho$  is the surface material resistivity in ohm-metres. This is a safe value for humans or animals.

A ground electrode requires a damp site of low resistivity both at the surface and in the underlying strata. Very fine soils or sands may be unsuitable because thermal or electrical osmosis could remove the water from the soil-coke surface. A careful survey of neighbouring installations is necessary to identify any electrical conductor which by intercepting the equipotential lines near electrodes would carry a residual d.c. current. This current may cause corrosion where the (anodic) current enters, unless protected by sacrificial anodes or an applied reverse d.c. voltage. Pipelines, railway line, telephone and power cable sheaths, and power distribution systems using multiple grounding of

**Figure 32.10** Typical ground electrode

neutrals may require additional corrosion protection or segmentation into insulated sections.

### 32.4.6 Sea electrodes

A sea electrode can be relatively simple. One design uses 24 concrete boxes each containing two 1.5 m high silicon cast iron electrodes.<sup>1</sup> The boxes prevent contact with marine life, protect electrodes from silt and damage and restrict the voltage gradient outside to 2.5 V/m. The resistance is 0.02  $\Omega$ , well below that of the connecting cables and 35 km overhead line to the converter station (1.1  $\Omega$ ). An alternative electrode material having good resistance to corrosion is platinised titanium.<sup>2</sup>

Electrodes can be built on shore, but assurance of contact with sea water is likely to require a pump installation and consequent maintenance. In both cases annual inspection of the anode electrode for deterioration is necessary. The cathode electrode consists of a simple single rod.

### 32.4.7 Staged construction of HVDC

HVDC systems can be built in stages to suit generation development. For example, the Nelson River Bipole I is made up of three six-pulse groups in series in each pole. Stage 1 was rated at 810 MW at +320 kV and -160 kV (Figure 32.11(a)) compared to final rating of  $\pm 460$  kV (Figure 32.11(b)). The low initial voltage implies higher losses until the final voltage was reached. Similarly, Nelson River Bipole II was first used at  $\pm 250$  kV and later at  $\pm 500$  kV.

If the time between stages of generation development is very long, the cost of operation at low voltage may prove to be too high. In such a case it is possible to start with converters at full voltage but low current, subsequently adding another converter in parallel. The 'parallel' build-up is more expensive than the 'series' build-up from the converter station point of view, but it is more economic from the line loss point of view.

The Pacific Coast Inertie is an interesting example of both series and parallel extensions, illustrating the flexibility of h.v.d.c., Figure 32.12. The original scheme was rated for

Figure 32.11 Development stages of Nelson River Bipole I scheme

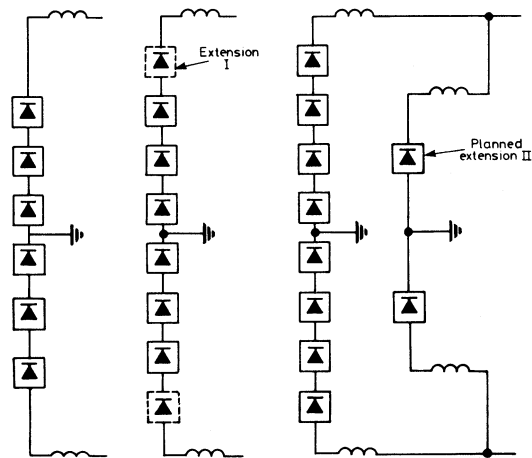

Figure 32.12 Development stages of Pacific Coast Inertie h.v.d.c. scheme

1420 MW at  $\pm 400$  kV using three mercury arc six-pulse groups in series per pole. The scheme proved to be capable of higher current rating, giving 1600 MW capability. By restringing parts of the h.v.d.c. line and by adding a 100 kV thyristor six-pulse bridge to each pole, it was possible to achieve a rating of 2000 MW at  $\pm 500$  kV. One thyristor converter rated for 500 kV has now been added in parallel with each pole (labelled 'proposed extension II' on Figure 32.12) to increase the h.v.d.c. line current to 3100 A. This gives a total external rating of 3100 MW at  $\pm 500$  kV, more than twice the original rating of 1420 MW.

## 32.5 Converter station design

### 32.5.1 Valve group arrangements

The size and number of converter groups will generally be dictated by the firm power requirements and will in turn dictate the complexity of the d.c. switchgear requirements. Firm power requirements will also influence the selection of which equipment should be switched simultaneously or independently.

Figure 32.13(a) shows the main equipment of a typical converter station arrangement: converter transformers,

Figure 32.13 Alternative bipolar h.v.d.c. converter connections: (a) single 12-pulse groups; (b) series connected 12-pulse groups

**Figure 32.14** Air-cooled, air-insulated quadrivalves (1000 MW back-to-back scheme, Chandrapur, India)

a.c. filters, valves, d.c. reactors and associated isolators form two separate and independent poles of a bipole. Surge arresters are essential components and are dealt with in Section 32.6. D.c. filters may be added in overhead transmission line schemes.

In Figure 32.13(a), the loss of any major component, say a transformer, would lead to the loss of the 12-pulse pole. If power requirements are such that 75% of rated power must be firm then the arrangements in Figure 32.13(b) should be considered. Firm power of 75% can be achieved by dividing the pole into two 12-pulse groups. There is no penalty in the thyristor valve arrangement, as the same number of thyristors is required to withstand the desired voltage. However, failure of a d.c. reactor would constitute a loss of 50% power.

In mercury arc schemes it was economic to use a six-pulse bridge as the operating unit. In thyristor schemes in most cases, it is more economic to use a 12-pulse converter group as the operating unit, and avoid the need for large filter, for fifth and seventh harmonic currents (Figure 32.14).

### 32.5.2 Converter valves

The valves are arranged in three-phase bridge circuit as discussed in Section 32.3. The rating of the thyristor valve is flexible and the operating voltage of the valve can be varied by choosing a different number of series connected thyristors. Thyristors connected in parallel have been used, but current ratings in excess of 5000 A d.c. bridge current can be accommodated by a single power thyristor of the type now available.

Physically the thyristor valves of a 12-pulse group are usually arranged in stacks with four valves mounted on top of each other to form a quadrivalve, as shown on Figure 32.14. This arrangement has the advantage of enabling insulation to ground for the valves operating at the highest voltage potential to be provided by the other valves in the stack (Figure 32.16). Figure 32.15 shows a section through such a valve hall. For the electrical power circuit of the equipment shown refer to Figure 32.21 in Section 32.6. An alternative design from floor supported valves is to hang them from the valve hall ceiling.

### 32.5.3 Converter transformers

The following transformer arrangements can be used to supply a 12-pulse converter group:

- (1) One three-phase transformer having one line (primary) and two valve (secondary) windings;
- (2) two three-phase transformers each having one line and one valve winding;
- (3) three single-phase transformers each with one line and two valve windings; and
- (4) six single-phase transformers each with one line and one valve winding.

Figure 32.17 shows a layout using transformer arrangement (1) in which transformer bushings protrude into the valve hall. This layout has the advantage of eliminating outdoor connections between the transformers and the valve hall which can be a source of radio interference.

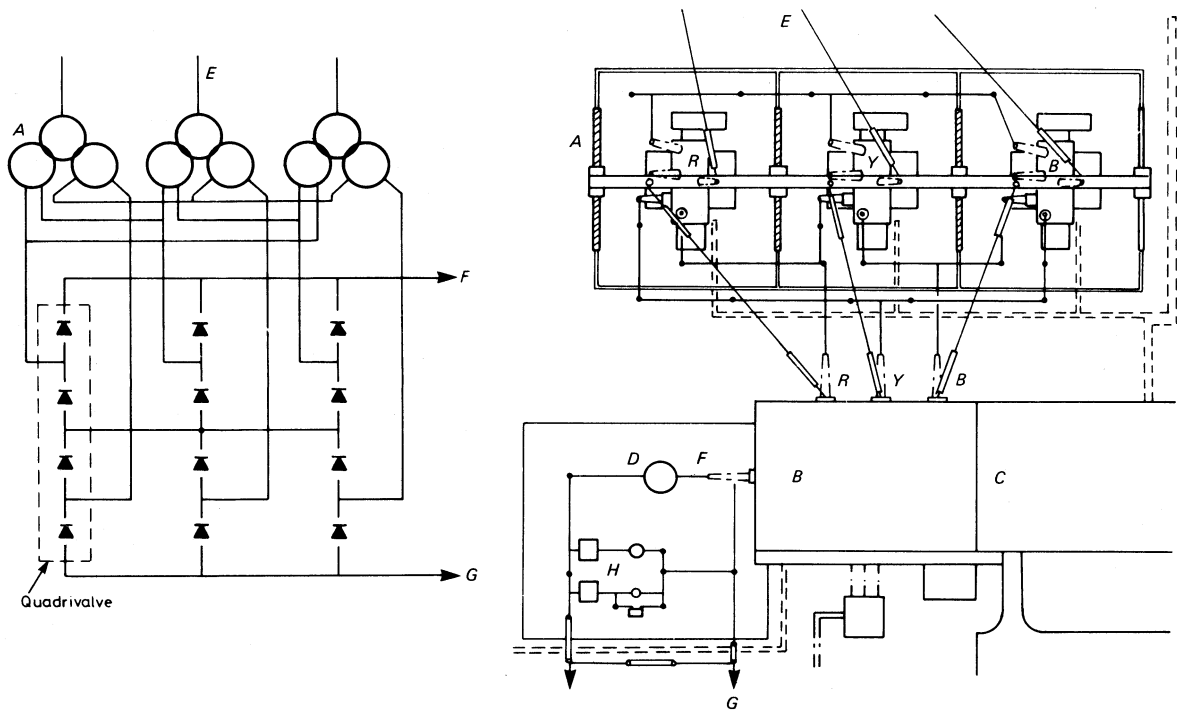

Figure 32.16 shows a layout using transformer arrangement (3). It may not be economic to arrange for transformer bushings to protrude into the building as this would necessitate a very long valve hall. Gas insulated busbars could be considered for such a layout.

For very large ratings, arrangement (4) may be used for a 12-pulse group, requiring a much larger area to provide the six a.c. connections between transformers and valve hall.

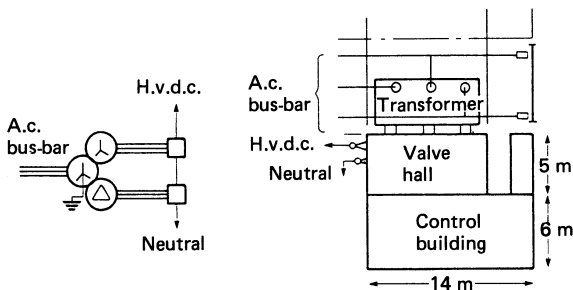

Because the converter groups are connected in series on the d.c. side, the windings of the outer converter transformers will be biased at a d.c. potential with respect to earth, which is equal to the sum of the voltage of the inner groups. D.c. potential has a different distribution between oil and paper insulation from a.c. which has to be considered in the design and test. The valve winding line-to-line voltage has a sinusoidal waveshape, but the design must take into account the significant harmonic current content due to the converter action. A major factor in the choice of transformer reactance is the prospective fault current in the thyristor valves during worst case fault conditions. This may dictate the use of a transformer reactance greater than the most economic value for a given transformer design.

**Figure 32.15** Section of valve hall: 1, thyristor quadrivalves; 2, surge arrester-valves; 3, surge arrester-valve group; 4, surge arrester-neutral; 5, through-wall bushing neutral d.c.; 6, earth switch; 7, through-wall bushing h.d.v.c.

**Figure 32.16** Single-phase three-winding transformer arrangement: A, converter transformers; B, valve hall; C, control building; D, d.c. smoothing reactor; E, a.c. connections; F, h.v.d.c. connection; G, neutral connection; H, d.c. filters

**Figure 32.17** Three-phase three-winding transformer arrangement

### 32.5.4 A.c. filters

Filters, to absorb harmonic currents and to provide reactive power, are connected to the same a.c. bus-bar as the converter transformers. It will normally be necessary to split filters into several banks, both for separate maintenance (e.g. capacitor replacement) and to restrict the voltage step at switching. Filter design and reactive power are considered in Sections 32.8 and 32.9.

### 32.5.5 D.c. smoothing reactor

The converter valve groups are connected to the d.c. transmission system via a smoothing reactor. In deciding the inductance of this reactor several factors have to be considered. The reactor ensures that the overcurrent transient

occurring during an inverter commutation failure or a d.c. line fault is kept within limits acceptable to the valves.

The smoothing reactor exhibits a very low resistance to direct current but provides a high impedance to the characteristic 12-pulse harmonic voltage resulting from converter operation. In the case of transmission schemes employing overhead lines the smoothing reactor acts to filter the harmonics appearing on the d.c. side of the converters in conjunction with shunt connected capacitors or filters. Unattenuated, these harmonics may cause telephone interference in the area surrounding the d.c. line.

Another important feature of the d.c. smoothing reactor, arising from its high impedance to high frequencies, is that it shields the remaining converter station equipment from being directly exposed to fast voltage transients which can occur on the d.c. line.

The reactor can be placed either in the h.v. or the l.v. connection. By placing the reactor in the l.v. connection savings can be made on reactor insulation costs and this arrangement is feasible for back-to-back schemes. The insulation to ground of the inner valve group would have to be increased however and for this reason, and because protection from fast voltage wavefronts is required for schemes with high voltage lines, it is usual to place the reactors in the h.v. end of transmission schemes.

In a back-to-back d.c. scheme large currents due to d.c. line faults and fast voltage transients which could occur on d.c. lines are not present. The first d.c. link at McNeill connecting Canadian eastern and western a.c. systems, which cannot be synchronised, was commissioned in October 1989. D.c. smoothing reactor is not used in this back-to-back scheme.<sup>3</sup>

There are some operational advantages when the d.c. reactor is not used. On the other hand, in some instances

the generation of harmonics and the transfer of harmonics between the two a.c. systems could marginally increase. It should be noted that the commutating (mainly converter transformer) reactance provides an inherent reactance in the d.c. loop.

The d.c. smoothing reactor was considered an essential requirement for h.v.d.c. operation. It was possible to omit it in the case of McNeill station thanks to modern controls and analytical study techniques.

### 32.5.6 D.c. isolators

Most isolators in a two-terminal scheme will be of the conventional slow type. In the few cases where fast operation is required, high-speed isolators which do not have a d.c. current interruption capability will normally be sufficient to provide the switching of lines and valve groups while zero d.c. current is temporarily imposed by the converter action.

When series connected 12-pulse groups are used in a pole it is usually necessary to incorporate across each group high speed bypass switches, to assist the blocking and deblocking sequences, and to allow independent operation of the groups.

### 32.5.7 Protection

The protective functions required of a converter terminal can be divided broadly into three groups.

- (1) *Conventional protection*: this group covers the standard forms of protection applied to transformers and reactors and would include differential, overcurrent, earth fault, Buchholz, etc.
- (2) *Special power equipment protection*: this group covers special forms of protection which have been developed for converter plant. High-speed systems based on fibre optic coupling used with circuit breakers having two-cycle interruption time, can provide tripping in less than 50 ms. For the capacitor banks used in a.c. filters and static compensators, capacitor unbalance in protection is utilised to detect fuse operations and will have alarm, delayed shutdown, and immediate trip settings.
- (3) *Protection control equipment*: special forms of protection for the converter equipment are incorporated as part of the electronic controls for the poles and valve groups. This protection will cover commutation failure, asymmetry, d.c. line or cable fault, d.c. undervoltage, etc. Transient occurrences do not cause shutdown, but if the condition persists for longer than say 300 ms shutdown would be initiated. Asymmetry protection would operate as a result of a converter valve misfire resulting in the generation of disturbed d.c. voltage waveforms. Again, this condition would cause shutdown if it persisted for more than 300 ms. Fault currents on the d.c. line or cable can be limited very quickly (within about 20 ms) by exerting control on the triggering of the valves. For cable schemes this action would be followed by shutdown, but for overhead line schemes, where recovery from the fault may be achieved by temporary reduction of the d.c. current to zero, one or more restarts can be attempted before shutdown is initiated.

These three groups of protection are co-ordinated where appropriate, and are used as back-up to each other to provide a comprehensive protection system. The functions of control and protection are increasingly being coordinated and carried out by microprocessors.

### 32.5.8 Converter station losses

The high cost of losses can appreciably influence the equipment design (thyristor size, and transformer copper size). Larger thyristors than required for the current rating of the schemer incur a lower current dependent loss. Also, by its ability to withstand a higher short-circuit current it permits a lower transformer reactance to be used.<sup>4</sup> This in turn favours lower transformer copper loss. Such a choice gives as by-products some overload capability and a reduction in converter var consumption. The specified filter performance and var control requirements also influence the converter station's losses. For all these reasons, losses for different schemes may vary greatly. The following loss figures are for a scheme having an average value of losses: at rated load the loss for the two converter stations is 1.6% of rated power and the standby loss is 1/12 of this figure. However, in general, losses for different converter stations may vary by 10% each side of this example. *Table 32.1* gives the distribution of losses for this case between the major items, at full load and at standby. It can be seen that transformers and valves account for over 80% of losses.

**Table 32.1** Distribution of converter stations' losses

	<i>Losses at standby</i>	<i>Losses at 1 p.u. power</i>
1 Valves	0.1	0.411
2 Converter transformers	0.755	0.407
3 Filters	0	0.044
4 Smoothing reactors	0	0.095
5 Auxiliaries*	0.145	0.043

\* Excludes building services

### 32.5.9 Converter stations' prices

As discussed in 32.2.1, h.v.d.c. converters plus h.v.d.c. overhead lines or cables were initially being proposed as a straight economic alternative for h.v.a.c. overhead lines or cables, provided the transmission distance was sufficiently long. To enable utilities to make a preliminary estimate of the 'break-even' distance, beyond which it was worthwhile considering h.v.d.c., curves of converter station prices were being produced. These price curves of \$/kW were of the shape given in *Figure 32.18*, but included a margin to allow for scheme differences. However, it has become almost impossible to give a meaningful value to the margin of this price curve.

The spare capacity of h.v.a.c. transmission systems and the spinning reserves have been greatly reduced, compared to the time when the \$/kW curves were introduced. The integration

**Figure 32.18** Variation of converter station price with the rated MW

Figure 32.19 Typical cost division for h.v.d.c. converter stations

of power electronics, h.v.d.c. or large a.c. FACTS (see Chapter 41), into a.c. systems has become a complex process involving a substantial amount of engineering and the use of specialised analytical tools. Each power system is different with respect to voltage, system strength, harmonic limits and reactive power limits and each utility has different operating requirements concerning overloads, availability and reliability etc. Each h.v.d.c. scheme is therefore unique and hence caution must be exercised when making cost comparisons between different schemes or indeed between indicative prices from different manufacturers for the same scheme. Appropriate division of costs between the various components of a station is illustrated in *Figure 32.19*.

### 32.5.10 Reliability

The term 'reliability' is often used to describe the overall operating performance of an h.v.d.c. scheme which is quantified by its average frequency of failure and average energy availability. The desired performance criteria are usually specified for a scheme at the early planning stages to meet the overall requirements of power transmission strategy. The inclusion of financial penalty clauses in scheme contracts has led to great emphasis being placed on system reliability and availability by system designers.

A quantitative analysis is used to assess the effect of the basic elements in the scheme on the overall performance. Whenever possible equipment with proven reliability is used, but the use of redundant capacity is also extensive. Equipment such as thyristor valves, cooling plant, auxiliary power supplies and control systems usually include redundancy.

The provision of adequate spares to minimise maintenance and repair times contributes to system availability. Spare converter transformers and smoothing reactors may be considered essential due to the long lead time for repair or replacement even though in practice both have proved to be highly reliable items.

The energy availability of a bipolar transmission scheme can be maximised if the scheme has the capability to transmit power during forced outages of one pole by operating its remaining pole as a monopole. This can be achieved in the case of converter station pole equipment failures by using its conductors as a metallic return path for the remaining operational pole. The availability can be further increased by utilising an earth return system rated at full current to permit power transfer even during outages of a transmission line conductor.

Emphasis is placed on providing independence between the poles of bipolar schemes such that the number of

possible common failure modes is kept to an economic minimum, while still sharing the transmission line and associated d.c. switchgear. Overhead transmission lines usually have both pole conductors on common towers. Experience has shown that common mode failures in this arrangement are unlikely. Even in areas of high lightning activity failures are usually restricted to one pole.

Typical performance targets would be a frequency of failure per pole of a converter station of 1 per year, an availability at full rated power of 98% and scheme total energy availability of 99.25%.

## 32.6 Insulation co-ordination of HVDC converter stations<sup>5</sup>

### 32.6.1 Introduction

Insulation co-ordination is the selection of the electric strength of equipment in relation to the voltages to which it may be exposed. Protective devices are chosen to reduce the voltage stresses imposed on the equipment to an economically and operationally acceptable level. The main object of insulation co-ordination for any system, whether a.c. or d.c., is to ensure reliable operation of the scheme at minimum cost.

Generally, an a.c. system is considered to consist of parallel-connected equipments which all have identical insulation levels. A d.c. converter station consists of both series and parallel connected equipment. However, when examining the insulating characteristic of individual a.c. equipment in detail, it is often found that the equipment has been designed and manufactured in discrete units which are connected in series. Obvious examples of this technique are found in shunt capacitor banks, insulators and a.c. circuit breakers which may use several interruptors in series. Less obvious examples include transformers and reactors.

Insulation levels on a.c. systems are relatively higher the lower the a.c. system voltage (facilitating co-ordination between different voltage levels). In a d.c. converter it is generally economical to have relatively lower insulation levels than on the adjacent a.c. system. These lower levels are made possible by close control of the voltages applied during both normal and transient conditions, but this does mean that a.c. system overvoltages can cause significant energy absorption in the converter surge arresters.

### 32.6.2 Sources of overvoltages

The magnitude and slope of overvoltages arriving at the converter station from the a.c. system will be attenuated by the action of a.c. filters and converter transformer reactance so that overvoltages with fast front times (less than, say, 10  $\mu$ s) do not penetrate the converter from the a.c. system.

Similarly, lightning or other impulsive overvoltages travelling along d.c. overhead line towards the h.v.d.c. converter station will be almost fully reflected at the d.c. smoothing reactor.

Thus, thyristor valves are protected from fast transient overvoltages arising from the a.c. system by the converter transformer, and from the d.c. system by the smoothing reactor. However, in the event of an insulation breakdown within the boundaries established by these protecting inductances, a fast transient overvoltage may occur across the thyristor valves. The most onerous overvoltage occurs if a flashover from an outer (highest d.c. voltage) converter transformer bushing to ground takes place when the converter station has been charged by a switching surge

originating in the a.c. system. During such an event the prospective valve overvoltage can be up to twice the switching surge protective level of the valve arrester. It is important to ensure that this surge arrester is able to limit the overvoltage to a level which is safe for the thyristor valve and that its energy absorption capability is adequate for this duty.

### 32.6.3 Surge arresters

The zinc-oxide non-linear resistor material used in modern surge arresters exhibits a very high impedance at normal applied voltage whilst at a voltage only some 50% higher a very low impedance is provided. The extremely non-linear relationship between voltage and current shown in *Figure 32.20*, has rendered obsolete the spark gaps which were a feature of previous arresters based on silicon carbide.

Gapless metal oxide arresters are simple in construction, consisting merely of enough resistor blocks connected in series to ensure that the current during normal operating conditions is very small, typically less than one milliamper. The zinc oxide resistor becomes unstable if the continuously applied voltage appreciably exceeds this level, which defines the *maximum continuous operating voltage (MCOV)*. It may also suffer thermal runaway if the surge energy absorbed is too high (unless the applied voltage is removed after the transient). Its capacity for energy absorption is limited either by the accumulation of the consequences of these two major thermal considerations or in some cases by instantaneous thermal shock.

The protective characteristic of the arrester is the envelope of the discharge voltage (being the maximum voltage developed across the arrester during the passage of a specified current impulse waveform) for various waveshapes. Parallel connected surge arresters can be made to share the total energy to be absorbed in limiting switching surge overvoltages if their voltage-current characteristics are properly matched during manufacture.

### 32.6.4 Surge arrester arrangement

A typical arrangement of surge arresters is shown in *Figure 32.21*. Arresters are normally connected across each individual thyristor valve, and also across each six-pulse group. In schemes employing more than one 12-pulse group in series per pole, the point of interconnection between groups is also protected by a surge arrester connected to ground. The d.c. line (and d.c. reactor) is similarly protected by a surge arrester.

The surge arrester protective level applicable to each item of equipment is obtained by examination of the circuit to

**Figure 32.20** Voltage-current characteristic of non-linear resistor material

**Figure 32.21** Arrangement of surge arresters in one pole of a 500-kV converter

**Figure 32.22** Arrangement of surge arresters on the a.c. side of a converter

find the path giving the lowest discharge voltage. Thus, the protective level between the outer converter transformer bus-bar and ground is determined by the series connection of the valve arrester and the six-pulse bridge arrester (in the case of two 12-pulse groups in series the protective level of the 12-pulse group arrester must also be added).

Surge arresters are also used on the a.c. system to protect the converter station in the manner shown in *Figure 32.22*. The phase-to-earth insulation is protected by surge arresters which are often placed close to the transformer terminals. Additional surge arresters may be applied within the a.c. harmonic filters specifically for the protection of filter reactors and resistors.

### 32.6.5 Safety margins

The source and magnitude of each credible overvoltage can be calculated, knowing the impedance of the circuit elements and the characteristics of arresters. Then the insulation level of the equipment in the converter station can be determined. For most items of conventional equipment the voltage withstand increases as the front time of the applied impulse decreases (*Figure 32.23*). For such conventional

**Figure 32.23** Insulation characteristics of conventional equipment

plant the safety margin between the protective level of the arrester and the withstand voltage of the equipment is 15% for switching surges. A minimum safety margin of 20% at lightning impulse waveforms and 25% at front of wave (FOW) waveforms is usually applied. The relatively flat protective characteristic of zinc oxide means that the actual margin between the protective level and the equipment withstand at lightning and FOW for most equipment is substantially higher than the minimum recommended. In practice, standard insulation levels (e.g. the IEC 71 series) are used for conventional equipment.

The safety margins applied to conventional equipment have evolved over many years and are intended to take into account both the measuring tolerances and the anticipated deterioration with age of the insulation of the protected equipment and of the surge arrester characteristics. A margin is also necessary to allow for the increase in voltage which may arise as the distance from the surge arrester to the protected equipment increases.

Arresters are placed immediately adjacent to valve terminals, so no allowance is needed for distance effects. The thyristor valves incorporate redundancy which can be restored at regular (e.g. annual) intervals by replacement of any failed thyristors ensuring that the insulating properties of the thyristor valve stay virtually constant throughout its life.

The withstand voltage of the thyristor valve in its off-state is dictated not only by the sum of the withstand voltages of all the thyristors (which is essentially independent of waveform), but also by the interaction between its distributed in-rush-limiting reactors and the thyristor grading and damping network. During slow wavefronts only a small proportion of the applied voltage will appear across the reactors. However, as the front time decreases an increasing proportion of the voltage will appear across the reactors, and as a result the valve withstand voltage increases. It is possible to match the valve voltage–time curve to the surge arrester characteristic, achieving the margins listed above for the various impulse waveforms.

### 32.6.6 Creepage and clearance

The selection of creepages and clearances for the converter station is an important part of insulation co-ordination. The creepage required for a given item of equipment will vary substantially with the environment in which it is

required to operate. The creepage length required is proportional to the maximum continuous voltage. In the clean air-conditioned environment provided by a valve hall, a creepage of 14 mm/kV peak will provide satisfactory performance. Under polluted conditions, such as may be present on d.c. overhead lines or on outdoor converter equipment in industrial areas, a creepage distance of 40 mm/kV peak, or sometimes even more, may be required to give adequate performance. Clearances within the converter station are determined primarily by lightning impulse and switching impulse withstand requirements.

### 32.6.7 Application examples

The economic incentive for using a low protective level across the thyristor valves is very strong, since the number of thyristor levels required is directly proportional to this voltage. Therefore, the valve arresters normally exhibit a low protective level, which means that they may be required to absorb large amounts of energy during overvoltages.

With all a.c. harmonic filters connected, recovery from a local three-phase short circuit to ground in a weak a.c. system may cause high prospective overvoltages. These overvoltages will have a high content of low order harmonics, and will therefore appear relatively unattenuated on the valve winding side of the converter transformer. The a.c. system phase to ground arresters will limit the peak amplitudes of these recovery overvoltages, but the thyristor valve surge arrester may nevertheless be required to absorb a large amount of energy.

A flashover from the outer converter transformer valve winding bus-bar to ground, occurring when the d.c. line is charged to overvoltage can also lead to high energy absorption in the thyristor valve surge arrester. During this event the surge arrester absorbs a substantial part of the energy stored in the capacitance of the d.c. line and d.c. filters (where applicable). Although this event is not very likely, the surge arresters across the top three thyristor valves are sometimes specified to be capable of higher energy absorption than the other valve arresters to accommodate it.

Figure 32.24 shows typical lightning and switching impulse levels in a 500 kV d.c. pole as applicable at various locations, (a) to (e), shown in Figure 32.21. It should be noted that the thyristor valves use non-standard insulation levels.

During normal operating conditions the inductor and resistor of an a.c. or d.c. harmonic filter experience only a small fraction of the total line-to-ground voltage. However, a major fraction of any transient overvoltage can appear across the inductor and/or resistor. Filter energisation is an example of a routine event causing an overvoltage across the filter components. If the a.c. system is strong or if several filters are already connected to the bus-bar, the voltage across the inductor when energised at peak voltage can easily approach the full line-to-ground voltage. By connecting a surge arrester in parallel with the inductor or resistor as shown in Figure 32.22 it is possible to utilise components with an insulation level significantly below that applicable to the rest of the a.c. system. However, if it is fitted, such an arrester may be subject to very fast-rising wavefronts,

	a	b	c	d	e
BIL	1300	603	650	60	1175
BSL	1172	586	586	35	992

**Figure 32.24** Typical lightning and switching impulse levels in a 500-kV d.c. pole

associated with high energy discharge duties. For example, if a flashover occurs from the a.c. bus-bar to ground, most of the energy stored in the main capacitor will be discharged into the surge arrester. Such an event can lead not only to high energy absorption in the arrester, but also to very high discharge current amplitudes. For example for a filter connected to a 400 kV system the arrester protecting the inductor of the filter may need a co-ordination current of 80 000 A. By using the arrangement shown in *Figure 32.22* it becomes possible to specify for inductors the Basic Insulation Level (BIL) of 650 kV, whereas the a.c. system BIL is 1425 kV.

## 32.7 HVDC thyristor valves

### 32.7.1 Introduction

Together with the central control system, the valves and their auxiliary cooling and overvoltage protection equipment account for approximately one-third of the equipment cost of the converter terminal. In addition, between 30% and 40% of the total station loss is incurred by the valves. At typical capitalised values of US \$3000–8000 per kilowatt, the evaluated cost of losses can approach and sometimes exceed the capital cost of the valves. In such cases, it is economical to invest more in the hardware to reduce the level of losses.

The single most significant variable that influences both the capital cost and the level of losses is the number of series connected thyristors in each valve. The most economic solution is one that uses the minimum number of series levels consistent with reliable long term operation.

A valve is required to act as a switch. It should switch on (turn-on) and switch off (turn-off) efficiently. When off, it should withstand the applied forward and reverse voltages and when on, it should have low resistance.

Unfortunately, thyristors are not perfect switches. At turn-on, they initially have reduced current carrying capacity. At turn-off, the current reverses for a brief period while the thyristor stored charge is extracted and the thyristor's ability to withstand forward voltage is severely limited for some time after negative recovery starts.<sup>6,7</sup> *Table 32.2* summarises how the principal thyristor characteristics are influenced by design parameters. The thyristor designer can trade-off one characteristic against another to achieve the most economic solution for a given application.<sup>6</sup> Close collaboration between the converter valve designer and the thyristor designer is essential in order to achieve the best economic solution.

When properly applied, the thyristor does not suffer from any 'ageing' effects which would cause deterioration of its characteristics with time and it has proved to be a very reliable device provided it is used within its rating. *Figure 32.25* indicates the significant advances which have been achieved in recent years in both voltage and current ratings of thyristors.

**Table 32.2** Interaction between thyristor parameters

<i>Thyristor parameter</i>	<i>Desired magnitude</i>	<i>Increased by</i>	<i>Reduced by</i>
Current rating	High	Increased area, increased carrier lifetime, packaging (improved cooling), reduced thickness	Reduced area, reduced carrier lifetime  Increased thickness
Voltage rating	High	Increased resistivity, increased thickness, shallow impurity gradients, uniformity of purity distribution (NTD silicon), edge profiling (reduced peak surface field), edge passivation (stability)	Lower resistivity, reduced thickness, steep impurity gradients, less uniform purity distribution, steeper edge bevels
Turn-off time	Low	Increased carrier lifetime, increased thickness, emitter geometry	Reduced carrier lifetime, thinner slices
Stored charge	Low	Increased carrier lifetime, increased thickness	Reduced carrier lifetime, thinner slices
Surge current	High	Increased area, reduced thickness, increased carrier lifetime	Reduced area, increased thickness, reduced carrier lifetime
$dV/dt$ withstand	High	Shorted emitter pattern density, vertical diffusion geometry	Trigger sensitivity
In-rush $dI/dt$ capability	High	Fast rising gate pulse, amplifying gate, interdigitated gate	Heavy shorted emitter pattern, minimal gate area
$V_{gt}$ , $I_{gt}$	Low	Design for high $dV/dt$	Favourable lateral patterns, favourable diffusion profiles
Turn-on delay time	Low	Carrier lifetime control	Favourable vertical diffusion profile, vertical geometry
Forward voltage drop	Low	Thicker slices, shorter emitter pattern density	Thinner slices, less dense shorter emitter pattern

Figure 32.25 Advances in thyristor ratings

32.7.2 Thyristor level circuits

To cater for high voltages for h.v.d.c., each valve is made up of many thyristor levels connected in series.

Figure 32.26 shows the basic electrical circuit of one thyristor level as it may typically be implemented. Many variants are possible but all key features are shown. In some designs one series reactor serves several thyristor levels.

The power thyristor is electrically triggered via its gate and logic unit in response to an optical command received via a fibre optic waveguide from earth potential. Electrical power for energising the electronics is derived from the main damping circuit, local to the thyristor.

Figure 32.26 Basic circuit of one thyristor level

The gate and logic unit and the associated power supply are designed to ensure that full and adequate control and protection of the thyristor is afforded, not only under normal steady-state operation, but also under abnormal and disturbed conditions, such as operation with discontinuous current or the loss of a.c. system voltage for up to the maximum a.c. system fault clearance time (typically 200–300 ms).

In series with the thyristor is a saturable reactor to control inrush current and across each thyristor the usual capacitor and capacitor resistor circuits used for voltage grading and damping purposes.

32.7.3 Voltage rating

The required d.c. voltages can vary from 25 kV for a 50 MW back-to-back scheme to 600 kV to ground (1200 kV –ve to +ve line) for a 3000 MW, long transmission scheme. Thyristors for h.v.d.c. having a withstand capability in excess of 5 kV are already available and the economic pressure to reduce the number of series levels will continue to force ratings upward.

In the case of long distance schemes, the need to optimise the transmission line costs and losses usually results in a defined optimum transmission voltage for a particular power transfer requirement.

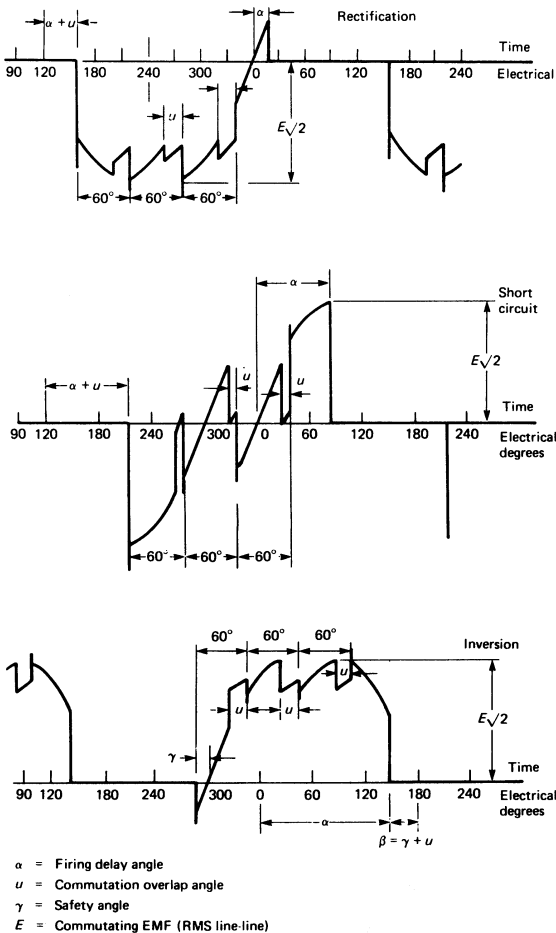

Figure 32.27 Voltages across a valve operating in a six-pulse bridge for rectification, zero voltage and inversion

For back-to-back interconnections the designer can choose the operating voltage and current to suit the capability of available thyristors. This usually results in a scheme with low operating voltage and high current. Whatever the application, the general form of the normal valve terminal-to-terminal voltage is similar. The voltage waveshape is complex (Figure 32.27), containing fundamental frequency components, fast transient components and a d.c. off-set.

Each valve is protected against overvoltages by a zinc oxide surge arrester, connected directly across its terminals. For maximum economy, the protective level of this arrester should be as low as possible. The achievable protective level depends on the performance requirements of the arrester, which in turn is determined by the system voltage conditions. While the nature of transient overvoltages is important because it determines the energy rating of the arrester, it is the ability of the arrester to withstand the peak of the fundamental frequency voltage after a maximum energy surge, which is normally the determining factor. Once the voltage rating of the arrester is chosen, the protective level arises naturally from the zinc oxide voltage-current characteristic and the value of co-ordinating current.

The protective level of the arrester is not a single value but is somewhat dependent on the front time of the incident voltage wave, the value being higher for faster fronted impulses. This must be taken into account in the valve design. In addition, the valve must contain enough thyristors in series to be capable of being tested at values sufficiently above the arrester protective level to give confidence that long service life will be achieved.

In accordance with international standard IEC 700, valves are normally designed for the following test margins with respect to the surge arrester protective levels:

15% for switching impulse,  
15% for lightning impulse, and  
20% for front-of-wave.

Having established the test voltages to be applied, the number of thyristors may be determined. This number is a

Figure 32.28 Typical insulation co-ordination for a thyristor valve

function of the reverse voltage capability of the thyristors and on the achievable accuracy of the grading circuit.

Thyristors can be damaged if they are exposed to excessive voltage in the forward direction. Further, the forward voltage capability is usually lower than that in the reverse direction. For this reason, protective firing of the thyristors is often employed for overvoltages in the forward direction. Figure 32.26 shows this feature implemented by a breakover diode (see Section 32.7.5.). The valve voltage, above which protective self firing may occur, depends on the detailed application but, as a general rule, it will not be below 90% of the surge arrester protective level for switching surge wavefronts (see Figure 32.28).

#### 32.7.4 Current rating

For an h.v.d.c. application it is desirable that any credible fault current, arising from insulation failure, can be blocked by the thyristors at the first current zero. It is therefore necessary to ensure that the post-fault thyristor junction temperature is below the critical value, above which the thyristor may not be able to block the ensuing recovery voltage.

The problem is a thermal one, bound by two limits: one limit is the temperature above which the thyristors may be

Figure 32.29 Typical breakdown of temperature rise between the coolant-thyristor junction

unable to block the post-fault recovery voltage, the other limit is the ultimate heat sink temperature to which all losses are finally dissipated (e.g. ambient air, river water, etc.).

Figure 32.29 shows a typical breakdown of temperature rise between the two limits. In practice, the designer has direct or indirect control over each component of the temperature rise and, for any given application, aims to achieve an optimum economic balance. As can be seen, nearly 60% of the available temperature rise has to be kept in reserve as a margin for transient overloads and fault currents. It is most important to be able to determine the temperature rise resulting from any fault current.

Figure 32.30 indicates how junction temperature follows the current. A short circuit caused by a d.c. side flashover must not be allowed to raise junction temperature to a value that would prevent forward blocking after current zero.

There are sophisticated techniques for producing an accurate mathematical model from which the worst case thyristor junction temperature excursion, for any applied current waveform, can be derived.<sup>6,8</sup> Using such models, the sensitivity of junction temperature to changes in fault current produced by changes in transformer leakage reactance can be determined and an optimum value of reactance chosen.

Technically, the method of cooling employed is irrelevant to the performance of the thyristor as it is only a means of achieving a defined steady-state condition from which junction temperature excursions due to transients and faults can commence. Because heat generated at the thyristor junction does not reach the heat sink in times less than 1 s, the design of heat sink and the method of cooling have no influence on the transient excursions due to faults and disturbances, which rarely last more than a few hundred milliseconds.

**Figure 32.30** Variation of thyristor junction temperature for typical fault current waveforms

Increasingly, the cost of losses is such that it is often justified to select a larger thyristor than could technically satisfy the current requirements of a scheme. Under these conditions, considerations other than overcurrent rating may become limiting (e.g. maximum coolant temperature).

### 32.7.5 Turn-on behaviour

When thyristors are gated, there is a short (1 to 2  $\mu$ s) delay before any significant change in impedances takes place. After this initial delay, the impedance of each thyristor collapses rapidly, but the steady-state impedance is not reached until several hundred microseconds later. During this turn-on phase, the thyristors have reduced current carrying capacity and it is necessary to protect them from the prospectively high rates of rise of current arising from the discharge of the circuit stray capacitances. Series connected saturable reactors are used which are active during the initial stages of turn-on but exhibit a low inductance value after conduction is established.

The rate of rise and amplitude of voltage applied to the thyristors, when fast fronted voltage waves appear at the valve terminals are controlled by the reactor and capacitor grading circuit.

Normally, valve turn-on is initiated by the coherent triggering of all thyristors in response to a firing command originating in the central control system. It is clear that if a thyristor is late turning on, it could be destroyed by excessive voltage. Protective self-firing described earlier can be achieved by electronic means or, if very high reliability is required, by use of a break-over diode (BOD) at each thyristor level. The BOD is a voltage-sensitive semiconductor switch that operates in response to an overvoltage. It gates the main power thyristor directly and, unlike the electronic alternative, is fully independent of the normal firing system. Because of tolerances, overvoltage firing of the valve is non-coherent and a cascading type of turn-on may take place, and the last level to turn-on may experience increased stress. Being independent, the BOD firing circuit acts as a back up to the normal firing circuits. If normal firing on any one levels fails, the BOD responds to the rapid rise in voltage arising from firing of other thyristors in the valve and safely initiates conduction before damage to the thyristor can occur. Efforts to integrate the BOD into the main thyristor, making it self-protecting against overvoltages will eventually remove the need for such circuits.

### 32.7.6 Turn-off behaviour

At turn-off, the switching action of the valve excites an oscillation between the transformer leakage reactance and the circuit stray capacitances. This oscillation cannot be critically damped but the degree of voltage overshoot can be minimised by the correct choice of values for the components of the valve grading network. The thyristors themselves aggravate the recovery overshoot as they do not cease conduction immediately the current reaches zero, but shortly after. The reverse current flow that is established before turn-off occurs allows energy to be stored in the magnetic fields of the inductive components, and this energy has to be dissipated in the damping circuits.

Immediately after turn-off has occurred, thyristors are unable to support any forward voltage without spontaneously re-conducting. Gradually the thyristors acquire some forward hold-off capability, but it is typically more than one millisecond before their full off-state capability is attained.

**Figure 32.31** Water-cooled assembly with 14 thyristors, levels in series. (Courtesy of GEC Alsthom Transmission and Distribution Projects Ltd)

The economics of converter design dictate that inverter operation be achieved with the smallest practicable extinction angle margin ( $\gamma$ ) but the value of  $\gamma$  chosen must not only allow time for the thyristors to recover sufficient forward voltage capability, but must also include additional margin so that temporary minor distortion of the a.c. system voltage waveforms does not result in an unacceptably high incidence of commutation failure. Severe transients, such as those arising from nearby a.c. line faults, will result in loss of margin angle such that commutation failure becomes inevitable (see Section 32.10).

Two aspects relating to commutation failure are worthy of mention. First, a thyristor may be exposed to positive voltage (arising from, for example, disturbed a.c. network voltage) before its recovery process is complete. Forward recovery failure of thyristors may be in itself potentially destructive to the thyristors, particularly when re-application of forward voltage is rapid. The mechanisms leading to failure are complex and are discussed in more detail in references 6 and 7. It is essential for the security and reliability of the system that proper protection is afforded to the thyristors. This usually has to be carried out at each thyristor level.

Second, in marginal cases, some thyristors may re-conduct while others do not. This leaves the valve in a partially blocked state with only a portion of the thyristors supporting the applied voltage. Those thyristors which have successfully blocked are now exposed to a prospective overvoltage, even though the valve terminal voltage may not exceed 1 p.u. The use of individual overvoltage protection, at each thyristor level, and/or whole valve protective firing in

response to a data-back signal, ensures that no damaging overvoltage can occur.

### 32.7.7 Valve arrangements

Oil-cooled, oil insulated and air-cooled, air-insulated valves have been used in the past. However, most economic arrangements at present use air-insulation and water cooling.

The following description of a valve is given as an example of how a 1500 MW  $\pm 500$  kV d.c. converter is built up. Two six-pulse bridges connected in series are used to form a 500 kV 12-pulse valve group. Therefore each valve has to be capable of operating in a 250 kV six-pulse bridge. To achieve this voltage between 70 and 80 thyristor levels (*Figure 32.26*) would have to be used, including two to three levels for redundancy.

*Figure 32.31* shows a water-cooled assembly (valve section) comprising 14 series-connected thyristors arranged into seven subassemblies (banded pairs), though the number of thyristors in a valve section will vary depending on the application. Each banded pair has interleaved heat sinks and is held in compression by glass fibre composite bands and internally mounted spring washers. Replacement of a thyristor is possible without disturbance of the water circuit and the main electrical connections. The banded pair is raised into the position shown and the bands are stretched by means of an integral hydraulic ram to enable packing pieces and then a thyristor to be removed. Two counter-flow water circuits provide uniform temperature through the valve.

The valve sections which form one tier are mounted in a structure with support insulators as shown diagrammatically

**Figure 32.32** Diagrammatic illustration of part of a valve structure showing four valve sections connected in series at each tier

in *Figure 32.32*. Four such tiers are required to form one valve for the example chosen. Four valves are stacked on top of each other to form a quadrivalve. Electrical connections form a spiral from ground level (neutral voltage) through four series valves forming a quadrivalve (i.e. four valves associated with one phase of a 12-pulse valve group). Three such quadrivalves form a complete 12-pulse pole contained in one valve hall, rated 500 kV, 1500 A, 750 MW (see *Figure 32.15*).

### 32.7.8 Valve tests

The testing of thyristor valves for h.v.d.c. is covered by IEC 60700 (1998) and IEEE 857 (1996). Broadly speaking, these two standards have similar requirements.

Dielectric tests are performed on complete, single, valves and, when required, on multiple valve units and their supporting (or suspending) structures.

The testing of the normal operating duty of a valve is difficult because of the power limitations of practical test circuits. As a result, operational tests are normally performed on valve sections at realistic current but at proportionally reduced voltage. In order for 'realistic' stresses to be reproduced, both standards normally require the valve sections for operational tests to have five or more series-connected thyristor levels.

Two basic test methods for operational tests can be used: the first one uses 12 valve sections configured as two 6-pulse bridges in back-to-back connection and the second uses single valve sections in a synthetic test circuit with repetitive (50 Hz/60 Hz) capability. In a synthetic test circuit, various voltage and current sources are combined in an appropriate

manner to reproduce representative stresses (see *Figure 32.33*). Synthetic circuits offer greater flexibility, are more accommodating of increases in thyristor rating and require lower test plant MVA than the back-to-back alternative.

## 32.8 Design of harmonic filters for HVDC converters

### 32.8.1 Introduction

The a.c./d.c. converter is a source of harmonics, and since excessive levels of harmonic distortion on an a.c. system can lead to a number of undesirable effects (overheating of induction motors, generators and capacitors, telephone interference, etc.) shunt harmonic filters are used on the a.c. terminals of all h.v.d.c. converter stations.

Harmonic distortion on the d.c. line may in some cases cause unacceptable interference in adjacent telecommunication circuits. In order to minimise this interference, harmonic filters are often fitted at the terminations of d.c. overhead lines.

### 32.8.2 A.c. harmonic current generation

Due to large inductance of the d.c. smoothing reactor the current conducted by each converter valve consists of a train of nearly flat topped current pulses. Thus, the current at the a.c. terminals of the converters is not sinusoidal.

*Figure 32.34* superimposes the a.c. current pulses from two ideal six-pulse bridge converter circuits connected via star-star and star-delta transformers with zero commutating

**Figure 32.33** (a) Synthetic circuit for valve testing (block diagram); (b) Voltage response of thyristor level with back-up triggering. ( $\alpha_s = 90^\circ$  firing conditions)

reactance but with infinite d.c. circuit inductance. A Fourier analysis gives, for a d.c. current of  $I_d$ , the following series for the star-star and the star-delta transformer, respectively:

$$i = \frac{2\sqrt{3}}{\pi\zeta} I_d [\cos(\omega t) - 1/5 \cos(5\omega t) + 1/7 \cos(7\omega t) - 1/11 \cos(11\omega t) + \dots]$$

$$i = \frac{2\sqrt{3}}{\pi\zeta} I_d [\cos(\omega t) + 1/5 \cos(5\omega t) - 1/7 \cos(7\omega t) - 1/11 \cos(11\omega t) + \dots]$$

By addition of these two currents the fifth and seventh harmonics cancel and only harmonics of orders  $12k \pm 1$  will enter the a.c. system for a 12-pulse group.

In practice, because the converter transformer reactance is not zero, the current takes a finite time to transfer from one valve to the next. As shown in Figure 32.35 the resulting current waveform is smoother than that shown in Figure 32.34. The amplitude of each harmonic component of current depends on the value of overlap angle  $u$  which is a function of the commutating reactance, of the firing angle  $\alpha_s$  (or  $\gamma$ ) and of the load current. The effect of  $u$  can be judged from Figure 32.36. The 11th harmonic with  $u=0$  would be 1/11 (9.1%) of the fundamental, while in practice it is nearer to 4%. Figure 32.37 shows the variation of characteristic harmonics with d.c. load. Text books should be consulted for a full analysis of harmonic currents.

**Figure 32.34** Idealised phase current on the a.c. side of a converter station

**Figure 32.35** Phase current with firing and overlap delays

The theoretical analysis above is valid for balanced a.c. systems and converter operation. In practice, neither the a.c. system nor the converter circuit are perfect, and cancellation of harmonics will be incomplete. The major causes of harmonics other than  $12k \pm 4$  are:

- (1) a.c. system phase unbalance including non-linear loads;
- (2) unbalance between six-pulse bridges; and
- (3) unbalances within six-pulse bridges.

### 32.8.3 Filtering

Shunt harmonic filters connected to the converter a.c. bus-bars provide a low impedance into which most of the

**Figure 32.36** Eleventh harmonic as a percentage of the fundamental harmonic

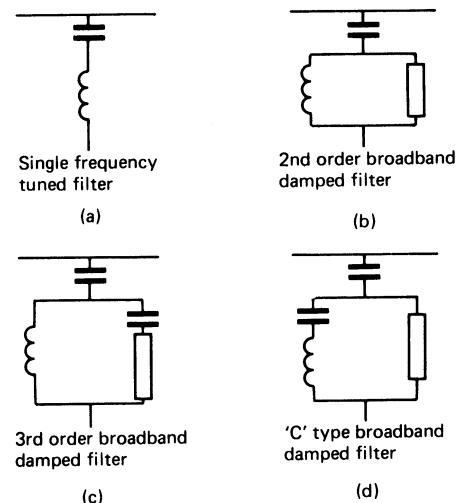

**Figure 32.37** Harmonic generation

harmonic currents are diverted. Shunt filters also generate reactive power at fundamental frequency providing some or all of the reactive power required by the converters.

The most direct method of achieving a low impedance at a given frequency is by means of a tuned filter as shown in *Figure 32.38(a)*. The admittance of a tuned filter varies sharply around the resonant frequency as demonstrated in *Figure 32.40*. The sharpness of tuning and the var rating of the filter must be chosen to achieve the specified performance over the required range of system frequency, temperature and component tolerances.

Each sharply tuned filter is capable of providing significant attenuation at one frequency, but gives virtually no damping at other frequencies. This means that the a.c. bus-bar voltage during transient phenomena may exhibit ringing at low order non-characteristic frequencies, and that this ringing may persist for a long time. The bus-bar voltage shown in *Figure 32.41* is typical of the transient occurring during the energisation of a combination of tuned filters and a single high pass damped filter.

It is possible to combine two separate tuned filters in a single filter as shown in *Figure 32.39*. The characteristics

**Figure 32.38** Alternative types of harmonic filter

Figure 32.39 Alternative types of double-tuned harmonic filters

can be altered by increasing the damping thus reducing the sharpness of 'tuning'. Combining the main capacitors of two individual tuned filters to create one double-tuned filter can often give significant cost savings.

The damped broadband filter shown in Figure 32.38(b) requires a significantly higher var rating than a corresponding sharply tuned filter to provide the same harmonic absorption at a given frequency, but Figure 32.40 shows that damping and filtering is provided over a range of harmonic frequencies.

Damped filters must have a higher var rating than the corresponding tuned filters to achieve same filtering performance, and their losses are higher. The losses can be reduced significantly by the use of an additional capacitor as shown in Figure 32.38(c) and 32.38(d). In the third-order broadband damped filter the fundamental frequency losses in the resistor are reduced by the use of a capacitor C2 in series with the resistor. In the 'C'-type damped filter a capacitor C2 is connected in series with the inductor L and the fundamental frequency losses are minimised by tuning C2 to resonate with the inductor at fundamental frequency. The 'C'-type filter attenuates low order non-characteristic harmonics, where the losses in a second-order filter would be uneconomically high.

Figure 32.42 shows the bus-bar voltage following energisation of a combination of a 'C'-type and second-order damped filter. The transient can be seen to be virtually damped out within 10–15 ms after energisation.

In general, a combination of tuned and high-pass damped filters will provide the lowest loss solution. However, a combination of damped filters can often provide substantially better service to the a.c. system by preventing resonances.

Figure 32.40 Filter performance

Figure 32.41 Switching transient tuned combination single- and high-pass damped filter

### 32.8.4 Harmonic performance evaluation

The harmonic current generated by the converter is injected into the parallel combination of the filter impedance and the a.c. network impedance as shown in Figure 32.43. Whilst the impedance of the filters can be determined the harmonic impedance of the a.c. system can vary substantially because of line switching operations and load/generation changes in the network. Variation of system impedance with harmonic number for a typical system condition is shown in the polar  $R$ - $X$  diagram of Figure 32.44. Information presented in this manner is more informative than that provided in tabular form at integral harmonics because it gives a clear indication of where the resonant frequencies occur, i.e. when the locus crosses the  $R$  axis. When resonance occurs close to a particular harmonic under

Figure 32.42 Switching transient C-type and second-order damped filter

**Figure 32.43** Circuit diagram for the calculation of harmonic distortion  $V_n$  at harmonic number  $R_n$

consideration there will be a rapid change in impedance with frequency, making it difficult to assess performance accurately. Where the supply system has many different operating configurations it can be assumed that the impedance lies within a circle limited by the impedance angles  $\phi$ , or within a segment of a circle of specified radius. The co-ordinates of such a circle encompass all the anticipated system conditions and enable the determination of the worst case of harmonic distortion to be carried out. A typical example of an harmonic impedance locus specified for filter performance evaluation purposes is given in *Figure 32.45*.

The a.c. network impedance locus is converted into an admittance locus and the worst case of harmonic voltage distortion  $V_n$  due to the converter harmonic current is determined by assuming an a.c. system admittance giving the minimum resultant admittance of the parallel combination of the a.c. harmonic filters and a.c. system.

Pre-existing distortion originating in the a.c. network must be added to the voltage distortion caused by converter harmonic currents. Permitted harmonic voltage distortion levels vary from country to country and according to the a.c. network voltage level, but typical values are 1% for odd harmonics, 0.5% for even ones, and 2% for the total root of the sum of the squares.

Filtering performance must normally be achieved for system voltage and frequency variations and ambient temperatures which can persist for long periods. For conditions which can only exist for short times, it is often acceptable to allow the specified harmonic distortion to be exceeded.

**Figure 32.44** Typical supply network impedance diagram

**Figure 32.45** A.C. network impedance

However, the equipment must be rated for these more arduous conditions.

### 32.8.5 D.c. filtering

The converters produce harmonic voltages between the d.c. terminals of the valve groups. In a 12-pulse scheme the lowest order characteristic harmonic is the twelfth, but because of inevitable imperfections in the a.c. system and the converter circuit, harmonic voltages of other orders will also be present.

The converter circuit contains a d.c. reactor which exhibits a large impedance at high harmonic orders, minimising the harmonic current flowing into the d.c. line. Nevertheless, the voltage and current profile along the line should be calculated and the possible induced noise in nearby communication circuits checked. The current and voltage profile is dependent on the earth resistivity and the line characteristics, and it will vary along the line.

If calculation suggests that unacceptable noise is likely to be induced in nearby circuits it may be necessary to provide filters at the converter station terminals. These filters interact closely with the d.c. reactor and the line, but often it is possible to achieve the required performance by means of a simple damped filter.

*Figure 32.46* shows a typical arrangement of a d.c. filter on a converter pole.

**Figure 32.46** Second-order damped d.c. filter

## 32.9 Reactive power considerations

### 32.9.1 Introduction

Generation and absorption of reactive power constitute major consideration for long h.v.a.c. overhead lines and for much shorter a.c. cables. There is usually a surplus of reactive power at light load and a deficit at heavy load, and it often becomes necessary to provide fixed or variable, shunt and/or series compensation which also affects the stable power transmission limit. While h.v.d.c. lines do not consume, generate or transmit reactive power, converters do. At the a.c. terminals of the converter stations, the solution of reactive power requirements of the converters is combined with the reduction of harmonic distortion.

### 32.9.2 Reactive power requirements of HVDC converters

The converter absorbs reactive power irrespective of whether it is operating as a rectifier or an inverter as explained in Section 32.3.

At the rectifier end the a.c. system has normally some excess reactive power capability. Therefore, the a.c. filters are usually designed to achieve economically the filtering requirements. This may lead to the fact that the MVar rating of filters is lower than the reactive power consumption of the rectifier, the a.c. system supplying the difference. At the receiving end the situation is normally different. Here, reactive power is required not only for inverter operation but also for loads supplied by the inverter. It is normal to specify that the converter station must as a minimum supply all inverter reactive power requirements. System requirements for reactive power can be supplied by additional shunt capacitors in the converter station or situated elsewhere in the system. In bi-directional schemes each end will in turn act as the receiving or the sending end stations.

Figure 32.47 shows the variation of the reactive power  $Q$  with changes in d.c. power for the converter of a 2000 MW scheme. The two continuous curves must allow for all the relevant design and operating tolerances. The nominal reactive power demand of the converters at full load is about 50% of the megawatt rating for this scheme.

In the example considered in Figure 32.47 assuming that the filters are designed to supply all inverter var,  $Q_i$  at rated load, there would be an excess of reactive power supplied to the system at lower powers. This may not be acceptable. In

Figure 32.47 Reactive power of h.v.d.c. converters

such cases filters are designed so that parts can be switched out at lower loads, reducing  $Q_f$ , but always having sufficient filtering capacity. For the example in Figure 32.47 the filter has been divided into four identical banks for filtering of lower order harmonics (indicated as 1C etc. in Figure 32.47) and four banks for filtering higher order harmonics (indicated as 1D etc.).

### 32.9.3 Steady-state voltage control and total ratings of reactive equipment

A.c. system load flow studies including the effects of d.c. link P and Q should be carried out for all likely network situations in order to determine the limiting levels of  $Q$  that the a.c. system would be able to absorb or generate if the network and converter station voltages were to remain within the usual operating limits (e.g.  $\pm 5\%$ ).

The size of harmonic filters necessary from voltage distortion considerations at different power levels should first be determined. Further studies would indicate the required positive and negative range of additional reactive compensation taking account of the tolerances of all components. This additional reactive compensation equipment may be switched in steps or may have a proportion under smooth or continuous control, as determined by the following further considerations.

### 32.9.4 Voltage disturbances caused by switching operations and requirements for smooth reactive control

Step changes of reactive power caused by switching of shunt capacitors and filters have to be limited in order to minimise voltage disturbances to other consumers and to the h.v.d.c. converter itself. The permissible magnitude of voltage step may be appreciable for infrequent occurrences (e.g. 3%) but for frequent events the value may have to be smaller (e.g. 1% or 1.5%). Such step changes may be regularly imposed by filter switchings corresponding to the daily load cycle. If the minimum practical step change is not acceptable some form of smooth acting var compensator should be considered, such as a static var compensator as described in Chapter 41.

### 32.9.5 Control of temporary overvoltages caused by faults resulting in partial or total loss of d.c. power flow<sup>15</sup>

Changes in the system conditions, such as line and load switching, may cause sudden changes of reactive power; the balance between the demand and the supply of reactive power will be disturbed which will result in voltage changes. The overvoltage which may result from such a reactive power change is termed the temporary overvoltage (TOV). TOV refers to the total overvoltage waveform: the fundamental component of TOV plus any oscillatory superimposed component.  $TOV_f$ , the fundamental component of TOV can be calculated from the following equation (in per unit) for complete loss of full d.c. load at rated a.c. bus voltage. ( $TOV_f$  replaces the previously used term DOV (dynamic overvoltage)):

$$TOV_f = [1 + 2Z_e(P_d \cos \phi + Q_d \sin \phi) + Z_e^2(P_d^2 + Q_d^2)]^{1/2}$$

where  $Z_e$  is the a.c. system effective impedance which includes station shunt and filter capacitors,  $\phi$  is the damping angle of the a.c. system impedance,  $P_d$  is the d.c. power, which is positive for the rectifier and negative for the

inverter, and  $Q_d$  is the reactive power consumed by the converter, which is positive for the rectifier and the inverter. All quantities (except the angle  $\phi$ ) are in per unit of  $P_d$ . From Section 32.12.3 it can be seen that the effective a.c. system impedance is  $1/[Y_m + Y_c] = ESCR$  for  $P_d = 1.0$  p.u.

D.c. load rejection resulting, for example, from a d.c. line fault can lead to excessive temporary overvoltage at converter station bus-bars because the connected filters and capacitors represent a substantial surplus over the reduced var demand of the converter. The worst disturbances for a converter at one end of the d.c. link are usually due to faults in the a.c. system at the other end. This normally results in reduced power flow, the exact nature of it being dependent on whether the converter is operating as a rectifier or an inverter.

Faults in the a.c. system, at the remote rectifier end, cause low d.c. line voltage giving low d.c. power flow. The d.c. link is usually designed to attempt to ride through such temporary system faults. Usually the rectifier-end fault situation is communicated to the receiving end by a telecommunication link, but, in order to discriminate against temporary, rapidly cleared rectifier-end faults, no protective switching action is initiated at the inverter terminal for a few hundred milliseconds. Subsequently the converter is blocked and the filter and other capacitors are switched off to reduce the overvoltage.

The transient load rejection effect on the a.c. system of such inverter blocking should be investigated for the a.c. network conditions of minimum fault level at which full power could be transmitted. As an example, a theoretical fundamental component of temporary overvoltage,  $TOV_f$  of about 1.35 p.u. at power frequency, may be expected at the inverter station a.c. bus-bars for a system short circuit level of three times the d.c. power level (short-circuit ratio (SCR) =  $\frac{3}{2}$ ; see Section 32.12), if the a.c. system impedance were a pure reactance. In practice a lower overvoltage will be more usual, due to the resistive effect of network loads. In many urban networks such an overvoltage, even for a fraction of a second, may not be acceptable.

For a rectifier, faults in the remote receiving system have the same effect as a d.c. short circuit. The reactive power demand of the rectifier is then determined by the low voltage current limit (l.v.c.l., see Section 32.10) setting of its current controller. A typical value of l.v.c.l. of 0.3 p.u. would result in reduced var demand compared with the levels provided by the connected filter capacitors, so that there would be some surplus var generation and the rectifier a.c. terminal voltage would rise.

The reduction of such temporary overvoltages due to load rejection cannot generally be achieved by d.c. converter controls themselves. Fast responsive equipment capable of absorbing a large part of the filter Mvar temporarily until the filters can be disconnected is required. Synchronous compensators can only influence this in accordance with their effect on the system SCR, on the basis of  $x_d''$  for two or three cycles and  $x_d'$  for somewhat longer. If a.c. system requirements demand faster control of temporary overvoltage, this can be achieved by switching actions, variable static var compensators may have to be used.

Figure 32.48 compares the calculated dynamic overvoltage for a converter station with and without the presence of static compensators following a fault leading to total d.c. load rejection. To achieve the desired control of the temporary overvoltage, the saturated reactor compensator was designed for reactive absorption overcurrents of three times its rated current. In Figure 32.48 the main parameters of a thyristor controlled reactor (TCR) or of a saturated reactor (SR) compensator required to achieve this rating are summarised.

Figure 32.48 Overvoltages due to h.v.d.c. link blocking

A very large bank of non-linear zinc oxide type resistors could be considered as an alternative as a voltage limiter of high energy capability suitable for repetitive current surges lasting up to 0.5 s or more. At present this would be expensive. (See also Chapter 41.)

## 32.10 Control of HVDC

### 32.10.1 Summary of HVDC controls

Figure 32.50 shows the general arrangement of controls for a typical h.v.d.c. bipole. Progressing backwards from the converter valves these are as follows.

**Valve firing circuits:** these have some protective and monitoring functions, but in normal conditions they act only as an interface between the pole controls and the valves.

**Pole controls:** these are the main controls responsible for changing the firing angles of converters in response to various control loops, and are fast (response time typically 5 ms to 50 ms).

**Tap-changer controls:** these are relatively slow (about 5 s per step) and act only to optimise working conditions of the converters for minimum reactive power, losses, and harmonics.

**Master control:** this is at one station only and controls the whole bipole in response to a power order; it has a slower response than pole controls.

**Telecommunication:** this transmits current order digitally to the remote station, with a check-back signal on a return channel. It may also carry supervisory and other signals.

Figure 32.49 Voltage-current characteristics of static variable reactors in the overload region

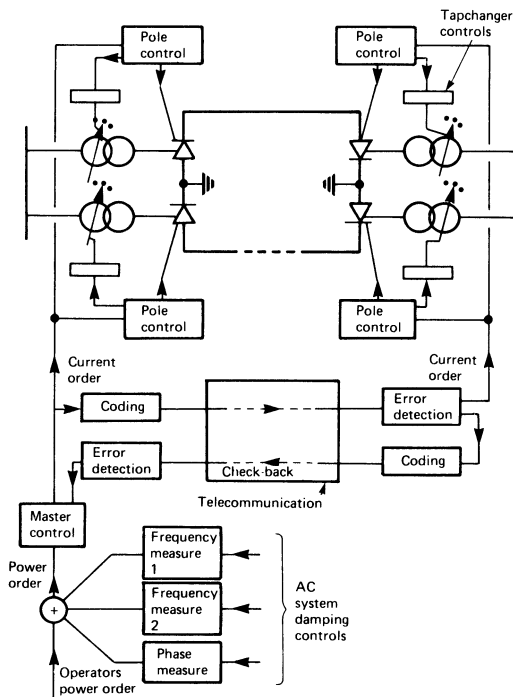

Figure 32.50 Control hierarchy for a bipole h.v.d.c. link

*A.c. system damping controls:* measurement and feedback of various a.c. system quantities to provide damping to one or both a.c. systems, normally acting via the master control. These are discussed individually in Section 32.11.

### 32.10.2 Pole controls

Figure 32.51 shows typical d.c. voltage–current characteristics for the rectifier and inverter respectively as seen from the d.c. line. This diagram effectively summarises the various control loops used in the converters as follows.

**Rectifier:** AB is from a voltage limit loop. BC is from a minimum alpha limit at about  $\alpha = 2^\circ$ , CDE is from a constant current loop at a current equal to current order. FG is the low-voltage current clamp (l.v.c.c.) characteristic and also acts via the current loop, switched to a fixed current order of 0.3 p.u. if d.c. voltage falls below 0.3 p.u.

**Inverter:** HD is from a constant-extinction angle ( $\gamma$ ) loop, typically at  $\gamma = 45^\circ$  to  $18^\circ$ ; KD is a ‘current-error characteristic’ to ensure stable operation near normal voltage.<sup>16</sup> KL is from a constant current loop, at a current lower than current order by the current margin (0.1 per unit). LM is a low-voltage current limit (l.v.c.l.) characteristic obtained by compounding a current loop with measured d.c. voltage.

In normal operation the working point is at the cross-over point D of the two characteristics, corresponding to the inverter in constant gamma ( $\gamma$ ) control determining d.c. voltage, and the rectifier in constant current control determining d.c. current at the ordered value.

If rectifier a.c. voltage falls relative to inverter a.c. voltage, then BC falls, sweeping the working point along DK and perhaps down KL, in a stable manner, i.e. the inverter takes overcurrent control at a current below order by up to 0.1 p.u. It is not satisfactory to omit slope KD because the

Figure 32.51 Typical  $V_d/I_d$  characteristics of rectifier and inverter stations

transition is then too abrupt. The master control will normally correct the resulting power error by increasing current orders.

### 32.10.3 The phase-locked oscillator control system

The type of converter control used in the pole controls of all modern h.v.d.c. schemes is the phase-locked oscillator control system<sup>17</sup> giving nominally equidistant pulse firing. The principal reason for this is its freedom from harmonic instability<sup>18</sup> when the converter is connected to a relatively weak a.c. system, as generally applies when the d.c. power forms a substantial part of the a.c. system infeed.

Figure 32.52 shows the principles of the phase-locked oscillator control in simplified form. Its basic components are a voltage-controlled oscillator, and a 12-stage ring counter (for a 12-pulse converter) which feeds the 12 pulses to the respective converter valves.

The oscillator comprises an integrator, comparator, and short pulse generator, and normally runs at 12 times supply

Figure 32.52 Basic phase-locked oscillator control system

frequency, hence valve firing pulses are normally once per cycle per valve, at an accurate  $30^\circ$  spacing. The oscillator input has a fixed bias  $V_1$ , plus an error signal equal to the difference of the measured quantity for the particular loop (d.c. current as shown) and an order signal. The system settles as for an integral control system, with zero steady-state error, and with firing pulse times (firing angle  $\alpha$ ) at the correct values to obtain this.

In its recent form, the feedback signal is applied 'raw', i.e. without extra smoothing lags, giving fast response and good stability. This applies not only to approximately smooth signals such as d.c. voltage or current, but also to mark/space type signals such as  $\alpha$  or  $\gamma$ . Because this method integrates the input signal, it correctly controls the *mean* value of the controlled quantity. Some methods (including some forms of digital control) do not have this property and tend to respond more to sampled values of the measured quantity near to the normal firing times; this gives excessive response to ripple and sudden disturbances, with poor stability, unless extra smoothing lags are added, which also degrades stability.

All practical control systems must be *multi-loop*, as seen from Figure 32.51 since the operating mode must change according to system conditions at each break. As an example, operation changes between alpha control ( $\alpha \approx 2^\circ$ ) to constant-current control at point C of the rectifier characteristic.

Figure 32.53 shows a recent development of multi-loop control based on multiple oscillators.<sup>19</sup> As an example this is shown for three loops, respectively for d.c. current,  $\gamma$  and  $\alpha$ . (A scheme may use ten or more loops.) Each loop has an individual integrator and comparator, and is coupled via OR and AND gates to a common pulse generator; the latter resets all integrators together, and also operates a common ring counter (not shown) as before. This gives extremely fast and precise handover between modes, without the extra smoothing lags and amplifier desaturation delays which characterise systems which use handover in the pre-oscillator portions of the controls.

The most modern controls include  $\gamma$ -balancing circuits, which equalise  $\gamma$  values even in conditions of a.c. system unbalance; this gives the control the combined advantages of the equal pulse-spacing method (stable operation on weak a.c. systems) and the individual phase control method (maximum real power and minimum reactive power during unbalanced a.c. system conditions).

Flux-control circuits are included to prevent core saturation instability in converter transformers, and also to reduce the effects of even harmonics from the a.c. system or of a small fundamental frequency component on the d.c. line.

Figure 32.53 Loop control system

### 32.10.4 Tap-changer controls

At the inverter station the converter transformer tap-changers are automatically controlled from d.c. voltage to obtain rated d.c. voltage.

At the rectifier the tap-changers are controlled from measured firing angle to hold it within set limits, say  $8-18^\circ$ . The lower limit is as low as possible to give minimum reactive power, losses, and harmonics, while preserving a small control range in case of small a.c. voltage dips. The upper limit is also as small as possible without giving tap-changer control instability [i.e.  $(\cos 8^\circ - \cos 18^\circ) > \Delta \text{tap voltage stepper unit}$ ].

The tap-changers are conventional, and rather slow, but any errors in power before they reach steady values are corrected by the master control.

### 32.10.5 Master control

The principal duty of the master control is to adjust the current orders of the two poles so that measured power is equal to a power order. This is done by direct measurement of total bipole power from the d.c. quantities, subtracting it from the power order signal, and integrating the resulting error signal to generate the 'master current order', which is then applied to both poles in both stations.<sup>20</sup> It is therefore a feedback loop, at a higher level than pole controls, but rather slow (settling time of say, 100–300 ms, depending on telecommunication rate); the telecommunication gives a direct delay when the remote station happens to be controlling current, and an indirect delay even when the local station is in control because it may then have to wait for the checkback signal (see Section 32.10.6 below). However, the master control contains various other functions including special forms of limit; an example of the latter is in recovering from a zero-voltage fault, when it would otherwise try to generate an infinite current order.

The master control will normally control to constant power in the presence of changes of a.c. voltages and other disturbances, subject to maximum current limits applied locally in pole controls. This applies even if the inverter temporarily takes over current control; the master current order will then be temporarily above the actual current.

Where the rectifier and inverter stations are a long distance apart, a telecommunication system (see below) is required to send current order to the remote station. Although schemes have been operated without telecommunications, optimum performance cannot be obtained without it. Generally the master control is at one end and the remote station acts only as a 'slave' without any master control function. It is not in principle important whether the master control is in the rectifier or the inverter station. Both have been used in practice, though a.c. system damping controls (see Section 32.11) may influence the choice.

The power order signal input will normally be set by an operator; either locally or in a remote control centre. It may be modified by a.c. damping controls.

Back-to-back schemes have both converters in one station, hence do not require a long-distance inter-station telecommunication, but their control and performance is otherwise similar to that for long-distance schemes (except that their response is much faster due to the omission of d.c. line capacitance and telecommunication delays).

### 32.10.6 Telecommunication

The main duty of this is to send a current order signal to the 'remote' station. Because practical telecommunication media are subject to noise and interference, signals are

always sent in digital (binary) form, with error checking code.<sup>21</sup> The coding must generally be much more powerful than normally used for sending computer data, because of the serious effect of an undetected error on power flow.

Detected errors are less of a problem since they are arranged to 'freeze' pole current orders in both stations at the last correct value, using a check-back channel.<sup>21</sup> The latter must itself have error-detection coding; this is usually shared with other signals, e.g. supervisory signals or a.c. network damping signals. Since normal operation is steady state, or with very slow change, the effect of brief errors is then negligible. For permanent telecommunication failure the controls are transferred to a simpler manual mode.

Various media are possible for telecommunication. Direct wires via private land lines or the telephone system have been used, but usually only for emergency operation because of their high cost and poor reliability. Power-line carrier is probably the cheapest method. It would require two or three repeaters for say 900 km of overhead line. Interference generated by the converters, penetrating via the d.c. reactors, is greater than normally seen on a.c. systems, and requires special measures. Microwave radio has been used on several schemes. It requires rather short repeater intervals of about 40 km since line-of-sight transmission is required, but its bandwidth is very large and can accommodate many telephone and even television channels in addition to the h.v.d.c. control requirements.

Tropospheric scatter radio is another possible method, requiring repeater intervals between 200 and 500 km depending on transmitter power. It is subject to heavy fading, and requires multiple redundant channels and multiple antennae to give an acceptable basic signal error rate. Optical fibre is being used more and more for medium-distance telecommunications, and has been installed experimentally inside power conductors and overhead earth wires. It is almost immune from interference and has wide bandwidth but would require repeaters about every 100 km at present, though future improvements to this are expected.

The choice of telecommunication will depend on cost and the policy of the utility. Generally a baud rate of 2400 (block period about 50 ms) will be adequate to obtain sufficient bandwidth for damping a.c. system swings up to about 1 Hz.

### 32.10.7 Performance examples

Figures 32.54–32.57 are oscillograms taken from simulator tests showing the behaviour of a typical h.v.d.c. link for a.c. and d.c. faults. These are all for the relatively onerous case of a weak receiving system (effective short-circuit ratio 2.4, impedance angle  $75^\circ$ ), and at rated power.

Figure 32.54 Three-phase 100% fault at the inverter

Figure 32.55 One-phase 40% fault at the inverter

Figure 32.56 Three-phase 100% fault at the rectifier

Figure 32.54 is for a three-phase fault close to the inverter a.c. bus-bar. There is an initial current surge, then the current settles to 0.3 p.u. during the fault, at zero d.c. voltage. After fault removal, most of the recovery occurs in about 100 ms, but the last part of the recovery is relatively slow because of the effect of magnetising inrush current of converter transformers on a.c. voltages.

Figure 32.55 is for a more remote fault in the a.c. system fed by the inverter, which reduces a.c. voltage by about 40%. There is an initial commutation failure, but commutation is then restored at reduced voltage until the fault is removed, with recovery as before.

Figure 32.56 shows a three-phase fault at the rectifier. D.c. current falls to zero during the fault, and recovery afterwards is similar to Figure 32.54.

Figure 32.57 shows a fault, e.g. due to lightning, about halfway along a d.c. overhead line. The fault reduces d.c. voltage to an average of zero, with line oscillations and a rectifier current surge. The rectifier starts to reduce current to 0.3 p.u., but a line fault detector relay operates at 30 ms after the fault, forcing complete (temporary) shut-down; by about 40 ms both rectifier and inverter currents are at zero.

Figure 32.57 D.c. line fault

Figure 32.58 Three-phase fault at the inverter (ESCR=1.5)

After waiting about 100 ms for transient line currents to decay, and the fault arc to de-ionise, power is then restored to normal. This simple action appears to be sufficient in most real cases, though if necessary operation can be more complicated, with several re-starts.

To illustrate several of the points discussed above, Figure 32.58 shows an oscillogram from simulator tests showing the behaviour of an h.v.d.c. link for a three-phase fault at the inverter, similar to Figure 32.54 but with a very low value of effective short circuit ratio (see Section 32.12)  $ESCR = 4.5 \angle 75^\circ$ . This gives good performance, only slightly worse than for Figure 32.54 ( $SCR = 4$ ), with fast recovery and good stability without using special controls. However, in practice, for an a.c. system so weak, the excessive a.c. voltage changes to which consumers may be exposed following, say, a d.c. line fault, may not be acceptable. In such a case some form of fast reactive control, such as a static var compensator, may have to be used.

### 32.11 A.c. system damping controls

The normal duty of an h.v.d.c. link is to transmit power at a preset level set, usually, by an operator. However, h.v.d.c. is a very powerful control device as it is capable of changing transmitted power in a controlled manner, rapidly and by a large amount and thereby influencing the a.c. system transient performance significantly. Three main system conditions are discussed below.

#### 32.11.1 D.c. link supplies power from dedicated generators or from a very strong system to a small system<sup>22-24</sup>

Figure 32.59 shows a block diagram of the Nelson River h.v.d.c. transmission scheme in Manitoba, Canada. The scheme is essentially a 900 km long, 'asynchronous' interconnection from remote hydro generation to an urban industrial load area. The d.c. link controls are arranged to produce a current order in response to four principal signals:

- (1) Steady-state power order from the system dispatch control.
- (2) Transient power order in response to the receiving end load area frequency changes; this provides receiving frequency control by the d.c. link of the form usually carried out by governors with defined droop characteristics.

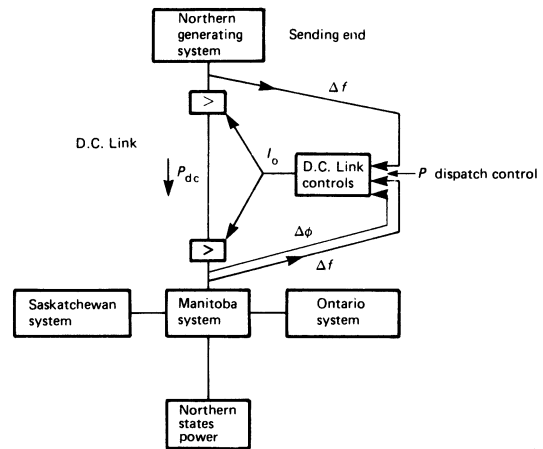

Figure 32.59 Block diagram of the Nelson River transmission scheme

- (3) Transient power order in response to frequency changes at the sending end; this assists the hydrogenerator governors in controlling the sending end frequency.
- (4) Transient power order in response to the inverter a.c. bus voltage phase angle changes; this signal modulates d.c. power to provide swing damping within the local network and also between the local (Manitoba) power system and the three neighbouring systems of Ontario, Saskatchewan and the USA Northern States Power Pool. The power change required for swing damping is usually quite small, typically less than 10% of rated h.v.d.c. power.

Figure 32.60 illustrates the damping effectiveness of the frequency controls on the speed (frequency) of the receiving end (Manitoba) system equivalent machine and on the sending end generator at the Kettle generating station. Figure 32.61 shows site measurements of an inadvertent loss of h.v.d.c. system damping control; before this event the system frequency is well damped, but after the loss of damping, sustained oscillations at about 0.3 Hz are to be observed on the nominal 60 Hz frequency trace. (These appear rather small on a frequency trace, but power oscillations in tie-lines are much larger in proportion.) In this scheme the damping

Figure 32.60 Nelson River transmission scheme: rotor frequencies following on disturbance without (left) and with (right) d.c. link system damping controls

**Figure 32.61** Site measurements showing the effect of loss of h.v.d.c. damping controls on a.c. system frequency

signal (4) is based on measurement of the rate of change of the absolute phase of the inverter a.c. bus voltage using a phase-locked oscillator. Direct derivation of a network frequency signal would require filter circuits which generally reduce the sensitivity and accuracy of the measurement.

Signal (4) is effectively 'a.c. coupled' having no effect in steady state; signals (2) and (3) may be either of this type or may be d.c. coupled to influence steady-state operation. Various other signals are also possible for particular systems, for example power in a tie-line.

The use of a damping signal such as (4) above (which is relatively fast) may influence the location of the master control. The average response to modulation at the master control is not much affected by its location (at rectifier or inverter stations) but if it is remote from the source of the fastest damping signal then an extra delay will occur in its loop because of the necessity for sending the damping signal via telecommunication; this is undesirable, hence the master control should be at the end where the highest natural frequency (e.g. 1 Hz) is to be damped. This may require the operator's power order to be sent via a telecommunication channel, but this is rather easy since a relatively slow channel can be used.

### 32.11.2 D.c. link connecting two systems which are not synchronised but are of similar size

Care must be taken that the requirements of one system do not adversely affect the other. For example, two systems of similar size may have the same dominant natural frequency, say, in the region of 0.5–1 Hz. In this case it will generally be necessary to provide damping signals from both a.c. systems, so that a disturbance in one system is shared between the two; this will slightly disturb the healthy system, but in a heavily damped manner. (Taking a damping signal from one a.c. system only will cause disturbance in the healthy system which may not be damped by the d.c. link.) It should be noted that even if the converter is operated at its maximum rating, a degree of damping can be achieved by power reduction modulation only.

### 32.11.3 D.c. link connecting two parts of an a.c. system or two separate systems having also a parallel a.c. link

Figure 32.62 shows a simple diagram illustrating parallel a.c. and d.c. transmission.

The Pacific Intertie on the USA West Coast is an example of an h.v.d.c. link between two a.c. systems which also have long interconnecting a.c. lines. Initially this scheme was operated with constant power control, but in the mid-1970s additional power modulation controls were provided which

**Figure 32.62** Block diagram of simple parallel a.c. and d.c. transmission

considerably enhance its use by arranging for the transient stability of the a.c. lines to be improved. In such applications, the amount of power modulation required to achieve beneficial transient stability and swing damping effects is generally small compared with the transmitted power.

There are several examples in Canada, USA and Europe of back-to-back h.v.d.c. links between two large systems where an a.c. interconnection would have been much less advantageous technically and economically. By providing controllable d.c. power flows in the interconnection, even in the event of a major disturbance in either a.c. system, the h.v.d.c. links can help reduce the instabilities, and prevent complete system collapse situations by avoiding the cascading of disturbances which could otherwise occur in uncontrolled a.c. ties.

## 32.12 Interaction between a.c. and d.c. systems<sup>25–27</sup>

### 32.12.1 Study of HVDC systems

The relationship between an h.v.d.c. link and the a.c. system to which it is connected can be considered in two categories.

- (1) The line commutated converter depends for its operation on being supplied with a reasonable sinusoidal voltage. A distorted voltage, or a significant unbalance of the three-phase system voltage such as occurs during faults, will detract from the essentially symmetrical rectification and inversion processes.
- (2) The rectifier takes from its a.c. system both power ( $P$ ) and reactive power ( $Q$ ). The inverter feeds power to its a.c. system but takes the reactive power from it. If the d.c. link is relatively large compared with the a.c. system to which it is connected, any large changes in  $P$  and  $Q$  could have significant effects on the system.

A.c. system disturbance can affect the operation of a small converter but maloperation of a small converter will have negligible effects on the a.c. system. However, it is not uncommon for an h.v.d.c. link to supply a large proportion of the a.c. system load so that the loss of d.c. power and associated reactive power changes can have a profound effect on the system.

The effects of h.v.d.c. operation and maloperation can be simulated accurately using loadflow, transient stability and other digital programmes as regards category (2) above and by the use of an h.v.d.c. simulator and digital programmes, such as electromagnetic transient programmes (EMTPs) as regards category (1) above.

An a.c./d.c. simulator is an important tool in the study of h.v.d.c. In particular, its use is important in the development

Note that both SCR and ESCR always have an angle as well as magnitude. Thus, for example, for a system with  $\text{SCR} = 3 \angle 80^\circ$  the addition of 0.6 p.u. of capacitors plus filters gives  $\text{ESCR} = 2.4 \angle 78^\circ$ . If the simplification of a system impedance angle of  $90^\circ$  is assumed, then, in short-circuit MVA form

$$\text{ESCR} = \frac{S - Q_c}{P_d} \quad (32.11) \Leftarrow$$

where  $Q_c$  is equal to the sum of the fundamental frequency MVA of a.c. filters and of any additional shunt capacitors connected to converter station terminals.

Figure 32.64 indicates the definition of SCR and ESCR.

**SCR:** the value of the admittance  $Y$  at the fundamental frequency, on the base of the rated d.c. power at the rated a.c. voltage.

**ESCR:** is defined as SCR except that the admittance includes the admittance of the capacitor,  $Y = Y_s + Y_c$

It should be noted that because a.c. systems are largely inductive, it is the change of reactive power which is mainly responsible for the effect of converter behaviour on the a.c. network voltage. Most schemes in the past were designed with transformer reactance of the order of 20% or more to limit the thyristor fault current. The availability of large thyristors and the pressure of cost of losses, are responsible for some schemes being designed using a larger thyristor than necessary in order to reduce the losses. An additional benefit is that it is possible to design the transformer for any suitable reactance down to, say, 11%, as the oversized thyristor has correspondingly larger surge current capability.<sup>28</sup>

Lower converter transformer reactance can bring a number of advantages, including:

- (1) converter reactive power consumption ( $Q_d$ ) will be reduced;
- (2) a.c. filters and any additional shunt capacitors are normally designed to supply at least all converter reactive power (the amount of shunt-capacitor compensation can be reduced, reducing the cost and increasing ESCR);
- (3) temporary overvoltages will be reduced, due to smaller shunt capacitors; and
- (4) rating of equipment such as surge arresters may be reduced.

SCR and ESCR represent the a.c. system reasonably accurately for the short time-scale considered. However, the SCR concept should be used mainly to get a 'feel' of the system, which should be followed with adequate studies.

### 32.12.3.3 QESCR

Two converters may be rated for the same d.c. power, but their transformers may be designed to have different reactances and they may be operating at different values of  $\alpha_s$  and  $\gamma_s$  and, therefore, they would consume different amounts of reactive power. Both SCR and ESCR are referred to d.c. power and do not take into account the converter reactive power,  $Q_d$ .  $Q_d$  can be partly taken into account by referring the SCR to the sum of the power and the reactive power ( $P_d + Q_d$ ). Thus,

$$\text{QESCR} = (S - Q_c) / (P_d + Q_d) \quad (32.12) \Leftarrow$$

### 32.12.3.4 Operational short-circuit ratios (OSCR, OESCR and QQESCR)

For operation at conditions other than at rated load, often at loads lower than rated, the corresponding operational

short-circuit ratios (OSCR, OESCR and QQESCR) must be used: appropriate minimum short-circuit capacity of the a.c. system, actual values of shunt capacitors and power level, not the rated power, must be used.

## 32.12.4 Voltage/power curve

A simplified representation of two a.c. lines feeding a load is given in Figure 32.65(a) and the well known voltage/power curve of the simple a.c. system is drawn in Figure 32.65(b). As the load current increases, the power factor rises until it reaches a maximum. After that point, due to the increasing line voltage drop, a sharp decrease in power occurs. The operating point is normally at a power level sufficiently smaller than the maximum power point to avoid voltage collapse due to, say, a temporary load increase or trip of a line. The curve in Figure 32.65(b), for illustration purposes, was calculated assuming operation at the point of maximum power; it was further assumed that the load power factor is unity and the small a.c. line resistance was neglected. The fundamental component of the temporary overvoltage (TOV<sub>f</sub>) for total load rejection for assumed conditions is equal to  $\sqrt{2}$ , as can be seen from Figure 32.65.<sup>29</sup>

A converter, rectifier or inverter, behaves as a static a.c. load. At the sending end, the rectifier can be represented as a  $P$  and  $Q$  load, with  $P$  positive and  $Q$  also positive (lagging). At the receiving end, the inverter delivers power, but consumes vars;  $P$  is negative, while  $Q$  is positive as for the rectifier. If, for approximate calculations, the small a.c. line resistance is neglected, the voltage/power curves of an a.c. load, a rectifier and an inverter are identical, for the same values of  $P$  and  $Q$ . Moreover, d.c. converters are normally compensated to operate near unity power factor and, therefore, the curve

(a)

(b)

**Figure 32.65** (a) Representation of a simplified a.c. system. (b) A.c. voltage/power curve (unity load power factor)

Figure 32.66 D.c. power/current curve for minimum  $\gamma$

of Figure 32.65(b) is in general relevant to h.v.d.c. operation near the point of maximum power, as discussed later.

### 32.12.5 Maximum-power curve

D.c. transmission is carried out at maximum designed d.c. voltage, for reasons of economy; the transmitted power is regulated by variation of the d.c. current. For this reason it is customary to plot d.c. power against d.c. current as shown in Figure 32.66. Maximum d.c. voltage is obtained by operating the inverter at the minimum permissible commutation margin angle ( $\gamma$ ), as discussed in the Section 32.3.3. The power/current curve for operation at the constant minimum  $\gamma$  is termed the maximum power curve (MPC). This curve is generated by increasing and decreasing d.c. current from the initial conditions at the operating point A. Usually the starting point corresponds to the rated d.c. current and d.c. voltage at the rated a.c. voltage. MPC corresponds to transient conditions after the d.c. current was changed. The a.c. voltage is not controlled, but drops as the d.c. current increases; automatic voltage regulators, tap-changers, shunt reactors and capacitors are assumed fixed, which is what happens in practice for the first 100–300 ms after the onset of a transient disturbance. For definition of MPC, it is assumed that fast voltage control by thyristor-controlled rectifiers or saturated reactors, which would be comparable in speed to d.c. current changes, are not used.

No power greater than that corresponding to MPC can be obtained, unless the a.c. voltage feeding the converters is increased. On the other hand, any power can be obtained below the MPC by increasing  $\gamma$ . Similar MPC curves can be drawn for rectifier operation by replacing  $\gamma$  with  $\alpha$ .

As indicated in Figure 32.66, a d.c. link is provided with a current limit, acting at the rectifier. This means that d.c. converters can operate closer to the maximum power point without risking a voltage collapse (see Figure 32.65(b)). In fact, a d.c. link can be made to act as its own thyristor-controlled rectifier (see Chapter 28) and respond to an a.c. voltage signal to reduce its power, and therefore its reactive power, and so prevent excessive a.c. voltage reductions.

### 32.12.6 Maximum available power

The maximum value of the MPC has been termed the maximum available power (MAP). The value of MAP, for a given a.c. system impedance (SCR), depends on the converter station rated reactive power and, therefore, it is a function of the commutating reactance  $x_c$ , usually equal to the converter transformer reactance, the value of minimum  $\gamma$  (or  $\alpha$ ) and the amount of shunt capacitance of the station.

Figure 32.67 Variation of inverter a.c. terminal voltage and power with d.c. current

MPC curves of an inverter of given characteristics ( $x_c = 0.15$ ,  $\gamma = 18^\circ$ ,  $Q_c = Q_d = 0.54P_d$  at  $U_L = 1.0$  p.u.; see Figure 32.64 for interpretation of the symbols) for four different values of SCR are plotted in Figure 32.67. These curves assume that the rectifier will not cause limitation of power demanded by the inverter. However, it should be noted that similar MPC curves apply for the rectifier operation. Depending on the strength of the sending-end a.c. system and on the design of its a.c. to d.c. converter system, i.e. on the voltage control and on the value of the operating  $\alpha$ , the rectifier may transiently impose limitation on d.c. power. Therefore, the design of the sending and receiving a.c. to d.c. converter systems must be co-ordinated.

### 32.12.7 Classification of the a.c./d.c. system strength

An a.c./d.c. system has to be designed to be able to deliver the specified power for the specified a.c. system conditions, including outage situations. Loss of a part of a system or of a transmission line will increase the impedance of the a.c. system. The SCR of the simple system shown in Figure 32.65 (a) may be assumed, for example, to reduce from 3 to 2 with one line tripped with consequent reduction of maximum power, as shown in Figure 32.68.

The relationship between MAP and the required power for specified system conditions is used to classify the a.c./d.c. system strength.

#### 32.12.7.1 High SCR a.c./d.c. system

The strongest a.c./d.c. system of the four considered in Figure 32.67 is the one corresponding to  $SCR = 4.5$  and having  $MAP = 4.28$  p.u. of rated power. With this much power margin, MAP is unlikely to get reduced for expected outage conditions below the rated power and such a system is termed a *high SCR a.c./d.c. system*.

**Figure 32.68** A.c./d.c. system: low SCR power and a.c. voltage curves; sudden change of SCR from 3 to 2

### 32.12.7.2 Low SCR a.c./d.c. system

For the system represented by  $SCR=3$  in Figure 32.67,  $MAP=0.8$  of the rated power, and it is likely that MAP will reduce below the rated power for some outage conditions. For the example shown in Figure 32.68 MAP is reduced to 0.96 p.u. of rated power at point A, following the trip of one line. This intermediate condition is termed a *low SCR a.c./d.c. system*. As described in, Section 32.10.5, the current of a d.c. link is automatically adjusted so that the measured power is equal to the power order. If the power order has a higher value than MAP, then an increase of current beyond  $I_{MAP}$  would result in power reduction, because the line voltage drop increases at a higher rate than the current increase due to the increased inverter reactive power consumption. In general, there are three possible ways to deal with such outage conditions.

- (1) For operation beyond MAP, change from power mode of control to constant-current control, and accept operation at a lower power level until a.c. system conditions are restored. The disadvantage of this approach is that the transmitted power would vary in sympathy with the a.c. voltage variations and would not be suitable for schemes where the d.c. power is used to respond to an a.c.-system-stabilising signal.
- (2) Reduce the power level order and continue to operate in power control mode on the 'stable' part of the power curve, that is at the left side of MAP. This has the advantage that the control of d.c. power would be retained, albeit at a lower power level.
- (3) If it is important to maintain full power without waiting for system conditions to improve, automatic switching of additional shunt capacitors should be used to maintain a.c. voltage and, therefore, the power level.

### 32.12.7.3 Very low SCR a.c./d.c. system

If the normal operating point is on the 'unstable' part of the power curve, i.e. at the right of MAP, where  $dP/dI$  is

negative, as for the case of  $SCR=4.5$  (point A in Figure 32.67) then the system is described as a *very low SCR a.c./d.c. system*. (There may appear to be an operating point (B in Figure 32.67) on the stable part of the curve on the left of MAP on MPC for  $SCR=4.5$  for 1 p.u. power. However, examination of Figure 32.67 for  $SCR=4.5$  will show that this point corresponds to an a.c. voltage which cannot be utilised as it is much higher than the rated voltage.)

Figure 32.67 shows that the a.c. voltage at total load rejection ( $TOV_f$ ),  $I_d=0$  for  $SCR=4.5$ , may be in the region of 1.7 p.u., ignoring transformer saturation.

The main criterion in the design of synchronous compensators, when used to reduce the a.c. system impedance as seen by the converter, was the limitation of  $TOV_f$  to acceptable values. This inevitably changed a *very low SCR* system to a *low SCR* system and shifted the normal operating point to the left of MAP, i.e. to the 'stable' part of the power curve. However, the availability of zinc oxide arresters has made it possible to control TOV without the need to use a synchronous compensator for that purpose.

There are two possible ways of operating with very low SCR systems, and thus avoiding the need to use the synchronous compensators for the sole purpose of reducing TOV.

- (1) A.c. voltage can be controlled by a fast static var compensator (SVC). This can be a satisfactory solution, provided the SVC operation is continuous and faster than the required d.c. power-control loop. Automatically switchable shunt-capacitor banks are needed to keep the current of the thyristor-controlled reactor (TCR) or saturated reactor (SR) of the SVC in the controllable range.
- (2) A more economic way is to use the inverter to control the voltage as shown in Figure 32.69. Controlling the d.c. voltage by varying  $\gamma$  makes  $dP/dI$  positive in the normal operating range (along the line A-B), providing stability in power-control mode. For operation at constant  $\gamma$ ,  $dP/dI$  is negative (point B and beyond) and an increase in current would cause a decrease in power; as discussed in Section 32.12.7.2 for transient operation, in that region constant current control mode must be employed.

**Figure 32.69** Operation with variable  $\gamma$  control to maintain the d.c. voltage constant

The inverter must be designed to operate at  $\gamma$  larger than the minimum in the steady state. In the example in *Figure 32.69*,  $\gamma$  is assumed to be  $24^\circ$  at the rated conditions (point A). By keeping d.c. voltage constant, the a.c. voltage changes near point A are reduced. Capacitor switching and transformer tap-changing are used to control the a.c. voltage in the steady state to keep  $\gamma$  in the required range, between, say,  $30^\circ$  and the minimum value of  $18^\circ$ . The effects of a.c. voltage control and the use of the inverter in TCR mode to control a.c. overvoltages are not shown.

Inverter data for the examples given in *Figures 32.67* and *32.69* are the same, except that in *Figure 32.67* the 1 p.u. power corresponds to  $\gamma = 48^\circ$  and in *Figure 32.69* to  $\gamma = 24^\circ$ . As  $Q_d$  is larger for  $\gamma = 24^\circ$ , the potential value of  $TOV_f$  is larger, as can be seen by comparing a.c. voltages on the two figures for  $SCR = 4.5$  for zero current. It should be remembered that, in practice, these overvoltages would be reduced by transformer saturation; the value of the oscillatory component of  $TOV$  will depend on the a.c. system damping and the system resonant conditions.

By increasing the current from 1.0 p.u. and allowing  $\gamma$  to reduce from  $24^\circ$  to the minimum value of  $18^\circ$ , power will be increased to the maximum value of 1.07 p.u. More power could be obtained only by restoring the a.c. voltage as discussed above.

The method of operation described has been employed in a number of recent d.c. schemes. To summarise, the most economic operation is at the minimum  $\gamma$  (minimum cost of equipment, minimum losses, minimum generation of a.c. harmonics, and minimum consumption of vars), which can be done for high and low SCR systems. For operation with very low SCR systems the variable  $\gamma$  mode of control must be adopted, at a normal value of  $\gamma$  above the minimum, or fast SVCs should be used.

## 32.12.8 Critical short-circuit ratios

### 32.12.8.1 Definition and calculation

If the operating point coincides with MAP ( $SCR = 2$  in *Figure 32.67*), then the corresponding SCR is termed critical (CSCR, CESC, or CQESC). The exact equation for CESC can be found in references 25 and 27.

The angle  $\phi$ , representing the system damping, has a small effect on CESC in the region of  $70^\circ$ – $90^\circ$ . Therefore, by assuming  $\phi = 90^\circ$ , a simple formula is obtained for CESC:

$$CESC = \frac{1}{\sqrt{2}} [-Q_d + P_d \cotan \frac{1}{2}(90^\circ - \gamma - \phi)] \quad (32.13)$$

where  $U$  is the converter a.c. bus voltage per unit,  $P_d$  is the power supplied by the inverter per unit,  $u$  is the overlap angle of the inverter,  $\gamma$  is the commutation margin (extinction angle) of the inverter, and  $Q_d$  is the reactive power consumed by the inverter. CESC can be calculated from equation (32.13) by adding to it  $Q_c$  in per-unit of  $P_d$ .

For a given  $P_d$  and  $U$ , CESC depends on  $\gamma$  and  $u$ . As  $u$  is a function of  $\gamma$  and the commutating reactance ( $x_c$ ), CESC is a function of  $x_c$  and  $\gamma$ . In *Figure 32.70* CESC (calculated using the exact formula given in references 25 and 27), CSCR and CQESC are plotted against  $x_c$  for  $\gamma = 45^\circ$  and  $20^\circ$ ;  $\phi = 90^\circ$  and  $70^\circ$ ; and for  $Q_c/Q_d = 4$  and 1.5.

CSCR varies by just over 50% for the assumed data. As discussed earlier, CESC takes into account the value of  $Q_c$  and the variation is reduced to 27%. CQESC takes account of  $Q_c$  and  $Q_d$ , and varies by 10%, from 0.9 to 1.0.

Figure 32.70 Sensitivity of critical short-circuit ratios

### 32.12.8.2 Significance of critical short-circuit ratios

**Control-mode requirements** CSCR represents a borderline between 'stable' and 'unstable' parts of the power curve when the rectifier is in power control and the inverter is in constant  $\gamma$  control. Normal operation at the right side of MAP can be carried out only if a.c. voltage is closely controlled. Moreover, if the operation is very close to MAP, even on the stable side, fully satisfactory operation can be achieved only if a.c. voltage is well controlled.

**Expected levels of temporary overvoltages** CSCR provides an indication of the expected temporary overvoltages.  $TOV_f$  for load rejection from MAP, i.e. at SCR will have a value near 1.4 p.u.; for higher values of SCR,  $TOV$  will be smaller and for lower values it will be higher, as can be seen from *Figure 32.67*.

**Expected resonant frequency** The resonant frequency which may occur between the converter station and the system is principally governed by the system impedance and the station shunt capacitors and can be expressed as

$$f_r = f_o \sqrt{S/Q_c}$$

where  $f_r$  is the resonant frequency and  $f_o$  is the system frequency.

From  $SCR = S/P_d$  for the case when  $Q_c = 0.5 P_d$

$$f_r = f_o \sqrt{2SCR} \quad (32.14)$$

From equation (32.14), for  $SCR = 2$  the resonant frequency would be near the second harmonic. From *Figure 32.67* it can be seen that  $SCR = 2$  corresponds to CSCR for average inverter data.

**Instantly available additional power** The value of the short-circuit ratios gives an indication of additional power immediately available for high and low SCR systems, as indicated by the difference between the rated power and the MAP value (*Figure 32.67*). For the average inverter data used in *Figure 32.67*, the immediate power margin for  $SCR = 4.5$  is equal to 1.28 p.u. at  $I_d = 4.74$  p.u., and for  $SCR = 3$  it is 1.08 p.u. at  $I_d = 4.32$  p.u.

## 32.12.9 Short-circuit ratio as a guide to system planning

For average converter data ( $x_c = 45\%$ , and minimum  $\gamma = 48^\circ$ ) it can be concluded from *Figure 32.67* and the

discussion in Section 32.12, that SCR will have the following approximate average values for different system strengths:

High SCR (strong), a.c. system:  $\text{SCR} \gg 3$   
 low SCR (weak), a.c. system:  $\text{SCR} \gg 2$   
 Very low SCR (very weak), a.c. system:  $\text{SCR} \ll 2$

The above values of the SCR are only approximate. As described in the previous section, it is the value of the critical SCRs which determines whether a system behaves as having high, low or very low SCR values; as discussed and seen from Figure 32.70 for different inverter data the CSCR values vary greatly.

The cost of a converter station will be higher for low and particularly for very low SCR systems. It is therefore important to obtain an approximate value of CSCR as early as possible in the planning stages of a scheme. In the early planning stages, the short-circuit MVA of the a.c. system, the proposed d.c. power and the amount of desirable reactive power compensation, may be the only known data, which would have a bearing on the CSCRs. An approximate value of CSCR can be obtained quickly from equation (32.12), by using the following equation, expressing all quantities in per unit of  $P_d$ ,

$$\text{SCR} = \text{QESCR}[1 + Q_d] + Q_c \quad (32.15) \Leftarrow$$

and, as CQESCR is approximately equal to 1, a good approximation for CSCR is

$$\text{CSCR} = \text{CQESCR} + Q_d + Q_c \quad (32.16) \Leftarrow$$

In Figure 32.71 CQESCR and  $Q_d$  (average value for  $\gamma \leq 18^\circ$  to  $20^\circ$ ) are plotted against the commutating reactance, which is normally equal to converter transformer reactance. Consider two examples.

- (1)  $x_c = 15\%$ ,  $\gamma \leq 18^\circ$  and  $Q_c = Q_d$  (average data): using values of CQESCR and  $Q_d$ , from Figure 32.71 equation (32.16) gives CSCR = 2.05, while the correct value is 2.0.
- (2)  $x_c = 20\%$ ,  $\gamma \leq 20^\circ$  and  $Q_c = 1.5 Q_d$ : as for (1), equation (32.16) gives CSCR = 2.6, while the correct value is 2.58.

### 32.12.10 'Island' receiving system<sup>25</sup>

It is possible to supply most or all of the system power requirements to an island system by h.v.d.c. The example for such a scheme is the d.c. link supplying power from the Swedish mainland to the island of Gotland.<sup>30</sup> A more recent scheme bringing power to the South Korean island Cheju has a similar requirement.<sup>43</sup>

Figure 32.71 CQESCR and  $Q_d$  as a function of  $x_c$

The a.c. line commutated converter, as used in h.v.d.c., depends for its operation on being supplied with an a.c. voltage of reasonable sinusoidal waveform. During a fault disturbance, say an a.c. system short circuit, the inertia of turbines and generators provides the energy to maintain the required system e.m.f. If all or most of the power is supplied to a network by h.v.d.c., the system inertia will be inadequate to provide transiently the required e.m.f. following a fault. In such cases a synchronous compensator is installed so that its inertia acts as a 'transient generator' to maintain the e.m.f. for sufficient time following a fault to enable the d.c. link to resume transmission.

Analogously to SCR, the required  $H$  constant of the synchronous compensator can be referred to  $P_d$ :

$$H_{dc} = H \cdot \text{MVA}_{sc} / P_d$$

where  $H$  is the inertia constant of the synchronous compensator and  $\text{MVA}_{sc}$  is its MVA rating.

$H_{dc}$  can be calculated as

$$H_{dc} = P_{dc} \cdot dt \cdot f_o / 2 \cdot df \quad (32.17) \Leftarrow$$

If the frequency drop ( $df$ ) is limited to 5%, for loss of power for  $dt = 200$  ms (fault duration, breaker clearance, and time to get back to full power), then from equation (32.17)  $H_{dc} = 2$  s.

A synchronous compensator dimensioned from the inertia point of view, will contribute sufficiently to the SCR value to convert a very low SCR system to a system having a high or, at least, low SCR value.

### 32.12.11 System interaction when the a.c. system impedance is high relative to d.c. power in-feed (low short-circuit ratio)<sup>25-27,31</sup>

The important and desired interaction between a.c. and d.c. systems is beneficial. D.c. can bring power into an a.c. system in a controlled way and can assist the a.c. system by improving its frequency control, stability and damping. The design of the converter system must allow for:

- (1) steady-state stability;
- (2) recovery after a.c. or d.c. faults; and
- (3) a.c. and d.c. overvoltages.

#### 32.12.11.1 Steady-state stability

**Power and voltage instability** This is a steady-state cumulative type of instability which can occur at low and very low SCR at the inverter end when power control modes are used. The simplest cure is to design the master controller to give a not-quite constant power-control when necessary. This and other methods<sup>25,32,33</sup> to prevent this form of instability have been discussed earlier in this section.

**Core saturation instability** This is an instability which involves saturation of converter transformers, and occurs when there is a resonance near to fundamental frequency on the d.c. side between d.c. reactors and d.c. line, with an antiresonance (or at least a high impedance) near to second harmonic on the a.c. side. The mechanism involves fundamental frequency on the d.c. side, d.c. components in valve windings which cause transformer saturation, and second harmonic on the a.c. side. The control system is also involved. Build up of this type of instability is very slow (several minutes) because of the transformer saturation

effect. It can be cured by control system additions which effectively monitor the effect of saturation, and oppose it by feedback in the converter.<sup>34</sup>

**Subsynchronous instability** This can occur typically at frequencies of the order of 10–40 Hz, assuming the worst case of transmission via a long d.c. line or cable. It corresponds to ordinary control loop instability and can be studied by, for example, the Nyquist Criterion or by eigenvalues and cured by proper choice of control parameters such as loop gain settings at the rectifier and inverter. Synchronous machines with steam turbines exhibit mechanical shaft resonances in this frequency region, hence guaranteed stability is particularly important where these are present in the a.c. networks, to prevent their resonances being excited.

Suitably designed h.v.d.c. controls should not excite subsynchronous instability and in fact can be used to damp such instability.<sup>35</sup>

#### 32.12.11.2 Recovery after a.c. and d.c. faults

Satisfactory recovery of the h.v.d.c. link after a major a.c. fault at the inverter can present problems, because the a.c. voltage distortion caused by magnetising in-rush current of transformers during recovery may be substantial. The most important criterion is the shock to machines caused by the loss of megawatt-seconds, which must be minimised to prevent pole-slipping in the a.c. system (transient instability). From the control point of view this requires a control system which re-starts as rapidly as possible on re-establishment of a.c. voltage, which has static and dynamic characteristics chosen to give fast restoration of power, and which gives freedom from commutation failures during recovery. As can be seen from oscillograms in the section on controls, modern controls can cope well even at low values of SCR. The situation can be helped further by suitable design of the converter transformers to give low magnetising in-rush current when economic, and of the a.c. filters to give substantial damping at low frequencies of the order of second to fourth harmonic.

Recovery following d.c. faults represents a less severe condition.

#### 32.12.11.3 A.c. and d.c. overvoltages

Where a converter is connected to a low or very low SCR a.c. system, the effect of sudden blocking of the converter (load rejection) is to cause a substantial a.c. voltage rise. This may be caused for example by an a.c. fault at the remote station, or because of the necessity to cut off direct current to clear a d.c. line fault. Another case is where an a.c. fault near to the converter bus-bars is removed by a circuit breaker opening; when the a.c. voltage re-appears it is likely to be excessive, particularly if for some reason the converter does not commence commutation immediately. The control of these and other overvoltages is discussed in Section 32.9.

Overvoltages on the d.c. line are generally lower, at least with a d.c. cable scheme, because of the isolating effect of the d.c. reactors. However, with weak a.c. systems it is advisable to provide each station with voltage limiting loops in its controls; d.c. voltage surges can then be effectively reduced in most conditions, with benefit to cable insulation. A d.c. overhead line is subject to lightning overvoltages, which can be reduced by conventional methods.

#### 32.12.11.4 Conditions at the rectifier end

The above are primarily concerned with the inverter (receiving system) end. The rectifier end source impedance has a much smaller effect on stability and recovery. However, the rectifier end is still liable to moderate a.c. voltage changes caused by disturbances. If the source is an isolated generating station without local loads, the a.c. voltage changes are generally acceptable. If there are local consumers then static compensators may again be a suitable solution to reduce a.c. voltage changes.

### 32.13 Multiterminal HVDC systems<sup>36–38</sup>

The applicability and flexibility of h.v.d.c. systems can be enhanced in some conditions if several converters are coupled to form a multiterminal h.v.d.c. system. The earliest application of this philosophy was the paralleling of bipoles I and II of the Nelson River Scheme onto one line in the event of an outage of one of the bipolar transmission lines. This procedure has now been carried out in response to a major storm damage to transmission lines. The first true multiterminal h.v.d.c. scheme has been achieved with the construction of a parallel tap (50 MW) on the Sardinia–Italian Mainland h.v.d.c. scheme (200 MW).<sup>44</sup>

Multiterminal h.v.d.c. systems may be divided into series and parallel types, illustrated in *Figures 32.72 and 32.73*, respectively. However, there are many permutations of each type, depending on system requirements.

#### 32.13.1 Series connection

*Figure 32.72* shows an example, in which one pole of a 500 kV, 1000 A rectifier supplies two inverter stations in series, respectively of 100 kV, 1000 A, and 400 kV, 1000 A.

Figure 32.72 Three-terminal series scheme

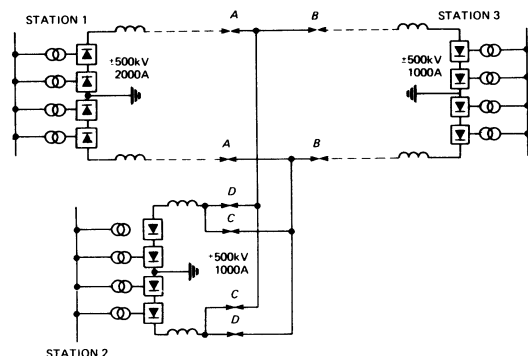

Figure 32.73 Three-terminal parallel scheme

In the case shown, one method of control is to operate the rectifier permanently at constant current equal to full rated current, and vary inverter powers individually as required by varying their voltages. This makes the series method expensive in terms of line losses, filter losses, damping losses, and reactive compensation, but does give virtually independent control (including smooth power reversal in any station), and very little interaction between stations during most disturbances. Some economy is obtained by reducing current when total power is less than full load, so that at least one inverter is at its rated voltage, but the sum of the ratings required of each item of plant (including filters, etc.) is always greater than for a parallel scheme.

### 32.13.2 Parallel connection

The example in *Figure 32.73* shows an arrangement for a three-terminal parallel scheme intended principally for operation as a 2000 MW rectifier supplying two inverters each of 1000 MW. This is an example of a system of medium control difficulty. Switches A and B are solely to isolate their respective lines in case of permanent d.c. line faults. Switches C and D form in addition a reversing system for station 2. The switches shown may be slow-acting isolators, plain fast switches, or true d.c. circuit-breakers.

Control of parallel rectifiers is easy since by using normal constant current control loops at each rectifier, their currents (and powers) are easily set to any desired values (including zero) and there are no current sharing problems.

The basic problem of control of parallel inverters is that an h.v.d.c. inverter operating in the most efficient mode, of constant extinction angle ( $\gamma$ ), has an effective slope resistance which is negative, so that two such inverters in parallel are obviously unstable.

Many ways round this problem have been proposed, such as operating one inverter at constant extinction angle (to control direct voltage), and the other in a constant-current mode; this means that the second inverter requires higher plant rating. However, the system is in a rather delicate state for even minor transients.

*Figure 32.74* shows an alternative control characteristic, originally developed to enable parallel operation of the two bipoles of the Nelson River Scheme, and which gives stable operation without requiring excessive plant rating. The current order at each station is communicated from a master control. Obviously the actual currents obey Kirchhoff's first law, so current orders should be restricted so that the sum of the rectifier current orders is equal to the sum of the inverter current orders.

**Figure 32.74** Normal steady-state operation

**Figure 32.75** Inverter 1 tap-changer slightly low

*Figure 32.74* has been drawn for the normal steady-state case where respective transformer tap-changers have been adjusted to the ideal positions, for the particular a.c. voltages, d.c. currents, etc. The working points of the inverters are right on the constant characteristic (in the ideal positions) at their correct currents, and the rectifiers have the usual small voltage margin in hand (i.e. their firing angles are in the range  $2^\circ$  to  $15^\circ$ ).

The example of *Figure 32.75* shows the case in which inverter 1 a.c. voltage becomes relatively slightly low. The working points ABC must still obey Kirchhoff's and Ohm's laws, but are now not quite at their ideal positions, inverter currents being slightly high and low respectively, with inverter 2 operating at slightly high extinction angle. This is a stable operating condition. Powers are corrected in the short term by master control action, and normal (optimum) working conditions are re-established in a longer time by transformer tap-changers.

A commutation failure is a relatively frequent (and inevitable) minor disturbance, usually caused by a switching transient from the a.c. system at an inverter. Its effect is to cause temporary collapse of inverter operation for say 100–200 ms, momentarily giving zero d.c. voltage and a.c. current. In a multiterminal scheme there is a tendency for the whole of the d.c. current to be diverted temporarily into the 'failed' inverter. The rectifier controls will restrain this automatically after a cycle or two; the inverter will not be able to re-commutate (particularly with weak receiving system) until actual inverter current and firing angle fall below rated values.

### 32.13.3 D.c. circuit-breakers

One of the main advantages of an h.v.d.c. scheme is the controllability conferred by the ability of the converter valves to conduct or block the full load direct current as desired. This capability has meant that the need for true high voltage direct current circuit breakers has been small, since by appropriate converter action ordinary a.c. circuit breakers could be utilised for circuit switching on the d.c. side.

The first application for a d.c. breaker was the metallic return transfer breaker (MRTB). The MRTB is principally introduced to increase the independence between the poles of a bipolar scheme: A station fault requiring the blocking of a pole will divert the direct current from the healthy pole into the ground electrode. If the station fault is permanent, the faulty pole is isolated and bypassed, and transmission continues in the monopolar mode. However, although the metallic return conductor is then in parallel with the ground return, the major part of the current continues to flow into

the electrode because of the lower resistance of this path. The MRTB can divert this current into the metallic conductor by developing a significant back e.m.f.

High voltage direct current breakers have now been developed and tested, but have not yet been commercially applied.<sup>39</sup> Such d.c. breakers may give some small reduction in the duration of outages caused by permanent faults in multiterminal d.c. networks. Since their duty is significantly harder than the transfer duty of the MRTB, they are still costly, and thus justifiable only when the rather small time improvements are of considerable benefit to the stability of the a.c. system.

### 32.14 Future trends\*

H.v.d.c. is now a maturing technology which has proved its technical and economic worth in the field. Future trends will be towards reduced complexity and lower cost, the latter achieved through both lower installed equipment cost and reduced running costs.

Very large transmission projects for which the economic transmission voltage lies above 600 kV will probably materialise, prompting the evolution of new insulation techniques for the d.c. side equipment. At lower voltages, developments will be generally confined to the specialist items of equipment such as valves and controls.

Two major developments which have contributed to present-day h.v.d.c. valves are open to further extension.

First, the increased rating per thyristor, which has led to thyristors based on 125 mm diameter silicon, may continue, albeit at a reduced rate as the technical and economic limits of processing large area, high voltage rated thyristors based on silicon is approached. It is unlikely that practical, silicon-based thyristors with blocking voltages in excess of 10 kV will be realised. Further extension from 125 mm diameter (the present limit) to a theoretically possible 150 mm seems unlikely because current ratings of all present applications can be covered by using 100 mm or 125 mm thyristors without paralleling. Development will be more towards better optimisation of dynamic characteristics and reduction of losses.

Semiconductor devices based on silicon carbide (SiC), rather than pure silicon, offer the exciting prospect of switching devices with much higher voltage blocking capacity than 10 kV. However, at present, the technology is only in its infancy and there are many technical challenges to overcome before practical SiC devices become available for use in H.v.d.c.

Second, the development of light triggering of individual thyristors, initially via auxiliary electronics mounted at valve potential, has already extended to the production of thyristors incorporating light sensitive gates suitable for direct optical triggering. In many applications, this reduces the need for 'local' electronics at each thyristor level, with the prospect of substantial economic advantage. For h.v.d.c., in the first instance, small direct optically triggered 'slave' thyristors have been employed to gate conventional thyristors, and to enable local protective circuits to act directly via the electrical gate. The value of these thyristors to h.v.d.c. is limited by the continuing need for local protective circuits to prevent damage to the thyristors during forward overvoltage and adverse forward recovery conditions. Work to develop direct triggered h.v.d.c. thyristors with fully integrated self-protection has met with some success with regards to overvoltage and  $dv/dt$  protection

**Figure 32.76** Silicon slice of a direct light-fired, self-protected thyristor. (Courtesy of Marconi Electronic Devices Ltd)

(see Figure 32.76). However, integration of an effective forward recovery protection has proved illusive. Light triggered thyristors are practical and remain attractive but are generally uneconomic at present state of development.

The universal adoption in recent schemes of indoor air-insulated valves, rather than outdoor oil or SF<sub>6</sub> insulated, stems largely from the need for regular, perhaps annual, access to thyristor levels which must be replaced or renovated to restore acceptable redundancy. Reducing the component count in a valve through the use of higher voltage self-protecting light-fired thyristors may make the outdoor oil or SF<sub>6</sub> insulated valve attractive once more, at least in regions where extreme climatic conditions are not encountered. However, this approach is unlikely to be adopted until satisfactory operating experience of light-fired self-protecting thyristors has confirmed the high availability and low replacement rates which are expected.

Today's h.v.d.c. inverter is line commutated, that is it relies on the e.m.f. of the receiving a.c. system to commutate current from one phase to the next against the restraining action of the commutation reactance. Forced commutation inverters, in which the energy for commutation is stored locally, usually in capacitors, and is released by auxiliary thyristors to force commutation at any desired time, is too expensive in first cost, in losses, and in reduced reliability through complexity, to be a serious competitor in large systems. Such circuits could, in principle, be applied to small schemes feeding isolated a.c. systems, where the advantage of being able to operate without the support of rotating machinery is greatest.

The advent of Gate Turn-off (GTO) thyristors and, in recent years, of Insulated Gate Bipolar Transistor (IGBT) technology at power levels of use in high power converters has opened up opportunities for small power (typically below 100 MW) h.v.d.c. converters based on voltage sourced converter technology.<sup>45</sup> At present, schemes employing the self-commutating capability of such converters are restricted to niche applications where special circumstances offset the higher capital cost/MW and reduced power conversion efficiency of voltage sourced converter technology compared with conventional, line-commutated technology. Improvements in the basic power semiconductor switching devices and the evolution of novel converter circuit topologies could well see voltage sourced converters become the technology of choice for h.v.d.c. transmission, initially at

\*as considered in June 2000

low power and later, as technology matures, at increasing levels of power.

The performance of an h.v.d.c. scheme is critically dependent on the central control system, particularly if the a.c. system at the receiving end is weak. The cost of the controls is a small fraction of the overall cost of a scheme, hence improvement of control performance and operational reliability will continue even where this incurs somewhat higher costs.

Some parts of the controls will be implemented on programmable digital systems with internal self-checking and, in critical areas, with duplicated circuits and automatic change-over in the event of faults. Because of their relative simplicity and low component count, analogue circuits are likely to be retained in those areas to which they are best suited.

### 33.1 Introduction

A transformer consists essentially of two or more electric circuits in the form of windings magnetically interlinked by a common magnetic circuit. An alternating voltage applied to one of the windings produces, by electromagnetic induction, a corresponding e.m.f. in the other windings, and energy can be transferred from the primary circuit to the other circuits by means of the common magnetic flux.

References to various specialist papers relating to design and operation of power transformers are given at the appropriate points in the text and listed at the end of this chapter. A recommended comprehensive textbook on all aspects of transformer design is *Large Power Transformers*.<sup>1</sup> The relevant British Standard Specification<sup>2</sup> is *BSEN 60076-1:1997. Power Transformers*. BSEN 60076 contains information relating to standard characteristics, guaranteed performance and tolerances, testing and operation, and conforms with the International Electrotechnical Commission (IEC) *Publication 60076: Power transformers: Parts 1 to 12*.

The British electricity supply industry issued a series of documents relating to transformers. All are listed in The Electricity Council's *Catalogue of Engineering Documents* and the more important are:

*ESI Standard 35-1: Distribution transformers (from 16 kV A to 1000 kVA) (1985)*

*ESI Standard 35-2: Emergency rated system transformers (35/11.5 kV) (1982)*

*British Electricity Board Specification (BEBS) 72: Transformers and reactors (1966)*. In 34 sections, this specification relates to large transformers above 20 MVA

*BEBS T3 Transformers for 33 kV and 22 kV systems (up to 20 MVA) (1962)*

These documents are no longer maintained under revision by the Electricity Council as most Electricity Companies are now developing Functional Specifications, but they are available on demand.

### 33.2 Magnetic circuit

The magnetic circuit, or core, provides a closed ferromagnetic path for the flux. To prevent excessive eddy current loss within the metal of the core itself it must be laminated in a plane parallel to the flux path and the individual laminations must be insulated from each other.

#### 33.2.1 Core steel

For many years power transformer core laminations were cut from sheets of special 4% silicon steel produced by a hot-rolling process. During the 1940s, an improved material was developed, known as cold-rolled grain-oriented strip (c.r.o.s.). This material has a silicon content of approximately 3% and is produced in strip form in rolls of up to 5 t.

Because of the effect of the cold-rolling process on the grain formation, the magnetic properties in the rolling direction are far superior to those in other directions.<sup>3,4</sup>

A heat-resistant insulation coating is applied by thermochemical treatment to both sides of the steel during the final stage of processing. The coating is approximately 1  $\mu$ m thick and has only a marginal effect on the stacking factor.

Traditionally, a thin coat of varnish had been applied by the transformer manufacturer after completion of cutting

and punching operations, but improvements in the quality and adherence of the steel manufacturer's coating and in the cutting tools available have eliminated the need for the second coating and its use has been discontinued.

Guaranteed values of loss (in watts per kilogram) and apparent power (in volt-amperes per kilogram) apply to magnetisation at 0° to the direction of rolling. Both real and apparent power loss increase significantly (by a factor of 3 or more) when c.r.o.s. is magnetised at an angle to the direction of rolling. Guarantees do not apply and the transformer manufacturer must ensure that a minimum amount of core material is subject to cross-magnetisation. This is to minimise the total core loss and (equally importantly) to ensure that the core temperature in the area is kept within safe limits.

Cold-rolled grain-oriented strip cores operate at nominal densities of 1.6–1.8 T. This compares with 1.35 T used for hot-rolled steel, and is the principal reason for the remarkable improvement achieved in the 1950s in transformer output per unit of active material. British c.r.o.s. steel is produced in two magnetic qualities (each having two sub-grades) and four thicknesses (0.23, 0.27, 0.30 and 0.35 mm), giving a choice of seven different specific loss values. In addition, the designer can consider using Japanese-made steel of higher quality, available in three thicknesses (0.23, 0.27 and 0.3 mm).

The decision on which grade to use for a particular application depends on the characteristics required in respect of impedance and losses, and particularly, on the assigned capitalised value of the iron loss. The higher labour cost involved in using the thinner materials is another factor to be considered. The different materials are identified by code names. For example, the material previously known as 27 MOH is now called 103-27-PS, where the digits signify:

103: a guaranteed 50 Hz specific loss at  $B=4.7$  T of 1.03 W/kg;

27: a thickness of 0.27 mm; and

P5: the steel manufacturer's code for the higher quality steel previously identified by suffix 'H'.

The lower grade material is known as N5 and the first figure in the code is then an indication of the loss per kilogram at  $B=4.5$  T, e.g. the complete code might be 089-27-N5 (loss = 0.89 W/kg).

The Japanese grade ZDKH steel is subjected to laser irradiation to refine the magnetic domains near to the surface. This process considerably reduces the anomalous eddy current loss but the laminations must not be annealed after cutting.

#### 33.2.1.1 Cutting and punching

Cold-rolled grain-oriented strip is produced in the form of strip up to about 850 mm wide. In the past it was common practice for the transformer manufacturer to buy full-width coils and slit these to the width required. It is now more usual to purchase the strip ready cut to width. This is more expensive unless the manufacturer has a very high turnover of core laminations, but the extra cost is offset by the elimination of the slitting operation and the wastage incurred by ever-increasing stocks of unused off-cuts. The only cutting process now undertaken by the transformer manufacturer is to crop to length by guillotine.

Where bolt-holes are employed, it is preferable to use a single hydraulic press to crop the strip material to length and punch bolt-holes simultaneously. Following cutting and punching, the individual laminations may need to be

dressed to remove any edge burrs, but as deburring may harm the magnetic properties of the material, it is preferable that high quality cutting tools are maintained in good condition so that deburring is unnecessary.

Cutting and punching adversely affect the magnetic properties of the material and, until recently, it has been considered desirable that the finished laminations (or for small units the complete cores) should be stress-relief annealed to remove cutting strains. Various types of annealing furnace have been used, including the batch furnace and the continuous belt furnace, in which small stacks of laminations (up to 10 or 12 plates deep) pass slowly through a heating zone at about 800°C in an inert atmosphere of nitrogen. In the single-sheet roller hearth furnace, single laminations pass relatively rapidly through the heating zone; with this furnace the laminations are in the heated zone for a comparatively short time and it is unnecessary to provide an inert atmosphere to prevent oxidation.

The elimination of bolt-holes and improvements in cutting tools have led to a reduction in cutting strains and in the loss thereby incurred. The margin for reducing loss by annealing has been reduced and the process has generally been discontinued. (There is, for instance, obviously proportionately less area affected by cutting strains in a wide lamination than in a narrow one. As a rough guide, annealing is not considered to be necessary for strip over 200 mm wide.)

Although c.r.o.s. is now used for virtually all 'power' transformer cores from 1 kVA upwards, there are other special low-loss steels (e.g. Mumetal) used for the cores of instrument transformers. These materials have markedly superior magnetic properties (i.e. magnetising vars and power loss) at low densities, but they saturate at much lower levels than c.r.o.s. They are therefore not economic for power transformers, where the advantage of a high operating flux density overrides all other factors.

### 33.2.2 Magnetic circuit design

The two fundamental types of construction used, shown diagrammatically in *Figure 33.1*, are known as *core* and *shell*, respectively. The normal arrangement of a core-type transformer is for circular primary and secondary windings to be arranged concentrically around the core leg of substantially circular cross-section. In the shell type the magnetic circuit is of rectangular cross-section formed by a stack of laminations of constant width. The coils are straight-sided and the primary and secondary windings are interleaved in a sandwich fashion. The number of alternate high-voltage/low-voltage groups is dependent upon the required reactance characteristics of the transformer.

**Figure 33.1** Basic cell and magnetic circuit arrangements

**Figure 33.2** Core arrangements

In the UK the core-type transformer is used for all power-system applications. The shell form is used only for special applications, usually where very heavy current low-voltage outputs are required for such purposes as electric arc furnaces or short-circuit testing stations. The shell form is also used in the USA, France, Spain, Portugal and Japan for power transformers of the largest sizes and highest voltages. The fact that both core- and shell-type transformers have existed side by side for many years indicates that neither has any significant economic advantage. There is, however, a discernible trend away from the shell towards the core type of construction, due entirely to economic considerations.

Core-type transformers (circular coils on circular limbs) are built in various forms, as shown in *Figure 33.2*. The choice is dictated by the type of winding or the need to meet transport loading restrictions. Thus, a five-limb core will have a smaller overall height than a three-limb core for a three-phase transformer. A very large high-voltage single-phase transformer might also have to be designed with a multi-limb core.

The basic parameters of the core are: (a) the core circle diameter, (b) the yoke height, (c) the limb centres, and (d) the limb length. The normal practice in a design office is that the first three are related to a range of fixed standards, while a limited variation on core size is secured by change of limb length. The relation between the core circle diameter  $D$  and the rating  $S$  of a transformer is given approximately by

$$D = k(S)^{1/4}$$

where  $k$  is a constant depending on the type of transformer.

Thus, if a 500 kVA transformer has core circle diameter of 190 mm, then a 1000 kVA transformer of the same voltage ratio and service conditions would have  $D = 220$  mm approximately. The actual diameter adopted would depend on the nearest standard diameter available.

The e.m.f. per turn  $E_t$  is a function of the frequency  $f$ , the peak flux density  $B_m$  and the net core area  $A_i$ :

$$E_t = 4.44fB_mA_i$$

#### 33.2.2.1 Limb space factor

To obtain the most economical use of core steel and copper it is essential to utilise as much as possible of the available

**Table 33.1** Core utilisation factors

No of steps	1 (square)	2	3	4	5	6	7
Fraction of core circle areas	0.64	0.78	0.85	0.89	0.91	0.92	0.94

core circle. Consequently, the limb sections are built in steps; the greater the diameter, the larger the number of steps. Optimum utilisation factors for cores with 1–7 steps are given in *Table 33.1*.

In practice these areas are reduced by the lamination stacking factor, depending on the thickness of the inter-laminar insulation and the tightness of the core clamping. With the latest core steel insulation and without varnish, stacking factors of up to 97% can be achieved. With large transformers allowance must be made for loss of area due to cooling ducts in the core, and the area will also be affected by the relative size of the individual core steps, which can depend on the width necessary to accommodate core clamping plates.

Cores having more than seven steps (up to as many as 15 or more) are common, but the improvement in utilisation decreases with an increasing number of steps and is offset from the production point of view by the increasing complexity involved in producing a greater number of widths.

### 33.2.2.2 Yoke dimensions

As the yoke height is not restricted by a winding, the area selected may be larger than that of the corresponding limbs. Dissimilar steps between the limb and yoke packets, however, can give rise to cross-flux, and the resultant increase in core loss may offset benefits accruing from the greater yoke area; this factor is of particular significance with c.r.o.s. Apart from very small cores, modern practice is to step the yoke and limb sections in a similar, or preferably identical, manner.

When the magnetic circuit is completed by a single-path yoke, e.g. a one-phase two-limb core (*Figure 33.2(a)*), or a three-phase three-limb core (*Figure 33.2(c)*), yoke areas at least equal to the limb section are necessary. Where the yoke path is split, the yoke area can be appropriately reduced, e.g. with a one-phase centre-limb-wound core (*Figure 33.2(b)*), the yoke area can be halved, and with a three-phase five-limb core (*Figure 33.2(d)*), the yoke area can be reduced to about 0.55–0.6 of that of the corresponding limb.

### 33.2.2.3 Core clamping and core joints

Bolt-holes cause local flux deviation and crowding, which results in increased noise and loss. These effects have led to the development of boltless cores, which are held together by circumferential bands. These bands are sometimes of steel with suitable insulated sections, but synthetic-resin-impregnated glass fibre tape is preferable, as it eliminates any risk of the band becoming involved in an electrical failure or becoming overheated owing to eddy currents. Banded cores are now used even in the largest transformers. Other methods of clamping include bolts passing through oil ducts in the core to avoid holes in the sheet, and reduction of the bolt area by the use of high-tensile steel.

The introduction of c.r.o.s. necessitated a modification of the traditional rectangular overlap (*Figure 33.3(a)*) between yoke and leg laminations commonly used with hot-rolled

**Figure 33.3** Types of joint in cores (shaded portions indicate overlap areas)

**Figure 33.4** Strip-wound core (cuts in legs for butt-jointed core are shown by the dotted line)

strip cores. To achieve minimum loss by taking maximum advantage of the directional properties of c.r.o.s., the area overlap has been minimised by means of mitred joints (*Figure 33.3(b)*). The affected area can also be reduced by using split laminations (*Figure 33.3(c)*), with the split joint butted in small cores, or separated to form a cooling duct in the case of large cores.

By eliminating core joints, or by arranging that joints do not disturb the optimum flux path, maximum advantage can be taken of c.r.o.s. Such conditions are achieved with the wound core (*Figure 33.4*). This construction is widely used for transformers up to 25 kVA, the limitation in rating being imposed by special coil-winding requirements which involve a split former so that the coils can be wound on the completed core. A variation called a C core, of slightly reduced efficiency, is a wound core cut across the centre of the leg section, thus involving a butt joint in each limb.

### 33.2.2.4 Core building factor

The total core loss divided by the total mass of the completed magnetic circuit gives the specific loss of the built core. If this figure is divided by the specific loss of the material used (from tests on samples or from the steelmaker's guarantee), the result is the core building factor, a measure of the effectiveness of the magnetic circuit design. Building factors vary with the size of core, smaller cores generally giving factors near to unity. Building factors for large cores can be kept to less than 1.2 if full attention is paid in the design to make the best use of the directional properties of the steel.

## 33.2.3 Magnetic circuit characteristics

The magnetic circuit characteristics are the no-load core loss and the magnetising current. The former is commonly divided into hysteresis and eddy current components. The hysteresis loss depends on the peak flux density and the frequency, while the eddy current loss depends on the r.m.s.

flux density and on the degree of subdivision (i.e. lamination) of the core. The specific loss components are given by

$$p_h = k_h f B_m^n \quad \text{and} \quad p_e = k_e f^2 B^2 t^2$$

where  $B_m$  is the peak and  $B$  the r.m.s. flux density,  $f$  is the frequency,  $t$  is the lamination thickness, and  $k_h$  and  $k_e$  are constants for a given material. The exponent  $n$  is empirical, with a value generally not very different from 2.

The measured no-load loss includes  $I^2 R$  loss due to the no-load current; and dielectric loss (especially for large high-voltage transformers); these components can often be neglected.

The no-load current  $I_0$  can be taken as comprising an active component  $I_{0a}$  in phase with the applied voltage  $V$  and accounting for the no-load power input  $P_0$ , together with a reactive or magnetising component  $I_{0r}$  (Figure 33.5). The two components are not physically separable, as both are concerned together in the magnetisation of the core. The no-load current is normally expressed in terms of the full-load current as a percentage or per-unit (p.u.) value. For distribution transformers in the range 500–1000 kVA and built of c.r.o.s., the no-load current is of the order of 1.5% (0.015 p.u.). Values for large high-voltage transformers may be less than 0.5%.

The saturation characteristic of the steel is such that the no-load current increases rapidly when the transformer is overexcited. If with c.r.o.s. the normal peak density is 1.6 T, the no-load current will be at least doubled by a 10% over-voltage. Further, the harmonics in the current waveform will be substantially increased. Provided that the circuit connections permit, the most pronounced harmonic is the third, although fifth and seventh harmonics can become significant at high densities. If the circuit connections do not permit third-harmonic currents to flow (in a three-phase transformer there must be either a neutral connection to a source of zero sequence current, or a delta connection within the transformer in which third harmonics can circulate), the flux waveform will distort because of the lack of the component. The distortion appears as a third-harmonic ripple in the secondary line-to-earth voltage.

This effect is most noticeable in single-phase transformers or in a five-limb, three-phase core. In both cases there is a free path in the core for a third harmonic component in the main flux. In a three-phase, three-limb core a third harmonic in the flux is in phase in each limb and the lack of a return ferromagnetic path results in the suppression of the third harmonic components. The effect on the magnetising current is that, although there is not any true third harmonic therein, there is a triple frequency component divided 1:2:1 in the core. To a large extent this satisfies the need for a third harmonic and the distortion of the flux wave (and hence of the output voltage) is negligible.

The magnetic path length associated with the central phase of a three-phase three-limbed core-type transformer (Figure 33.2(c)) is significantly shorter than that of either of

Figure 33.5 Phasor diagram of no-load current

the outer phases. The configuration shows that the outer path lengths include two half-yokes in addition to the limb. As a consequence, the magnetising current and core loss values are asymmetric, to an extent depending on the path length ratio. If the central path length is one-half that of either outer, then its magnetising current is likely to be about 30% less, and this is independent of the peak flux density level.

### 33.2.3.1 Magnetising inrush current

When a transformer is 'switched-in' on no load, it may take an initial *inrush* current greatly exceeding normal no-load value, and sometimes greater than full-load current. The inrush transient decays to normal no-load level within a few periods. The first peak depends on the voltage at the instant of switching, and on the magnetic state of the core as left after the previous switching-out. If the instant of switch-on corresponds to a voltage zero, the flux must, in the first half-period, produce a complete change of  $2\Phi_m$  from zero, as shown in Figure 33.6. The peak flux therefore rises to twice normal peak  $\Phi_m$ . The maximum flux reached will be increased to  $(2\Phi_m + \Phi_1)$  if there is a residual flux  $\phi_1$  already present in the core in the same direction as that to be taken by the first half-cycle of flux growth. These high-flux conditions demand very high peaks of exciting current with large harmonic content. As the core steel will saturate, much of the flux will follow an 'air' path, and the peak inrush current is consequently influenced by the area enclosed by the winding excited.

Under adverse conditions the magnitude and asymmetry of inrush currents may cause maloperation of overcurrent or balanced forms of protection, but in practice the worst conditions are statistically unlikely, and terminal voltage drop will reduce the peaks. In a three-phase transformer the inrush conditions must differ for each phase.

### 33.2.3.2 Magnetostriction

Magnetostriction is a property of magnetic material whereby a small change in linear dimensions (usually an elongation) follows the flux cycle in a complex pattern. In transformer steel the linear change is a few parts in a million. It causes vibration of the core at twice supply frequency and at multiples thereof, producing sound waves. Magnetostriction in the material of the core is the main source of transformer noise.

### 33.2.3.3 Noise

The unremitting hum of a transformer installed in a residential area can lead to complaints and in extreme cases to legal action. Careful design and manufacture is necessary to ensure that the noise emitted is within the level normally

Figure 33.6 Flux transient for switching at voltage zero (no residual)

accepted as reasonable for a given size of transformer. The Electricity Supply Industry Standards (*ESI 35-1 Distribution transformers up to 1000 kVA* and *ESI 35-2 Emergency rated system transformers*) and British Electricity Board Specification (BEBS) T2 for the large units contain curves relating MVA rating and noise level which form part of the manufacturer's contractual obligations. BEAMA publication No. 227, *Guide to Transformer Noise Measurement*, is a useful reference work on the subject. IEC 60076-10 describes the way in which sound measurement tests are made.<sup>5</sup>

If it is expected that the noise emitted from a particular installation may create a nuisance, various mitigating measures are possible, including the following:

- (1) Specifying a noise level less than the normal standard. Usually not economic (or even feasible) if reductions of more than about 10 dB below the standard level are likely to be necessary.
- (2) Concealing the transformer behind a screen of trees or a wall. Sometimes the psychological effect is greater than the actual measured reduction in noise level at the point of complaint.
- (3) Completely enclosing the transformer in a 'sound-proof' housing. This is expensive, as obviously special measures have to be taken to emit heat without emitting noise.
- (4) A combination of (2) and (3) in which specially designed coolers form a screen wall completely surrounding the transformer. When introduced in the 1960s this appeared to be a promising development from the point of view of amenity in respect of both appearance and noise, but the idea never became popular.

In certain applications in Germany and Austria it has become necessary to install transformers with a very low noise level, up to 20 dB below the UK standard levels. In these cases it is necessary to design the transformers to operate at nominal flux densities of 1.2–1.4 T.

### 33.3 Windings and insulation

Because of their direct association with power systems, the windings and associated insulation are the most vulnerable parts of a transformer. They must be designed and constructed to withstand the voltage stresses and thermal conditions of normal service, the mechanical and thermal stresses resulting from system faults and short-circuits, and transient overvoltages such as those generated by lightning and switching. The core and windings together must meet specified impedance and loss requirements. In view of the almost total predominance in Britain of core-type transformers, the following section relates only to windings for this type.

#### 33.3.1 Types of coil

The simplest *helix* coil consists of a single layer, formed by turns lying directly side by side, extending over the axial winding length. Each turn may comprise a single conductor or a number of conductors in parallel, the helix at each end of the coil being supported by a suitably shaped edge block to give adequate mechanical strength in an axial direction (*Figure 33.7(a)*). This type of coil, single or double layer, is used for the low-voltage windings of small and medium-sized transformers.

When the current rating necessitates a large number of conductors in parallel for each single turn, the individual

Figure 33.7 Forms of coil

strips can be laid one above the other in a radial direction, as either a single column or two columns in parallel, each turn or column separated by spacers to provide sufficient cooling surface (*Figure 33.7(b)*). This type of coil, sometimes termed a *disc helix*, is used for the low-voltage windings of large transformers.

*Multilayer helix* coils can be employed for the high-voltage windings of large transformers. Because of the high capacitance between the individual layers, this type of winding has good inherent strength against incoming surge voltages. It is fairly simple to calculate the surge response of the multilayer winding, but difficult to ensure that the long thin layers of conductors have adequate strength to resist axial forces. As ratings increase for a given primary service voltage, a *disc* coil (see below) becomes relatively less difficult to design from the point of view of predicting surge strength and more satisfactory because of its high inherent strength against axial forces. The use of the multilayer helical coil is thus generally confined to the smaller megavolt-ampere ratings of any given voltage class above about 200 kV.

This type of coil shows particular advantage when the transformer neutral is directly earthed. The inside layer of the winding is then near earth potential, thus reducing the major insulation between high- and low-voltage windings. The length of the individual layers decreases progressively towards the outer layer to provide increased insulation to-earth at the line end. Interlayer connections, usually top-to-bottom, can either be arranged internal to the coil between the layers, or formed by external joints (*Figure 33.7(c, d)*). Multilayer coils are often used for the high-voltage windings of small distribution transformers, in this case wound as continuous layers, with top-to-top and bottom-to-bottom interlayer connections.

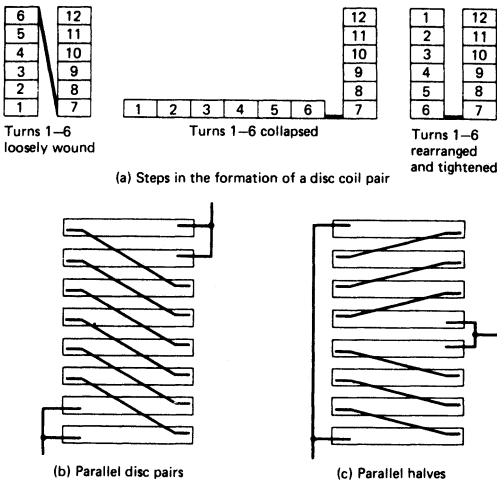

Another form of layer coil is a *multistart interwound* helix employed for the separate tapping windings of large transformers when a considerable range of voltage variation is required. The coil is so arranged that each single conductor forms one tapping section, with the requisite turns distributed over the winding length to provide axial ampere-turn balance for the various tapping positions. The individual conductors are physically located so that the voltage between them is reduced to a minimum (see *Figure 33.7(e)*).

A *crossover* or *bobbin* coil is wound on a former between side cheeks. It is, in effect, similar to a multilayer winding, except that the layers are short. The interlayer insulation

needs to be extended at the ends to guard against failure by creep at the edges; alternatively, it can be folded round the last turn of each layer, or the overhang crimped to form a trough of depth equal to the thickness of the conductor. The assembly of separate coils is connected in series, with horizontal cooling ducts provided by spacers between the individual coils. Intercoil connections are usually made back-to-back and front-to-front, with adjacent coils reversed. Back-to-front connection requires insulation of the intercoil connections corresponding to the voltage developed across the coil (see *Figure 33.8*). Cross-over coils, generally of round wire, are employed for the high-voltage windings of distribution transformers up to about 1000 kVA.

**Figure 33.8** Cross-over coils: intercoil connections

**Figure 33.9** Disc coil windings

Because of the increase in the cost of copper, more attention is being paid to the use of aluminium for transformer windings. Aluminium is a less effective conductor than copper, but despite this intrinsic disadvantage (which results in a larger transformer for a given efficiency) there is a net saving in overall cost. Aluminium strip can be used to wind any of the types of coil described above, but it is also uniquely used in foil form. This is because aluminium can be rolled to a thinner and more flexible foil than copper. The foil is used in bobbin-type coils of one turn per layer with intercoil connections as shown in *Figure 33.8*.

The *disc* coil differs from other windings in that adjacent turns, consisting of strip conductor, are wound one above the other in a radial direction from the centre outwards; thus, the coil might be compared with a cross-over coil comprising one turn per layer. To achieve the required disposition of turns, the coils are formed in pairs, the requisite turns for one disc being loosely wound so that the conductor finishes in a position to provide the start of the inside turn of the second disc, which can then be wound from the inside outwards, the turns of the first disc being rearranged by folding one inside another in such a manner that the start of the coil is located as an outside turn (*Figure 33.9(a)*). The coil is then tightened to remove slack from the reformed disc.

Disc coils can be wound either as individual pairs, which are then assembled and connected in series by external joints, or as a continuous winding where, following formation of one pair, the procedure is repeated without cutting the conductor or removing the coil from the lathe. The continuous coil avoids assembly and joining and saves joint space, an advantage with an inside winding. For large currents the coils can be wound with multiple conductors, or constructed as separate parallel connected pairs (*Figure 33.9(b)*). Alternatively, two half-windings, one half reversed with respect to the other, can be stacked as in *Figure 33.9(c)* with the line connection taken from the centre of the stack; this method is common for large high-voltage transformers having a directly earthed neutral. Horizontal cooling ducts are provided by spacers between individual discs and between disc pairs.

The disc coil is a general-purpose winding element, applied to the higher-voltage windings of transformers above 1 MVA up to the highest ratings and voltages, and also for the lower-voltage windings (normally 33 kV upwards) of medium and large power transformers. *Table 33.2* gives a survey of typical applications of the various forms of winding.

### 33.3.2 Insulation

Materials of classes A, E, B, F, H and C (in temperature sequence) are recognised in IEC 60076 as being suitable for transformers. A, B, H and C are most common, but F is being used to an increasing extent. All these are employed in dry-type transformers, the silicon treated materials being

**Table 33.2** Transformer windings

Service	Rating (MVA)	High-voltage winding		Low-voltage winding	
		kV	Type	kV	Type
Distribution	<1	11, 33	Foil, cross-over or multilayer	0.43	Helix
System	1–30	33, 66	Disc	11	Disc, helix or disc-helix
Transmission	>30	132–500	Disc or multilayer	11, 33, 66	Disc or disc-helix
Generator	>30	132–500	Disc or multilayer	11–22	Disc-helix

advantageous (but at extra cost) by reason of their water-repellent properties. For windings immersed in hydrocarbon oil (BSEN 60296) or in synthetic liquids, the coil insulation is usually a class A material. Cotton is confined to small units, with paper and paper derivatives used for most purposes up to the largest ratings; but synthetic enamel is widely used as interturn insulation in small transformers and in the low-voltage windings (up to about 17.0 kV) of large transformers.

Most power transformers are immersed in hydrocarbon oil. To reduce fire risk, chlorinated biphenyls (e.g. Pyroclor) were used in the past, but as these liquids are toxic (and difficult to dispose of safely), they have virtually been banned on environmental grounds. Silicone based liquids and synthetic esters are available without these disadvantages, but they are relatively expensive, and the varnishes and binders usable with hydrocarbon oil may not be suitable for use with silicone fluids. Where fire risk is unacceptable, air-cooled 'dry'-type designs with glass and epoxy resin insulation are usually preferred. Gas filled transformers using electronegative sulphur hexafluoride gas ( $\text{SF}_6$ ) at low pressure for distribution transformers and up to 6 atm for high-voltage power transformers eliminate fire risk, but the cost is high, the force-cooled heat exchangers are complicated, and the transformers have short thermal time constants, giving reduced overload capability. However, they are particularly suited to underground installations, and where land prices are high they can be justified when the cost evaluation recognises that no fire-fighting equipment is necessary.

### 33.3.2.1 Insulation design

For transformers of small and medium size, the inner (low-voltage) winding is insulated from the core by pressboard or a synthetic resin-bonded paper (s.r.b.p.) cylinder, with axial bars of pressboard or equivalent material arranged round it to form cooling ducts for the inside surface of the winding. With disc or disc-helix coils, the bars have a wedge section on which intercoil or interturn dovetail-slotted spacers can be threaded. Similar bars are placed over the outer surface of the inner winding and, if necessary, between layers of a helix winding. The main high-voltage/low-voltage insulation is provided by another pressboard or s.r.b.p. cylinder. The arrangement of bars and spacers is repeated for the outside (high-voltage) winding. Insulation to earth at the ends of the windings takes the form of blocks keyed to the axial bars in line with the spacers, to form a series of columns round the windings by which the windings can be effectively clamped. The cross-section of a typical arrangement is shown in Figure 33.10.

Insulation arrangements for dry-type transformers are similar to those described, except that the materials chosen

Figure 33.10 Typical insulation for small and medium-sized transformers

Figure 33.11 Insulation design

are appropriate to the insulation class. For example, the cylinders and bars can be made from suitably impregnated glass fibre; ceramic materials may be used for the coil spacers and glass tape for interturn insulation.

When operating voltages are such that thick major insulation is required between windings, it is customary to use a number of concentric thin-walled cylinders, spaced by axial bars, the insulation being carried round the ends of the outer (high-voltage) winding by means of flanged collars interfitting with the ends of the tubes (Figure 33.11(a)). Alternatively, with high-voltage windings at above 110 kV, so-called *solid* insulation can be used, comprising layers of pressboard or paper wound directly over the inner winding, the high-voltage winding being assembled directly over the outer layer, with cooling ducts transferred from the inside turns to some point in the winding. In this case the pressboard or paper wraps are extended beyond the axial winding length and flanged at the ends to assist with the insulation to earth (Figure 33.11(b)). A combination of s.r.b.p. cylinders and pressboard wrappings can also be employed, the wrappings being located over the outer cylinder again flanged at the ends. Further, the s.r.b.p. tube can be manufactured such that the bonding is limited to the central portion, leaving the ends plain so that these in turn can be flanged.

With multilayer helical high-voltage windings, the interlayer insulation is provided in the form of a combination of paper or pressboard wrappings, and bars for cooling ducts, with the paper between the individual layers flanged at the ends (Figure 33.11(c)). When internal interlayer connections are involved (Figure 33.7(c)), the interlayer paper wrappings may be formed in tapered halves so that the maximum thickness of insulation is provided at appropriate places between the actual connection and the layers. Paper is used almost exclusively for the interturn insulation of high-voltage windings.

### 33.3.3 Winding design

The main factors to be taken into account in winding design are:

- (1) To provide adequate insulation strength to withstand (a) power frequency applied or induced overvoltage tests to prove the insulation to earth and between windings; (b) an induced voltage test for internal winding insulation (interturn, intercoil and between phases);

- (c) an impulse voltage test to prove the ability of the insulation structure to withstand transient overvoltages such as may result from atmospheric surges; and (d), in some cases, a switching surge test to prove the strength to resist surges arising from switching operations. At system voltages of 500 kV and above switching surges rather than lightning control the design.
- (2) To ensure that the load loss (i.e. the sum of the  $I^2R$  and stray losses) does not exceed the guaranteed performance figure.
  - (3) To provide adequate cooling to meet guaranteed temperature rise limits.
  - (4) To ensure adequate short-circuit strength.
  - (5) To achieve the required impedance characteristic.

Transformer windings may be fully insulated, where the insulation to earth at all points will withstand the separate source voltage test specified for the line terminals, or have graded insulation, where the insulation to earth is reduced from that required at the line terminals to a smaller amount at the neutral end. The insulation on a graded insulated winding will withstand only a separate-source voltage test corresponding to the insulation level at the neutral. In the latter case an induced voltage test is employed to test not only the internal insulation and that between phases, but also the insulation to earth at the line end.

The required level of insulation at the line end is normally designated as the *basic insulation level* (b.i.l.). This value is specified by the purchaser of the transformer and is determined by taking into account the maximum expected atmospheric or switching surges which may be imposed on the transformer, plus a small margin of safety.

The b.i.l. for any particular installation at a given system voltage is governed by the type and effectiveness of the protection against lightning and the combination of line and circuit-breaker characteristics that control the switching surge limit.

For systems where the neutral is isolated, or earthed through an impedance (e.g. an arc-suppression coil) such that, during a line-to-earth fault, the voltage to earth of the unfaulted lines can exceed 80% of the normal line-to-line voltage, fully insulated systems are essential. They are called *non-effectively earthed* systems. Graded insulation is permitted in effectively earthed systems, where the method of earthing at each transformer is such that the 80% value is not exceeded for any operating condition. The requirement is met when the zero phase sequence/positive phase sequence (z.p.s./p.p.s.) reactance ratio of the system is less than 3, and the z.p.s./p.p.s. resistance ratio is less than 1.

Uniform insulation must be provided for all delta-connected windings, and for star-connected windings where the neutral is not earthed. Grading may be applied in the latter case if the neutral is earthed. Where earthing conditions permit grading, they also, in general, allow forms of overvoltage protection for which test voltage levels are lower.

Over the past 50 years a major effort has been made by the International Electrotechnical Commission (IEC) to arrive at agreed international standard test voltages for lightning and switching surge impulse levels and the associated power frequency induced voltage test levels. The effort to accommodate all the different test levels already established by different supply authorities on the basis of their own assessment of the insulation level required on their systems to minimise total cost has led to a complicated set of tables, including a variety of alternative choices for the test voltages appropriate to the various system voltages. IEC 60076: Part 3 includes over six pages of tables and text

relating thereto and reference should be made to this document if details are required.<sup>6</sup>

Two fundamental points arise:

- (1) The adoption of any one so-called 'standard' insulation level for a particular transformer installation is, of itself, of little or no value. There are at least ten major variables involved in the design of a large transformer (e.g. MVA rating, frequency, system voltages on both high and low voltage, and impedance) and the inevitable differences that arise in any one or more of these mean that each order will require a unique new design. It is of little importance whether or not the specified insulation level is one of the so-called 'standards levels'. The designer will provide what is appropriate.
- (2) At the highest voltage levels (>700 kV) there is growing evidence that the trend (particularly in the USA and Canada) towards progressively lower insulation levels for a given system voltage has gone too far. In its simplest terms a reduction in impulse test level represents a reduction in the margin of safety against insulation failure.

References 7 and 8 both include details of recent changes in customers' specification to call for significantly higher impulse test voltages than those previously specified and which have now proved to be inadequate for reliable service.

### 33.3.3.1 Surge voltage distribution

The voltage distribution in power frequency voltage tests is substantially uniform between turns and coils, and corresponds to the normal service condition in respect of voltage to earth. Under impulse test, however, the distribution can be far from uniform. An impulse voltage wave has a steep front and a long tail. The standard form, defined in IEC 60071, has a front rising from zero to peak value in 1.2  $\mu$ s, and falling thereafter on the tail to 50% of peak value in 50  $\mu$ s. This is termed a 1.2/50  $\mu$ s wave (*Figure 33.12(a)*). Impulse voltage tests on transformer windings include the application of a *full wave* and a *chopped wave* impulse, the latter being a full wave shortened by sparkover of a rod gap or its equivalent. American practice adds a front-of-wave test, in which a voltage rising at approximately 1 MV/ $\mu$ s is chopped on the wavefront. The three forms of impulse test voltage are shown in *Figure 33.12(b)*.

A full wave application tests the ability of the insulation structure to withstand voltage surges; a chopped wave test simulates stresses that occur on the collapse of a surge tail by operation of a rod gap or a flashover to earth. Transformers for systems operating at 300 kV or above may be also required to demonstrate ability to withstand switching surges, typically by a 100/1000  $\mu$ s wave (see Section 33.14).

Figure 33.12 Impulse testing

Figure 33.13 Voltage distribution

Ignoring resistance, a transformer winding and its surroundings may be represented by an inductor-capacitor network (Figure 33.13(a)). When a steep-fronted surge is applied to the line terminal, the initial voltage distribution is governed solely by the capacitance network, in particular by the ratio  $\alpha = \sqrt{(C_g/C_s)}$  of the capacitance to earth and in series. The greater the value of  $\alpha$ , the greater is the divergence from uniform voltage distribution from line to ground, as shown in Figure 33.13(b). For a uniform winding of identical sections having the same capacitance values  $C_s$  and  $C_g$ , the initial voltage to earth at any point  $x$  from the remote end (with  $x$  expressed as a fraction of the winding length) is:

$$\text{isolated-neutral winding } e_x = E(\cosh \alpha x / \cosh \alpha)$$

$$\text{earthed-neutral winding } e_x = E(\sinh \alpha x / \sinh \alpha)$$

for a surge voltage peak of  $E$ .

If the surge voltage is maintained, an approximately uniform voltage distribution will be reached, but between these two states (if they differ) a complex array of damped oscillations will occur, creating abnormal stresses in the insulation (Figure 33.13(c)).

A chop occurring between 3 and 10  $\mu$ s after application of the impulse voltage will result in augmented interturn and intercoil stresses, although the voltages to earth are normally reduced. The stressing again depends on the initial distribution and on the actual chopping instant. The chop may be regarded as a unit-function voltage, of polarity opposite to that of the incoming surge, and superimposed on the conditions existing within the winding at the instant of chopping.

With the front-of-wave test a higher voltage is applied, but its duration is shorter and the increased stresses are generally confined to the entrance insulation (particularly the bushing). Internal voltage stresses are usually less than those arising from a chopped wave test.

The ratio  $\alpha$  is high for a small transformer. For transformers of higher rating and especially for higher line voltage,  $C_g$  decreases because it is determined largely by clearances, while  $C_s$  increases because of the greater radial depth of the winding. Thus,  $\alpha = \sqrt{(C_g/C_s)}$  is lower and the initial voltage distribution approximates more closely to the uniform.

Figure 33.14 Disc windings fitted with stress rings and rib shields

To reduce stress concentrations at the ends, disc-coil windings are provided with stress rings that act as radial shields, although they do not materially improve the axial distribution. Axial improvement can be gained by the addition of rib shields to the line-end turns (Figure 33.14) or by several other means of controlling the electric field distribution.

Compared with a disc winding, a multilayer coil has a higher series capacitance and therefore a superior transient distribution, although electric field shielding at the ends of the layer may be necessary. The choice between disc-coil and multilayer windings depends, therefore, on the specified impulse level and on the rating.

### 33.3.4 Leakage field

Problems related to leakage field are significant factors in determining whether a transformer will be reliable in service. Figure 33.15 shows a cross-section of the core and windings of a 240 MVA autotransformer and a flux plot of the leakage field set up by the load currents in the windings. The critical areas, where special precautions would be necessary to prevent local heating, are the tank wall, the coil support bracket and, to a lesser extent, the face of the core.

A precise knowledge of the shape and magnitude of the leakage field is essential for calculation of impedance, determination of stray loss and consequent heating and the magnitude and direction of short-circuit forces.

Even with modern computer programming, it is difficult to obtain an accurate three-dimensional plot of the leakage field. The computer gives a good two-dimensional plot but approximation and simplification are necessary to determine the third dimension. In spite of this limitation, however, numerical calculation gives the best results in determining leakage field strength with the best results obtained using Finite Element numerical solutions. The difficulties in calculation arise because of the irregular geometry of the windings and the presence of both non-magnetic and magnetic (with non-linear characteristics) components within the field.

**Figure 33.15** The leakage flux point of a 240 MVA transmission auto-transformer, showing leakage flux concentration in the tank wall and the bottom yoke core clamp

### 33.3.5 Impedance voltage

The impedance voltage of a transformer can be defined as that voltage required to circulate full-load current in one winding with the other winding(s) short-circuited. It comprises a component to supply the  $IR$  drop and another to overcome the e.m.f. induced in leakage inductance. On larger transformers the resistance component is usually negligible and the percentage value of the impedance is the ratio between total magnitude of the leakage flux and the main flux in the core. The leakage flux is a function of the winding ampere-turns and of the area and length of the paths of the leakage flux. By adjustment of these parameters the transformer can be designed for a range of reactances. The most economical arrangement of core and windings results in a 'natural' value of reactance. This value can be varied to some limited extent without any great influence on the cost and performance of the transformer. Interleaving the windings and so reducing the effective area of the leakage paths will reduce reactance. High reactance requirements usually result in greater stray load loss, because of the necessarily greater leakage flux.

It is usual to express the leakage impedance  $Z$  of a transformer as a percentage (or per-unit) value. The per-unit

**Figure 33.16** Regulation

value is  $IZ/V$ , and the percentage value is  $100 (IZ/V)$ , where  $I$  and  $V$  refer to the full-load current and rated voltage of one of the windings, and  $IZ$  is the voltage measured at rated current during a short-circuit test on the transformer. In the case of a transformer with tapplings, the impedance is conventionally expressed in terms of the rated voltage for the tapping concerned.

#### 33.3.5.1 Regulation

The regulation is the difference between the no-load and full-load secondary voltages expressed in terms of the former, with constant primary voltage. The difference is the result of voltage drops due to resistance and leakage reactance; it is proportional to load but is strongly influenced by the load power factor. Figure 33.16 gives a diagram to show the voltage drop  $IZ$  in the leakage impedance  $Z$  of the transformer (as obtained from a short-circuit test). The regulation is a maximum when the load phase angle  $\phi$  is equal to the angle  $\theta$  in the impedance triangle of  $R$ ,  $X$ , and  $Z$ . If the load is leading reactive, the regulation is reduced; it may even be reversed so that the secondary voltage rises on load. Formulae (IEC 60076) for the regulation  $\varepsilon$  of a two-winding transformer on full-rated load, in terms of the percentage  $IR$  drop voltage  $\varepsilon_R$  and the percentage reactance voltage  $\varepsilon_X$  are:

$$\varepsilon = \varepsilon_R \cos \phi + \varepsilon_X \sin \phi + (\varepsilon_R \cos \phi - \varepsilon_X \sin \phi)^2 / 200\% \quad (33.1)$$

for transformers having impedance voltages up to 20% and

$$\varepsilon = \varepsilon_R \cos \phi + \varepsilon_X \sin \phi \quad (33.2)$$

is a simplified expression for cases in which the impedance voltage does not exceed 4%. For unity p.f. load, (33.1) reduces to  $\varepsilon = \varepsilon_R + \varepsilon_X^2 / 200$  and (33.2) reduces to  $\varepsilon = \varepsilon_R$ .

### 33.3.6 Losses

The load (or 'copper') loss comprises two components; a direct  $I^2 R$  loss due to ohmic resistance of the windings, and a stray loss arising from eddy currents in the conductors due to their own flux, influenced by the tank and by steel clamping structures. The eddy loss is negligible when the section of the conductor is small. When the current is too great for a single conductor without excessive eddy loss, a number of strands must be used in parallel. Because the parallel components are joined at the ends of the coil, steps must be taken to circumvent the induction of different e.m.f.s in the strands, which would involve circulating currents and further loss. Forms of conductor transposition have been devised for this purpose.

Ideally, each conductor element should occupy every possible position in such a way that all elements have the same resistance and the same induced e.m.f. Transposition, however, involves some sacrifice of winding space. If the winding depth is small, one transposition halfway through the winding is sufficient; or in the case of a two-layer winding,

**Figure 33.17** Conductor transposition

at the junction of the layers. Windings of greater depth need more transpositions.

Typical forms of transposition are shown in *Figure 33.17*. The methods apply mainly to helical coils. In disc windings where there are two or more conductors in parallel, the connections between the discs can be arranged to give the necessary effect.

Stray loss may also be produced by radial components of leakage flux, but can be minimised by careful ampere-turn balance of the windings.

#### 33.3.6.1 Efficiency

Efficiency is the ratio between power output and power input. Its actual value is less important than that of the magnitude of the losses, which determine heating, cooling, rating and the cost of supplying the losses under given loading conditions in a system.

For a given system voltage and transformer tapping, the flux density has constant peak value, and the core loss  $p_i$  is considered to be constant. The load loss  $p_c$  varies with the square of the loading, and because of the change of conductor resistivity with temperature is commonly stated at 75°C. If the power input is  $P_1$  and the power output is  $P_2$ , the efficiency is

$$P_2/P_1 = \frac{P_2}{P_1 + p_i + p_c} \text{ per unit.}$$

#### 33.3.7 Cooling

The majority of transformer windings are cooled by thermal circulation of oil. Even where pumps are fitted to provide forced cooling, it is common for the transformer to operate without the pump up to some proportion of its forced cooled rating. It is, therefore, important to ensure that the natural thermal circulation of the oil is such that there is a flow over the main cooling surface of the coils. This is a

simple matter where the main cooling surfaces are vertical, but when (as in disc windings and particularly on large transformers), the major cooling surfaces are horizontal, special means must be taken to ensure that the oil will flow across the horizontal surface under both natural and forced cooling conditions. Oil-flow barriers are introduced for this purpose.

#### 33.3.8 Short-circuit conditions

Under conditions of system fault, mechanical and thermal stresses of considerable magnitude can be imposed on a transformer winding.

Mechanical forces of magnetic origin may be resolved into two components: (1) *radial*, due to the coil currents lying in the axial component of the leakage flux, tending to burst the outer and crush the inner winding; and (2) *axial*, due to the radial component of the leakage flux arising from ampere-turn unbalance, tending to displace the windings (or parts thereof) with respect to each other. Axial forces may increase the unbalance that produces them, and repeated short circuits may have a cumulative effect. Windings must be designed and built to withstand the mechanical forces, an important aim being to minimise ampere-turn unbalance between windings, especially that caused by tappings.

Thermal stresses arise from the temperature attained by the windings when carrying sustained fault current. The limits of temperature rise permitted by IEC 60076 for copper windings are: 250°C for class A insulation in oil and 350°C for class B in air. Aluminium windings are limited to 200°C for both classes.

Mechanical forces have to be considered relative to the asymmetrical peak current, whereas thermal stresses are governed by the symmetrical r.m.s. value and duration. The fault current is controlled by the leakage impedance of the transformer and the impedance of the supply system. IEC 60076-5 states that for transformers rated 3150 kVA or less, the system impedance shall be neglected in the total impedance if it is equal to or less than 5% of the leakage impedance of the transformer.

The duration for which a transformer can withstand short-circuit current depends on thermal considerations. IEC 60076-5 states that the duration of the short-circuit current to be used for calculation of the thermal ability to withstand short circuit is 2 s unless otherwise specified by the purchaser. The temperature attained by the winding can be calculated by the method described in IEC 60076-5 on the assumption that, during the period of short-circuit, all heat developed by the loss in the windings is stored in the conductor material.<sup>9</sup>

### 33.4 Connections

Transformer windings can be constructed for connection to a one-phase, two-phase or three-phase power supply. Combinations are also possible, namely three-to-two or three-to-one phase conversion. Six-, 12- and even 24-phase connections may be needed in rectifier transformers. Single-phase transformers can be independent; arranged to provide a two- or three-wire supply, centre-point earthed, or combined to form a three-phase bank. In the case of three-phase windings, three forms of connection are possible; star, delta and interconnected-star (zig-zag). When combined on the same core, a delta winding and an interconnected-star winding can be arranged to provide zero phase displacement,

and when either of these is combined with a star winding, a  $30^\circ$  phase displacement results, either leading or lagging. By reversal of one winding with respect to the other when a combination of the same connection is involved, or where the combination is of connections giving the same phase displacement, a  $180^\circ$  phase displacement is produced. A summary of the combinations detailed in IEC 60076 and the corresponding e.m.f. diagrams is given in Figure 33.18.

In a star/star connection unbalanced load may result in neutral displacement and third-harmonic currents may circulate between lines and earth. These difficulties may be overcome by providing a delta connected stabilising (tertiary) winding with a rating sufficient to take short-circuit fault currents. The need for this winding depends, however, on the core construction. Where, as in banks of three one-phase units or in five-limb three-phase core-type transformers, there is an independent iron path for the zero-sequence flux in each phase, the z.p.s. impedance is consequently high, making a stabilising winding essential. With three-phase three-limbed cores the z.p.s. fluxes are forced out of the core and the z.p.s. impedance is lower; consequently, a tertiary winding may not be necessary.

### 33.4.1 Phase conversion

The Scott connection is the most common two-to-three phase conversion. Two one-phase transformers are generally used, with one pair of windings arranged to form a T connection for the three-phase supply. The 'main' unit is wound for the phase-to-phase voltage with a mid-point tapping, and forms the head of the T. The other unit, the 'teaser', is wound for 0.866 times the line voltage and both are designed to carry full line current. A neutral point can be provided by a tapping on the teaser winding at a point 0.577 of the turns from the line end (see Figure 33.19). The two units, for operational convenience, can be made interchangeable. A winding arrangement which results in a minimum leakage reactance between the winding halves of the main unit (for example, an interleaved winding) is essential to ensure correct current distribution and to avoid excessive voltage regulation. In the place of two single-phase units, a three-limb core, outer limbs wound, may be used if the unwound centre limb is proportioned to suit the flux conditions, i.e. given 41.5% greater section.

As an alternative to the Scott connection, which is basically a one-phase arrangement, a Leblanc connection can be used. It employs a standard, three-limb, three-phase core and a standard three-phase delta connected winding (Figure 33.20). Compared with the Scott arrangement, the Leblanc connection requires a smaller core but involves a greater winding section.

Three-phase to single-phase transformation can be achieved by an open delta connection which involves a standard, three-limb, three-phase core, with outer limbs wound. Alternatively, an arrangement similar to the Scott connection can be used. With the open delta connection the output voltages from each limb are  $120^\circ$  apart, so that the voltage applied to the load is 3 times the voltage across one winding, and in the case of the T connection the output voltages are  $90^\circ$  apart, so that the voltage applied to the load is 2 times the voltage across one winding. With either form of connection, if a three-wire one-phase supply is required and the loads on each side of the mid-point are liable to unbalance, the windings should be subdivided and interconnected to distribute more evenly the out-of-balance current and to avoid excessive voltage regulation.

Figure 33.18 Standard connections for three-phase transformers

Figure 33.19 Scott three-to-two phase transformation

Figure 33.20 Leblanc three-to-two phase transformation.  $S_s$  is the kilovolt-ampere rating of the two-phase load

It is important to realise that, although a three-to-one phase connection can be used to transform a line-neutral load on the secondary side to a line-line current on the primary side, it does not result in a balanced primary load. The same degree of unbalance must appear on the primary; or in terms of symmetrical components, all zero- and negative-sequence currents on the secondary will also flow on the primary side.

### 33.5 Three-winding transformers

Typical applications of three-winding transformers are:

- (1) feeding two secondary networks, of different voltage or phase relationship, from a common primary supply;
- (2) connecting two generators to the same high-voltage system while maintaining a relatively high impedance between them to limit cross-feed of fault energy;
- (3) feeding two parts of a sectionalised low-voltage network so as to limit the fault level of each part without too high an impedance between the high-voltage and the low-voltage sides; and
- (4) providing a rectifier with a multiphase (e.g. 12- or 24-phase) supply.

Provided that there is at least one delta connected winding, to permit the flow of third-harmonic currents, there is freedom to adopt star or delta connection to meet phasing or earthing requirements.

#### 33.5.1 Impedance characteristics

Two-winding technology does not apply. The essence of the procedure for a three-winding unit is that the leakage impedance can be represented by assuming each of the three windings to have an individual resistance and leakage reactance, and mutual impedance effects (other than those that result from these individual values) to be absent. The equivalent circuit can be represented by the star network in Figure 33.21. The leakage impedance values (in per-unit form to a common kilovolt-ampere base) are given in terms of the conventional two-winding impedances: for resistances

Figure 33.21 Equivalent circuit of a three-winding transformer

$$R_1 = \frac{1}{2}(R_{12} + R_{31} - R_{23}) \ll$$

$$R_2 = \frac{1}{2}(R_{23} + R_{12} - R_{31}) \ll$$

$$R_3 = \frac{1}{2}(R_{31} + R_{23} - R_{12}) \ll$$

$X$  being substituted for  $R$  to give the leakage reactances. These for the individual arms are then combined to give the effective values between any pair of terminals: e.g.  $R_{12} = R_1 + R_2$ ,  $X_{23} = X_2 + X_3$ , and so on. (As the equations for the individual arms include a negative term, some particular evaluations may be found to be negative.)

#### 33.5.2 Tertiary windings for harmonic suppression

The most common three-winding transformer is star/star connected with a delta tertiary to provide a path for z.p.s. currents. If third-harmonic distortion of the main flux (and, hence, of the secondary voltage wave form) is to be avoided, a tertiary must be used on any configuration of core that provides a low-reluctance path for third-harmonic components of the flux. This requirement applies to shell types, and to three-phase core types having more than three limbs; a three-phase three-limb core-type transformer has no ferromagnetic return path for third-harmonic flux components, so suppressing z.p.s. distortion of the flux, and it will operate satisfactorily provided that the load is not significantly unbalanced. For an unbalance exceeding 10%—or if a low zero sequence impedance is required for protection purposes—it would be prudent to include a tertiary. However, a two-winding transformer called upon to supply zero-sequence loads could alternatively be provided with an external source of zero-sequence power (a) by a direct connection between the transformer in question and the neutral of a stand-by unit having a delta winding, or (b) by the installation of a zig-zag connected 'earthing transformer'. If several star/star units are acquired and undue unbalanced loading is not expected, it would be preferable on grounds of cost to specify them without tertiary windings, subsequent remedial action being taken if and when it becomes desirable. Whether or not third-harmonic problems arise depends on the complete installation and how it is operated. The transformer characteristics do not alone determine the issue; other factors are (a) the level of the transformer core flux density (and, hence, the magnitude of the third-harmonic component of magnetising current); (b) the expected degree of load unbalance; (c) the impedance of external sources of zero-sequence current; and (d) the proximity of telecommunication circuits to the external zero-sequence current path. Tertiary windings fitted only for harmonic suppression and not connected to external terminals must be rated to withstand the effects of primary and secondary earth fault currents: tertiary current then depends on the p.p.s., negative phase sequence (n.p.s.) and z.p.s. impedances

of both the supply and the transformer. As such fault currents persist for only a few seconds, the temperature rise of the tertiary winding is determined by its thermal capacity.

### 33.5.3 Tertiary windings for external loads

Tertiary windings providing auxiliary power circuits, or supplying reactive power compensating capacitors or inductors, must have an appropriate continuous rating. The tertiary must withstand the effects of a short-circuit fault across its external terminals, as well as those due to earth faults on the main windings. The conductor sections and the bushings are designed for the most onerous operating condition.

## 33.6 Quadrature booster transformers

Consider two lines in parallel transmitting power between A and B (*Figure 33.22*):  $T_1$  and  $T_2$  are conventional transformers, either or both having on-load tap changing equipment. The division of load currents  $I_1$  and  $I_2$  between the lines is in inverse proportion to the impedances  $Z_1$  and  $Z_2$ . For better load sharing it may be desirable to adjust the division of current. Tap changing the transformers to give a voltage difference  $V$  between  $T_1$  and  $T_2$  will cause a circulating current  $I_t = V/(Z_1 + Z_2)$  to flow around the loop; and  $I_t$  will lag  $V$  by the natural phase angle of  $Z_1 + Z_2$  increasing the current and  $I^2R$  loss in the branches without achieving the desired change in load sharing.

If a booster transformer  $T_b$  is introduced into the loop to inject a small voltage in quadrature with the supply voltage, the resulting circulating current will be approximately co-phasal with the active-power component of the load current. It will therefore add arithmetically to the active current in one branch and subtract from that in the other, thus controlling the relation between  $I_1$  and  $I_2$ . The adjustment permits an increase in the total load that can be transmitted over the system. The quadrature booster is an important element for power control in parallel circuits. A simple method of deriving the necessary injected voltage is shown for one phase in *Figure 33.23*. A single transformer unit has a delta connected main winding and a tapped series winding to provide an adjustable voltage in quadrature with the phase voltage. For large high-voltage quadrature boosting, two transformers are commonly used in order to provide the necessary dielectric and short-circuit strengths. The first 'excitation' transformer supplies the second 'injection' transformer. By suitable choice of connections either

Figure 33.23 Connections for quadrature regulation

quadrature or in-phase regulation can be obtained. By use of two tap changers and more complex tapping windings, separate control of both in-phase and quadrature components can be achieved.

## 33.7 On-load tap changing

The essential feature of all methods of tap changing under load is that circuit continuity must be maintained throughout the tap stepping operation. The general principle of operation used in all forms of on-load tap changer is that, momentarily at least, a connection is made simultaneously to two adjacent taps on the transformer during the transition period from one tap to the next. Impedance in the form of either resistance or inductive reactance is introduced to limit the circulating current between the two tappings. The circulating current would represent a short-circuit between taps if not so limited. *Figure 33.24* shows in diagrammatic form the use of a centre-tap inductor or auto-transformer as the transition impedance. In *Figure 33.24(a)* the load current is shown passing from the maximum tap through the halves of the inductor in opposition, and hence, non-inductively. In *Figure 33.24(b)* one of the two tap-selector switch contacts has opened and the load current is carried inductively through one half of the inductor. In *Figure 33.24(c)* the inductor is shown bridging the two adjacent tappings. The load current is shared equally between the two tappings

Figure 33.22 Power flow along two parallel lines of different impedance

Figure 33.24 Inductor transition

and passes non-inductively in opposition through the halves of the inductor. The tap step voltage is applied to the whole of the winding of the inductor and the circulating current is limited by the total impedance. In this position, in which the tap changer can remain indefinitely, the effective voltage is equivalent to the mean of the two individual tap voltages. Figure 33.24(d) shows the momentary condition where one half is connected inductively to the incoming tap position, and Figure 33.24(e) shows the final stage of the transition where both selector switch contacts are connected to the incoming tap and the inductor is non-inductively connected.

Circulating-current limitation by centre-tapped inductor was common in the late 1940s, but has since been almost entirely superseded by high-speed resistor transition. The switching sequence is shown in Figure 33.25 and is similar to that with inductors, except that two resistors are used. Backup main contacts are provided which short-circuit the resistors for normal running conditions.

Advantages of inductor transition were: the inductor could be continuously rated and a failure of auxiliary supply during a tap change did not necessitate the main transformer being taken out of service; also, that the intermediate or bridging position could be used as a running position, giving a voltage equivalent of one-half tap step. The main disadvantage was that the circulating current between taps during the bridging condition was at low power factor, adversely affecting diverter-switch contact life. The inductor itself was costly and occupied a significant amount of space in the transformer tank.

Resistor transition is now used almost exclusively by British and European tap changer manufacturers, although inductor transition is still used in the USA, possibly because it is common practice there to specify a large number of small tap steps, a requirement met by using the bridging position as a running tap.

Resistor transition requires one winding tap for each operating position. The basic disadvantage is that the resistors cannot be continuously rated, if their physical size is to be kept small. It is essential to minimise the period during which they are in circuit. Some form of energy storage has, therefore, to be incorporated in the driving mechanism to ensure that a tap change, once initiated, is completed irrespective of failure of auxiliary supply. Early resistor tap

changers operated at low speed and the stored-energy mechanism was a flywheel or a falling mass. All modern tap changers use springs for energy storage, and the total time that a resistor is in circuit during a tap change is limited to a few periods. The advantages of the high-speed resistor tap changer are its compactness and lack of wear of diverter-switch contacts because of the high speed of break, and because the circulating current is at unity power factor. Contact life of 250 000 operations is common, compared with the 10 000–20 000 for reactor tap changers.

Irrespective of the form of transition, all on-load tap changers fall into one of three categories in respect of the switching arrangement. These are as follows:

- (1) The oldest (and now least common) arrangement is for a separate contactor to be connected to each winding tap. Contactors are operated by a camshaft to ensure the correct sequencing. A later development was to use mercury switches instead of open-type contactors, giving the advantage of freedom from carbonisation of the coil.
- (2) The winding tappings are connected to a series of fixed contacts of a selector switch of either linear or circular form, and an associated pair of moving contacts operates to provide the required switching sequence. Current making and breaking occurs at the selector switch contacts and some degree of oil carbonisation and contact wear is inevitable. This type of tap changer, usually called 'single-compartment', is now common for transformers up to about 20 MVA rating.
- (3) For the largest and most important transformers the tap selector switches do not move when carrying current. Current making and breaking is carried out by two separate diverter switches, usually in a separate compartment of the tap changer to minimise the amount of oil contaminated by carbon. The diverter switches operate to make and break the current and are mechanically interlocked with the selector switches, which move only when not carrying current to provide the correct sequence of connection to the winding taps.

At one stage of development of medium-sized tap changers, large mercury switches were used as diverter switches; these could be mounted in a selector switch compartment as there was no risk of oil contamination. A recent development along the same lines is the application of vacuum-switch diverters, capable of many thousand operations without attention and with freedom from contamination. Trials are being made with thyristors to provide 'contactless' switching: while this might yield marginal advantage in minimising maintenance and perhaps improving reliability, the cost and complexity of the control arrangements are likely to be inhibiting factors.

### 33.7.1 Tap changer control

Control gear can vary from simple local push-button control to a complex scheme for the automatic control of as many as four transformers operating in parallel. The objective of automatic tap change control is to maintain output voltage either constant or with a compound characteristic rising with load. The main component is the automatic voltage-regulating device, which consists of a voltage governor, a time-delay relay and compounding elements. The time-delay element prevents tap changes occurring due to minor short-time fluctuations of voltage. It can be set for delay periods of up to a minute. Tap change control circuits necessarily involve auxiliary switches mounted within the

**Figure 33.25** Resistor transition. (a) Outgoing tap operating; (b) load current in resistor; (c) resistors in parallel to load current and in series to circulating current; (d) load current in resistor; (e) incoming tap operating

driving mechanism of the tap changers themselves, and this has led to a proliferation of types of control schemes each designed to operate with a particular type of tap changer. These variations have made it extremely difficult for the British Electricity Supply Authorities to develop a national standard control scheme. Some of the differences arise in the method adopted to arrange simultaneous or near-simultaneous tap changes of transformers operating in parallel. A further complication arises because of differences between one transformer and another in the tapping range and the number and size of tapping steps. Some of the various types of parallel control schemes are as follows:

- (1) Simultaneous operation of two or more tap changers initiated from one voltage regulating relay. Closing of the 'raise' or 'lower' contact in the voltage-regulating relay closes the appropriate motor contactor in each tap changer, and auxiliary switches lock out further movement until all the tap changers have completed a single change of position. This scheme is, in general, only applicable to tap changers with identical main and auxiliary characteristics.
- (2) Master-follower operation initiated from one voltage-regulating relay. This is also suitable for two to four transformers in parallel, although the length of time to complete an initial tap change may be considered to be excessive where more than two transformers are involved. The voltage relay initiates the movement of the 'master' tap changer: when this has completed one tap step, the auxiliary switches operate to cause the second transformer of the chain to come into line with the first. This is followed in sequence by the movement of the remaining units. The time for completing one tap step on all units in the bank is, therefore, the sum of the individual operating times. As in (1), this scheme is suitable only for substantially identical tap changers.
- (3) Master-follower scheme with multiple voltage-regulating relays; a more complicated version of (2) in that each transformer is equipped with its own voltage-regulating relay and any one of the group may be selected to act as master, the remaining units following in any desired sequence.
- (4) Circulating-current control schemes. The foregoing schemes all require multipoint switches in each tap changer, interconnected by multi-core cable. The circulating-current schemes depend on the fact that if two transformers operating in parallel are out of step, a circulating current will flow between them in a direction depending on the relative ratio of transformation. Each transformer is controlled by its own voltage-regulating relay, and as individual characteristics are not absolutely identical, it follows that, when a change of voltage occurs, one relay of the group will initiate a tap change on its associated transformer earlier than the others. As soon as the first transformer of a group has completed a tap change, there will be an imbalance of ratio and a circulating current will flow in the main circuit connections between the transformers. This circulating current is used to control auxiliary relays in each tap changer of the group, so that no further movement can occur to increase the imbalance, i.e. the second and later transformers in the group can change step to come into line with the first unit which has already moved; alternatively, the first unit can move in the reverse direction to bring itself back into its original position and therefore directly in step with the others. This type of scheme allows transformers to operate indefinitely in a 'one step out' condition. The wiring is relatively simple, as

the only interconnections between units are the secondary leads of the circulating-current transformers. It permits automatic parallel control of transformers of different rating, impedance, tapping range and number and size of tapping steps, as the tap changers take up positions to minimise the circulating current between units. Provided that the c.t.s. are selected to correspond to the rating of each main transformer, optimum loading of the group is achieved.

- (5) Parallel control by reverse compounding. All of the schemes mentioned above necessitate secondary connections between the transformers that are to operate in parallel, and all except (4) suit only transformers with near-identical characteristics. Where parallel operation is required between transformers with differing characteristics, or where the transformers are situated some distance apart, it is possible to achieve stable operation with each being controlled by its own voltage-regulating relay by introducing negative compounding of the reactance element of a line-drop compensator. This tends to give a negative compounding characteristic (i.e. output voltage drops as load increases), but compensation can be provided by increasing the positive compounding of the in-phase element. Unless the negative reactance characteristic is introduced, any two tap changers controlled by independent voltage-regulating relays which are not positively locked together will inevitably move quickly to opposite extremes of their range.

### 33.7.2 Line-drop compensation

This device permits the output voltage of the transformer to be compounded so that it rises with load to compensate for voltage drop in the cables connected to the secondary side, and to maintain approximately constant voltage at a remote point. The line-drop compensator comprises an 'artificial line' circuit consisting of adjustable resistances and reactances connected into the voltage relay operating-coil circuit (*Figure 33.26*). A current transformer in the main secondary connection injects current into the adjustable resistance and reactance coils and thus biases the voltage applied to the voltage sensitive element of the regulating relay.

**Figure 33.26** Line-drop compensation.  $R_1$  and  $X$  are adjustable to suit line characteristics;  $R_2$  adjusts the output-voltage level

### 33.8 Cooling

Small transformers are air cooled and insulated. For units of larger rating and higher voltage, oil cooling becomes economical, because oil provides greater insulation strength than air for a given clearance, and augments the rate of removal of heat from the windings. With the exception of certain special installations, such as in coal mines or within occupied buildings where mineral oil is undesirable because of the fire risk involved, almost all power transformers are oil immersed. The combination of oil and paper insulation

has been used in transformers for many years and there appears little likelihood of its being superseded by any modern synthetic material. A principal reason for this situation is that both materials can be operated safely at the same maximum temperature, approximately 105°C. Any alternative materials would have to show significant advantages in either or both insulating and heat transfer properties compared with the combination of oil and paper.

The most common types of cooling arrangements, detailed below, are identified in IEC 60076 by a system of symbols which indicate the cooling medium in contact with the windings; the cooling medium in contact with the external cooling system; and the kind of circulation for each. The symbols for the cooling media are:

- O for mineral oil or an insulating liquid with fire point  $<300^{\circ}\text{C}$
- K for an insulating liquid with fire point  $>300^{\circ}\text{C}$
- L for an insulating liquid with no measurable fire point
- W for water
- A for air
- G for gas.

The symbols for circulation in a liquid immersed transformer are:

- N for natural thermosyphon flow
- F for forced fluid circulation, but thermosyphon cooling in the windings
- D for forced fluid circulation, with fluid directed into the windings.

IEC specifications stipulate temperature limits for windings (measured by resistance) and insulation and define normal standard values for the temperature of the cooling medium.

### 33.8.1 Air insulated, air cooled

#### 33.8.1.1 Natural air cooling (AN)

The temperature rise measured by resistance is limited by the class of insulation used. Typical figures are 60 K for class A, 90 K for class B and 150 K for class C materials; all rises being above a maximum ambient temperature of 40°C and a daily average of not more than 30°C. Type AN cooling is generally limited to relatively small units, although the development of high-temperature insulation, such as glass and silicon resins, has resulted in its use on transformers up to 1500 kVA and for special application as in mines.

#### 33.8.1.2 Forced air cooling (AF)

The temperature conditions are the same as for AN, but the improved heat transfer properties resulting from the forced air stream enables the current density in the windings and the flux density in the core to be increased and greater output to be obtained from a given size of unit.

### 33.8.2 Oil immersed, air cooled

IEC 60076 recognises two maximum oil temperatures: 60°C when the transformer is sealed or equipped with a conservator, and 55°C when the transformer is not so equipped. Winding temperature rise by resistance for oil immersed transformers with ambient air temperatures of 40°C and a daily average of not more than 30°C is limited to 65 K, irrespective of the type of cooling or the cooling medium.

The various types of cooling and the new symbols are as follows.

#### 33.8.2.1 Natural oil circulation, natural air flow (ONAN)

The great majority of power transformers up to ratings of 5 MVA are of ONAN type. A plain sheet-steel tank radiates about 13 W/m<sup>2</sup> per degree Celsius rise. Above about 25 kVA, three-phase, an increased cooling surface becomes necessary. This extra surface may be obtained by using fins or corrugations, but the most common method is to employ a tubed tank. The tubes are usually 40–50 mm in diameter, of welded steel construction, having a wall thickness of about 1.5 mm. For medium sizes (2–5 MVA) tubes of elliptical section are preferred, as a greater number can be accommodated on a given tank. For transformers larger than 5 MVA it becomes necessary to employ radiator banks of elliptical tubes, or banks of corrugated radiators.

Transformer tanks have been constructed with finned tubes in order to augment the surface. They are difficult to paint, and are liable to collect water if employed out of doors.

The power dissipated by a tubular tank is a function of the ratio between tank envelope and total surface, for radiation is a function of the envelope, while convection depends upon the whole surface.

#### 33.8.2.2 Natural oil circulation, air blast (ONAF)

By directing an air blast on to an ordinary tubular tank or on to separate radiators the rate of heat dissipation is increased; thus, while the transformer itself is not reduced in size, less external cooling surface is required.

#### 33.8.2.3 Forced oil circulation, natural air flow (OFAN)

OFAN is an uncommon system, but is useful where for reasons of space the coolers have to be well removed from the transformer. The oil is pumped round the cooling system, from which heat dissipation is by natural air convection. The forced oil circulation permits high current densities to be employed in the windings, so that there is a reduction in transformer size.

#### 33.8.2.4 Forced oil circulation, air blast (OFAF)

The OFAF system is employed for most large transformers. The forced oil enables the windings and core to be economically rated, while the forced air blast reduces the size of the radiating surfaces, an important point for transformers of 30 MVA upward. Depending upon the type and disposition of the radiators and on the purchaser's requirements, *mixed* cooling is employed in which the transformer operates as an ONAN unit up to 50% of its forced cooled rating (66% in the USA). As the load increases further, temperature sensitive elements start the pumps and fans of the forced cooling equipment.

### 33.8.3 Oil immersed, water cooled

Cooling-water inlet temperature limits as defined in IEC 60076 must not exceed 25°C. Oil temperature and winding temperature limits are as for air cooled units.

### 33.8.3.1 Natural oil, water (internal cooler) (ONWF)

A copper cooling coil is mounted above the transformer core in the upper portion of the transformer tank.

### 33.8.3.2 Forced oil, water (external cooler) (OFWF)

The OFWF system uses oil/water heat exchangers external to the transformers. The arrangement has a number of advantages over ONWF cooling:

- (1) The transformer is smaller in size, as the windings can be more highly rated owing to forced oil flow and the tank is not required to accommodate a large cooling coil.
- (2) Condensation troubles are non-existent.
- (3) Water leakage into oil is improbable with the oil pressure maintained higher than that of the water. In cases where the cooling water has a high head at the transformer plinth level, it is necessary to employ two heat exchangers in series, i.e. oil/water and water/water; the water in the intermediate circuit between the two coolers is separate from the main water supply and at a low head.
- (4) The cooling tubes may be easily cleaned. Water cooling of transformers is common at generating stations (particularly hydroelectric ones), where ample cooling water supplies are available.

### 33.8.4 Overload capability

The temperature limits for oil, windings and insulation laid down in IEC 60076 are chosen to ensure that a transformer operating within these limits will have a satisfactory life of 20 or more years. The relationship between operating temperature and life is complex. Experimental work indicates that each 8°C increase in operating temperature halves the life of the insulation, but there is little information available to enable an operator to determine precisely the actual life expectation under any given operating conditions. This obviously depends on other factors, including the incidence and severity of short-circuit forces to which the ageing insulation may be subjected. To some extent also the loss of insulation life due to overload operation during an emergency can be offset, provided that for some further and more protracted period operating temperatures are kept well below the specified limits.

Because of the considerable thermal inertia of the mass of oil and metal in a transformer, appreciable overloads can be carried for short periods without endangering insulation life. IEC 60076-7 gives details of permitted overloads.<sup>10</sup> These allowable overloads are, however, normally regarded as conservative and have been exceeded in service without adverse results. The overload recommendations in IEC 60076-7 are based on a maximum hot-spot temperature of 90°C at rated load and loss of life doubling for each 6°C increase in temperature above 98°C. It is important that the windings are not operated at a temperature above 140°C as air/water vapour bubbles are formed from cellulose insulation at higher temperatures. Bubble formation can lead to dielectric failure of the windings.

## 33.9 Fittings

The number of fittings and their siting on the transformer tank constitute major problems of transformer standardisation. It is recommended, therefore, that the fittings enumerated in IEC 60076 be used, careful consideration

being given to the essential points before any refinements and extras required for satisfactory operation are specified.

**Terminals and bushings** Transformer terminals must of necessity cover a wide range of voltages, currents and operating conditions. Outdoor type bushings are standardised in Britain and are detailed in ESI Standards 35-1 and 35-2 and BEB Specifications T<sub>1</sub>, T<sub>2</sub> and T<sub>3</sub>. Some outdoor bushings are fitted with arcing horns which provide a safety gap to discharge an incoming surge which might otherwise damage the transformer windings. It is important that there is the correct correlation between the insulation strength of the transformer winding and the flashover characteristics of the gap. The setting of the gap must be small enough to protect the windings without causing too frequent interruption of the supply due to power arcs following gap flashover due to surges on the system.

**Cable boxes** These are essential when paper or plastics insulated cables require connection to the transformer. Cable box arrangements depend on the number of cores in the cable and the number of cables connected in parallel. Several factors must be considered in designing a cable box: adequate electrical and mechanical clearances are necessary; the compound must not ooze out of the box nor any transformer oil leak in; and voids must not easily occur in the compound, either during pouring operations or during normal thermal expansion and contraction. In order to make transformers interchangeable the box flanges are standardised (ESI 35-1 and 35-2).

**Oil conservator** Transformer oil has a coefficient of thermal expansion of 0.000725 per degree Celsius at 0°C, equivalent to a 7.25% volume change over an oil temperature range of 0–100°C. The expansion may be accommodated in a free-breathing or sealed space at the top of the tank, or in a conservator tank mounted on the tank cover. It is desirable to avoid oxidation of the oil, which causes sludging and acidity to develop. With either the sealed tank or the conservator a nitrogen cushion can be maintained above the surface of the oil, thus preventing oxidation. A free-breathing conservator is preferable to an unsealed tank, as the temperature of the oil in contact with the air is lower and this in itself reduces the rate of oxidation. Some form of oil pressurisation is essential for large transformers and for those working at 33 kV and above; it is desirable also for small transformers, especially those subjected to heavy periodic peak load.

**Breather** This device allows ingress and egress of air to compensate for changes in oil volume. Except on small transformers, the breather should incorporate either a chemical or a refrigerating system for removing moisture from the air entering the transformer.

**Oil gauge** This can be a direct-reading glass window, or a dial instrument operated by magnetic coupling from a float on the oil surface. The dial gauge can be fitted with contacts to give a low-oil-level alarm.

**Oil temperature indicator** Normally of the dial type, oil thermometers can be arranged for remote electrical indication of oil temperature.

**Winding temperature indicator** The so-called winding temperature indicator is basically an oil temperature thermometer in which the bulb is associated with a heater coil which carries a current proportional to the load on the transformer.

The heater coil introduces an increment of temperature above that of the oil, to correspond to the gradient between winding and oil temperatures. The instrument thus indicates a figure which, although a reasonable analogue of the temperature of the windings, is not a direct measurement thereof.

Important new developments in direct measurement of temperature in high-tension windings are being introduced.<sup>11</sup> This measurement is achieved by the use of fibre-optic strands attached to one of the winding conductors. Two different applications are possible. The first uses a gallium-arsenide based sensor tip at the end of the fibre-optic strand to provide a single-point temperature detector.

The second application is to use the whole length of the fibre-optic strand itself as a distributed sensor. A technique known as optical time domain reflectometry interrogation from a single end enables temperature measurements to be made at points 1 m apart along the full length of a fibre-optic strand up to 4 km long, i.e. at up to 4000 data collection points. These applications may lead to considerable advances in determining safe overloading rules.

**Buchholz relay** Any electrical fault occurring inside a transformer is accompanied by an evolution of gas. Appreciable quantities of gas may be produced before the fault develops to such an extent that it can be detected by the normal protection equipment. The Buchholz relay, connected between the transformer tank and the conservator, contains two elements: (1) a float which operates a gas alarm device to give warning of gas discharge from within the transformer, and (2) a surge element connected to trip the transformer out of circuit in the event of a massive surge of oil and gas resulting from a major internal fault. In the event of a gas alarm being given, it is sometimes possible to deduce the nature of the defect within the transformer by observing whether the gas emission is at a constant rate (voltage dependent) or varies with load (current dependent).

The Buchholz relay provides sensitive protection against certain types of fault (e.g. flashover between tapping leads) to which the normal protection is relatively insensitive, and may not operate until extensive damage has been caused.

**Relief or explosion vents** Many users specify relief or explosion vents, which are intended to act as safety valves to reduce internal pressure in the event of a major fault within the transformer and thus to protect the tank from damage. The vents can be spring loaded or fitted with thin non-metallic material to fracture under pressure. Provided that the build-up of pressure is relatively slow, the relief vent can operate satisfactorily and prevent the tank from bursting, but in the event of a violent fault leading to a shock wave of pressure, the tank may be burst before the relief vent has time to operate.

**Tapping switches (off-load)** Almost every distribution and medium-sized power transformer is fitted with voltage adjusting tapplings, usually for five positions corresponding to  $\pm 2.5\%$  and  $\pm 5\%$  of the supply voltage. To obviate opening up the transformer to change tapping links, a tapping switch is necessary. Such a switch is often fitted on top of the transformer core and is gang operated on all phases by means of a hand wheel on the tank end.

- (1) output and temperature rise of the transformers;
- (2) polarity for one-phase units; angular displacement for three-phase units-IEC group reference or phasor diagram;
- (3) turns ratio on all tapplings;
- (4) percentage impedance at 75°C; and
- (5) percentage resistance drop at 75°C, or the load loss.

The polarity is basically determined by the direction of the primary and secondary windings and the position of the transformer line leads with respect to the start and finish of the windings. British transformers usually have a subtractive polarity. In the case of three-phase units it is the angular phase displacement, i.e. the angle between the primary and secondary phase to neutral voltages, which has to be considered. This angle may be  $0^\circ$ ,  $180^\circ$  or  $\pm 30^\circ$  depending on the direction of the windings and the interphase connections.

All groups of transformers having the same angular displacement may be connected in parallel. Those having  $+30^\circ$  displacement may be paralleled with  $-30^\circ$  units, provided that the line leads are suitably transposed. Parallel operation is not possible between a  $0^\circ$  or  $180^\circ$  group and a  $\pm 30^\circ$  group.

Some typical examples of connections are:

Connection	IEC ref. no.	Displacement ( $^\circ$ )
Delta/star	Dy.11	+30
Star/delta	Yd.1	-30
Star/star	Yy.0	0
Star/inter-star	Yz.11	+30
Delta/inter-star	Dz0	0

From this it will be seen that parallel operation is not possible between star/star and delta/star units. If the turns ratios of the transformers are not identical, a circulating current traverses the transformer windings, increasing the no-load losses. The magnitude of this circulating current for the case of two transformers A and B is

$$I_s = (V_A - V_B) / (Z_A + Z_B)$$

where  $V$  is the no-load secondary voltage for a common primary voltage and  $Z$  is the leakage impedance, all quantities being complexors.

The relative values of the percentage (or per-unit) impedance determine the proportion of the total load shared by each transformer. Thus, when all the percentage impedances are identical, each transformer will take its fair share of the load. Although it is advisable to have this condition, dissimilar impedance units may be connected in parallel in an emergency, provided that the current carried by any transformer does not exceed its normal rating or an acceptable overload value.

The percentage resistance drops of the transformers need not be the same. A difference in resistance drop, when the percentage impedances are numerically equal, results in an angular displacement of the individual transformer currents and reduces slightly the maximum permissible output. This is not normally of serious consequence.

### 33.10 Parallel operation

The following information is required when the parallel operation of transformers is considered:

### 33.11 Auto-transformers

The great advantage of the autoconnection, as distinct from the usual double-winding arrangement, is that the transformer

physical size and losses are much smaller, provided that the primary to secondary turns ratio is not large. The amount of apparent reduction is termed the autofraction

$$n = (V_1 - E_2)/V_1$$

where  $V_1$  is the higher and  $V_2$  is the lower voltage. Thus, the equivalent frame rating of an auto is equal to  $n$  times the load or throughput rating. For a 2/1 ratio this means that the auto-transformer is half the size of a double-wound transformer for the same duty. A requirement for tappings can have a marked effect on the apparent economy of using an auto-transformer.

Unfortunately this economy is not obtained without certain liabilities, so that care is required in specifying auto-transformers unless the conditions are known and appreciated.

The calculated reactance of an auto-transformer on a frame kilovolt-ampere base has to be multiplied by  $n$  to obtain the reactance on a throughput base, e.g. a 2/1 ratio auto-transformer with a frame reactance of 4% would present an impedance of  $4/2 = 2\%$  to through faults. Given a high fault MVA in-feed on the system, this could lead to short-circuit currents of more than the maximum permitted value of 25 times the normal one. System operating conditions must be clearly specified and, if necessary, additional impedance introduced to limit fault currents. It is the joint responsibility of purchaser and manufacturer to ensure that the transformer will not be subjected to excessive stresses.

The common electrical connection between the primary and secondary sides is a potential source of danger. The position of the earth connection with a three-phase star-connected auto-transformer is important and it is normally preferable to connect the supply neutral (assumed earthed) to the auto-neutral, and not to have the auto-neutral floating.

The use of the auto-arrangement on transformers inter-connecting different voltage levels (e.g. 400/275 kV) of a transmission system enables significant cost savings to be achieved. Small units are most useful as voltage regulating devices: they lend themselves readily to the provision of tappings, and as the loads generally have constant impedance characteristics, a small unit can control a large load. Consider a 10 kW, 400 V heating load, taking 25 A in an equivalent resistance of  $16 \Omega$ . It is required to control the heat in five steps by adjustment of the secondary load voltage  $E_s$ , using an auto-transformer. The secondary current for each tap is  $I_s = E_s/16$ , and the corresponding primary current is  $I_p = E_s(400/E_s)$ . The winding currents are  $I_p$ , in the part corresponding to  $(400 - E_s)$ , and  $(I_s - I_p)$  in the remainder. The winding could be graded to carry the maximum current in each portion, and it should be noticed that the 100 V tapping currents are less than those already determined for any portion of the winding. It is an axiom that, for constant impedance auto-transformers, any tappings below half the supply voltage do not influence the transformer size. The equivalent kVA is the sum of the part winding kVA values, divided by 2, and for the example this is 1.65 kVA.

### 33.11.1 Auto-starters

The principles above are applied to auto-starter transformers for three-phase induction motors. The value of the equivalent motor impedance (assumed constant) is:

$$Z = 4.25V/\sqrt{3}kI = 4.72V/kI$$

where  $V$  is the supply voltage,  $I$  is the full-load current of the motor and  $k$  is its ratio between short-circuit current and full-load current. The winding currents are determined

according to the number of tappings. These currents are of short duration.

## 33.12 Special types

### 33.12.1 Static balancer

The static balancer is a simple apparatus which in its three-phase form comprises an ordinary three-phase transformer core carrying two windings per limb in zig-zag connection. Normally, when connected to a three-phase line the balancer draws only a small magnetising current. When a load is connected between one line and neutral, however, so that the current balance of the feeders is upset, the load current flows through the balancer windings. This condition is illustrated in *Figure 33.27*, the current distribution being based upon a 100 A line-to-neutral load. Each balancer winding carries one-third of the neutral or out-of-balance current, and has one-third of the line voltage impressed across it. The rating of the balancer as a three-phase transformer is therefore  $2(\sqrt{3}V/3)(I/3)(3/2) = 0.58 VI$ , where  $V$  is the line-to-neutral voltage,  $I$  is the neutral current and  $VI$  is the one-phase load being balanced.

- (1) To supply a one-phase load. A balancer will be found to be cheaper than a one-phase transformer connected across two lines, and much cheaper than a three-to-one phase transformer. Overload protection is provided by a fuse in the load circuit as shown in *Figure 33.27(a)*, and the balancer neutral current corresponds to the load current.
- (2) To improve the voltage regulation of four-wire networks. Balancers have in the past been used chiefly for this application. The improved regulation has been useful on rural distribution systems with isolated one-phase loads. The balancer rating depends upon the out-of-balance current of the system, which usually is taken as 20% of the three-phase line current.
- (3) To transform a three-wire system into a four-wire one. Fuses, or even a circuit breaker, must not be employed in the balancer line. If one fuse were to blow, the neutral current would have to flow through the high-impedance paths offered by the sound balancer limbs and there would be a rise in the line-to-neutral voltage on the sound phases.

### 33.12.2 Welding transformers

Owing to their simplicity, economy and efficiency, transformer welding sets predominate over their rotary machine d.c. counterpart. Stick electrodes have been specially developed

Figure 33.27 A.c. static balancer applications

for a wide range of applications for use on a.c. sources, but even where a d.c. source is imperative, preference is shown for transformer/rectifier equipment over rotary machines.

The basic requirement for a.c. welding is a low-voltage power source (70–100 V), with an adjustable series inductor to ensure stability of welding current and provide phase shift between the source voltage and the welding current, enabling the arc to be re-struck in each half-period after the current has passed through zero.

Power sources are supplied for use either by individual operators when part of the series inductive reactance may be incorporated in the transformer, or by groups of operators when a single multiphase transformer of relatively low impedance provides low-voltage (90 V) supply through a number of separate adjustable inductors. In the latter case advantage can be taken of the diversity factor in minimising the power rating of the transformer. For general-purpose applications standard a.c. single-operator welding sets are also available with inbuilt rectifiers and a smoothing inductor enabling the operator to use a wider range of electrodes.

The inherently high reactance of the source produces a very low p.f. load on the supply which, owing to its variability and intermittent nature, cannot be continuously corrected by capacitors.

However, some correction is both possible and desirable, and most single-operator sets are designed to house a capacitor of a size recommended by the supplier. The performance of welding power sources, specified in BSEN 60638, covers the basic requirements for the majority of applications, but for other uses such as consumable electrode shielded gas systems, the characteristics of the welding set play a fundamental part in determining the quality of the weld. Typically, in transformer/rectifier power sources the internal impedance of the sets is very low and the open-circuit voltage is little more than the arc voltage; this produces a high rate of change of welding current when the arc length varies, and automatically adjusts the burn-off rate. In the past most welding sets supplied for the British market have been oil cooled, and these are most suitable for the onerous conditions found, for instance, in shipyards; but the development of new insulating materials has enabled air cooled dry-type sets increasingly to take their place in less onerous conditions and where light weight and portability are valuable.

### 33.12.3 Mining transformers

The operating conditions in coal mines impose special requirements on transformers for use underground. There must be no possibility of a defect in the equipment itself causing an explosion of the gaseous atmosphere in the mine, and head-room is normally extremely limited.

Until the early 1950s, special low-height oil filled non-flameproof mining transformers were used underground up to within 300 m of the coal face. The switchgear directly mounted on these transformers was of certified flameproof construction. As the size of the load increased, the problems of voltage drop in the low-voltage cables between the transformer and coal face machinery became greater, leading to the need for a completely flameproof transformer (and associated switchgear) which could be taken close to the coal face. The modern flameproof underground transformer is an air insulated unit constructed with class C insulation and contained in a flameproof case.

### 33.12.4 Small transformers

Small transformers are made in large numbers for electronic apparatus and similar equipment. The open construction

has been superseded by a hermetically sealed arrangement in air filled or oil filled metal containers. The connections are brought out through metal/glass or metal/ceramic seals soldered to the container. Transformers for mobile equipment, which may be operated at 400–1600 Hz for the sake of the saving in weight and size, are made of relatively costly materials to obtain larger magnetic and electric loadings. Thus, very thin cold-rolled silicon steel or thin nickel-iron cores may be used with coils insulated by high-temperature dielectrics such as glass fibre, silicones, etc. In this way a 30 VA, 1.6 kHz, fully sealed transformer weighs about 0.1 kg compared with its open-type equivalent manufactured in 1940 weighing 1 kg or more.

## 33.13 Testing

The normal practice for testing power and distribution transformers is to carry out a comprehensive set of tests at the maker's works—the number and nature of which depends on whether the transformer is the first of a new design or otherwise—and a few relatively simple tests after installation at site to prove that the transformer is ready for service. The three classes of works tests are referred to as 'type' and 'routine' and 'special'. The first transformer of a particular design or contract is subjected to both type and routine tests, while routine tests only are applied to later units. Special tests are only required at the specific request of the purchaser.

### 33.13.1 Routine tests

Routine tests consist of:

- (1) voltage ratio, polarity and phase displacement checked;
- (2) winding resistance measured;
- (3) insulation resistance measured;
- (4) load loss and short-circuit impedance measured;
- (5) no-load loss and magnetising current measured;
- (6) dielectric routine tests; and
- (7) tests on on-load tap changers, where appropriate.

#### 33.13.1.1 Ratio, polarity and phase displacement

Figure 33.28 shows the type of circuit used for measuring ratio. This involves the use of a 'ratiometer', which basically consists of a multi-ratio transformer from which tapplings are taken to coarse and fine adjusting switches. The ratiometer and the transformer under test are connected in opposition. When the ratiometer is adjusted to give a ratio exactly equal to that of the transformer under test, no current will flow in the secondary circuit. The ratio can then be read directly from the dial readings on the ratiometer. Polarity and interphase connections are checked by measuring voltages between various terminals when the transformer is energised at a low voltage.

#### 33.13.1.2 Winding resistance

The d.c. resistance of each phase of each winding is measured separately by the voltammeter method and is recorded together with the temperature of the winding at the time. This information is required for use in connection with later measurements of the load loss and the temperature rise of the transformer under rated load.

Figure 33.28 Ratio test

Because of the inductive effect of the core, care must be taken to ensure that a steady d.c. value is reached before voltage and current readings are recorded.

### 33.13.1.3 Insulation resistance

The insulation resistance between windings and from each winding to earth is measured by a special instrument such as the Megger or Metrohm.

The insulation resistance is commonly used as one of the criteria for determining that the transformer has been properly dried out. It varies widely and inversely with temperature, and care is necessary to ensure that the readings are correctly interpreted.

### 33.13.1.4 Load loss and impedance

Load loss and impedance are measured by short-circuiting the terminals of one winding of the transformer and applying a low voltage to the other winding sufficient to cause rated full-load current to flow. Because the applied voltage, and, hence, the magnetisation of the core, is extremely low, the core loss can reasonably be neglected and the measured input power represents the total load loss at rated load on the complete transformer. The short-circuit is applied to the low-voltage winding and the supply is connected to the high-voltage winding, at which side all readings are taken. In principle, the same result would be obtained if the high-voltage winding were short circuited and the supply connected to the low-voltage winding, but this involves measuring the heavier low-voltage rated currents, which may be too large for convenience.

In the past, a 2-wattmeter method was allowed to measure load loss of smaller transformers, but this method is no longer accepted and three wattmeters are necessary to make the measurement. Alternatively, an Electronic Power Analyser may be used to measure all quantities on a single instrument with higher accuracy.

It is important that the test is performed at normal frequency to ensure the correct proportioning of the PR and stray losses in the windings and structure of the transformer, which are dependent on frequency.

In transformers with exceptionally high reactance the voltage that has to be applied to circulate rated full-load current through the windings, even under short-circuit, may be sufficient to magnetise the core to a level at which the loss therein may be significant. In such cases the core loss during the short-circuit test may be determined by removing the short-circuit and measuring magnetising loss when the transformer is excited on open circuit, at the previously measured voltage required to circulate full-load current. The true load loss is then the difference between the two successive measurements.

It is important that the short-circuiting connections are substantial and applied in such a manner that the loss therein does not represent a significant fraction of the loss within the transformer. It is also important that the temperature is measured at the time that the load loss measurements are made, so that the necessary correction can be made to deduce the copper loss at the temperature (75°C) at which guarantees normally apply. IEC 60076 details the manner in which the load loss measurements at any given temperature can be corrected to the equivalent figure at 75°C.

### 33.13.1.5 No-load loss and magnetising current

The fundamental principle of this test is that normal rated voltage is applied to one winding while the other is left open circuit. The current flowing in the winding to which the supply is connected is the magnetising current and this is recorded as part of the test records. This magnetising current is normally a small percentage of the full-load current and the  $I^2R$  loss is negligible compared with the core loss. To avoid unnecessarily high voltages in the test circuit during the core loss test, it is normal practice to connect the supply to the lower voltage winding of the transformer (see Section 33.2.3).

### 33.13.1.6 Dielectric routine tests

Dielectric routine tests consist of an applied-high-potential (separate source test), a short duration a.c. test or a long duration a.c. test in combination with a switching impulse test, dependent on the voltage rating, and a lightning impulse test, dependent on the voltage rating.

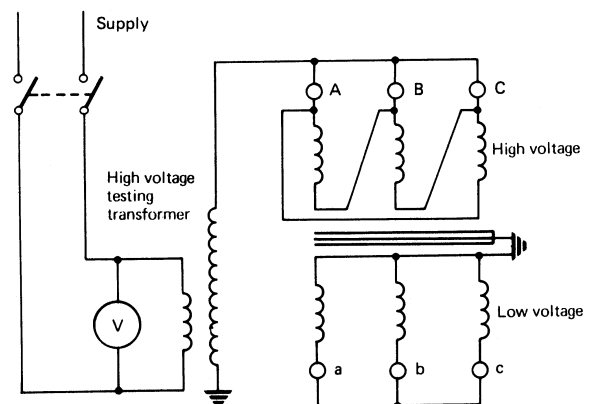

Figure 33.29 Connections for applied-high-potential test

*Applied-high-potential tests* These tests are normally made, in turn, between each winding, and the core and all other windings connected to earth.

Figure 33.29 shows the arrangement with the high-voltage winding under test and the low-voltage winding and core connected together and to earth. The magnitude of the applied potential test depends on the rated voltage of the winding in question and on whether the major insulation between it and earth is uniform or graded. For a uniformly insulated winding the applied voltage test provides the principal dielectric test of the main insulation. It is usually of the order of  $(2E + 1)$  kV, where  $E$  is the 'highest system voltage' for the winding in question. Full details are given in IEC 60076. On a three-phase transformer an applied voltage test of  $2E$  raises the line terminals to 3.46 times their normal operating voltage to earth.

For graded insulation windings the applied voltage test is at a value appropriate to the insulation level at the neutral point and therefore does not adequately prove the strength of the line-end insulation.

*Short-duration a.c. test* This induced voltage test is a short duration a.c. test that involves exciting the transformer on open circuit at a voltage higher than normal for a short period. This test is a routine test on transformers of up to 170 kV rating and a special test for transformers of higher voltage. For transformers with uniform insulation on which the applied high-potential test provides the principal check on the strength of the major insulation, the purpose of the induced test is to prove the strength of the insulation between turns and between other parts of the transformer operating at different potentials. The magnitude of the test is usually twice rated voltage, and to prevent overexcitation of the core the frequency of supply also has to be increased to at least twice normal.

On transformers up to 170 kV rating, with graded insulation the induced overvoltage test constitutes the main test of the major insulation. The magnitude of the test is fixed so that the potential to earth of each of the high-voltage terminals in turn is raised to the appropriate test voltage for the system on which the transformer is to operate. The magnitude of the test may be as high as 3.46 times normal rated voltage, and the interturn and other insulation is obviously tested to this degree at the same time.

The duration of the test is 60 s for any test frequency up to and including twice rated frequency. When the test frequency exceeds twice rated frequency, the duration of the test is for 6000 periods (i.e. 1 min at 100 Hz) or a minimum of 15 s, whichever is the greater. The magnitude of the test voltages for different system operating voltages and conditions are given in IEC 60076.

*Long-duration a.c. test* For transformers rated above 170 kV, the routine test is a combination of a long duration a.c. test, lasting 60 min and a switching impulse test.

The standard wave shape for a switching impulse test on air insulated equipment is of the order of 250/2500  $\mu$ s, i.e. a relatively slow rise of front followed by a tail of long duration. The practical difficulty in producing such a wave from an impulse generator connected to a transformer winding (related to the generator capacity and the transformer-core saturation) has led to a relaxation of the requirements for the switching surge wave specified for application to transformer windings. Limiting features are a wavefront rise time of at least 90  $\mu$ s, a time above 90% of the specified amplitude of at least 200  $\mu$ s, and a total duration from virtual origin to first zero passage of at least 500  $\mu$ s.

Partial discharge measurements are made during the long duration a.c. test to give a reliable check on the capability of the insulation in normal service.

Details of the tests and of the specified test levels are given in IEC 60076-3.

*Lightning impulse test* Although this is a type test for transformers rated up to 72.5 kV, the lightning impulse test is a routine test for all transformers of higher voltage.

The lightning impulse test simulates the conditions that exist in service when a transformer is subjected to an incoming high-voltage surge due to lightning or other disturbances on the associated transmission line.

Lightning impulse tests were introduced originally solely as type tests and, because of fears that they might cause undetected damage to the insulation of a transformer, the tests were largely confined to specially built prototype assemblies and were not applied to production units prior to going into service. Gradually it was realised that with increasing sensitivity of the equipment provided to detect insulation breakdown during the test, there was little risk of a service transformer suffering undetected damage. Still later it was appreciated that the sensitivity of the failure detection equipment was such that it would disclose hitherto unsuspected damage that might have occurred during a preceding power-frequency over-potential test. In Britain, therefore, common practice is for the lightning impulse test to follow the short-duration a.c. test, or the combined long-duration a.c. test and switching surge test.

Details of the lightning impulse test levels are specified in IEC 60076 for transformers for various system voltages. The precise form of a complete impulse test varies with customers' preferences and on whether the test is being applied as a basic type test on the first unit of a new design, or as a routine check on insulation strength following power-frequency test as described above.

The normal sequence for impulse tests in Britain is:

- (1) one reduced-level full-wave (voltage between 50% and 75% of the full-wave voltage test level);
- (2) one full-wave at specified test level;
- (3) two chopped waves with a crest value not less than the specified full-wave test level; and
- (4) one full-wave at the test level.

Evidence of insulation failure during an impulse test primarily depends on oscillograph records of the impulse voltage wave and either of the current passing through the winding under test or of the voltage induced by inductive transfer in another winding of the phase under test.

The normal sweep time for the oscillograph recording the voltage wave is 100  $\mu$ s for a full-wave and a shorter time for a chopped-wave test, e.g. 10  $\mu$ s. Current oscillograms are taken with the same sweep time, or preferably simultaneous records are taken of current with three different sweep times, e.g. 10, 100 and 500  $\mu$ s.

It is becoming difficult or impossible to purchase new analogue impulse recording instruments and many laboratories have now installed digital recording equipment. It is important that digital recording equipment used when testing power transformers has at least a 10-bit analogue-to-digital converter in the circuit.

The current and voltage wave shapes as shown on the oscillographic records are carefully compared with each other and particularly with the traces taken during the preliminary reduced voltage shots. Any discrepancy, however slight, in the wave shape of any one of the records compared with the others indicates a change in the conditions either in the test equipment or in the transformer under test. Such

discrepancies must be investigated and satisfactorily explained, and any failure to do so involves the risk of a transformer with damaged insulation being put into service. IEC 60722 states that in cases of any doubt as to the interpretation of discrepancies three subsequent 100% full-wave shots shall be applied, and that if the discrepancies are not enlarged by these tests, the impulse test is deemed to have been withstood.<sup>12</sup>

Before the development of the sensitive failure detection techniques now available, the principal criteria for determining whether an impulse test had been successfully withstood were that there should be no noise from within the transformer during the test, and no sign of smoke or bubbles in the oil. These remain as accepted criteria, but are now of secondary significance compared with the oscillographic procedures. The chopped wave test is not usually included when impulse tests form part of the routine tests on a transformer, because of the time involved in setting up the chopping gap and some doubt as to whether the chopped wave test is useful for the detection of defects of workmanship or material. The main purpose of the chopped wave test as part of the impulse-type test series is to increase the stress in the insulation within and between the coils adjacent to the transformer line terminal. This is normally regarded as a feature of the design rather than of the individual unit. The chopped wave test is, nevertheless, representative of the conditions that arise when an incoming surge is suddenly chopped because of a flashover of an insulator in or near the substation, and it is prudent to ensure that the transformer is capable of safely withstanding events of this nature.

#### 33.13.1.8 Tests on on-load tap changers

With the tap changer fully assembled on the transformer the following test sequences are performed:

- (1) With the transformer un-energised, eight complete cycles of operation are performed.
- (2) With the transformer un-energised, and with the auxiliary voltage reduced to 85% of its rated value, one complete cycle of operation is performed.
- (3) With the transformer energised at rated voltage and frequency one complete cycle of operation is performed.
- (4) With one winding short-circuited, and rated current in the tapping winding, 10 tap change operations over two tap steps on either side of the middle tapping, or where any reversing switch operates, is performed.

### 33.13.2 Type tests

Type tests consist of:

- (1) dielectric type tests;
- (2) a temperature-rise test.

Until the 1950s the distinction between type and routine tests was clearly defined, but operational experience, particularly on very large e.h.v. transformers, seems to be leading towards a compromise arrangement being adopted on transformers other than on the first of a new design. In particular, a simplified impulse test is frequently specified for application to all transformers purchased by certain customers. The logic is that many weaknesses disclosed by impulse test have been found to be due to poor materials or workmanship and not to fundamental errors of design. In the light of this experience it is obviously prudent to adopt the highly sensitive impulse test, even in modified form, as a routine check on materials and workmanship.

#### 33.13.2.1 Dielectric type tests

The lightning impulse test is a type test for transformers rated below 72.5 kV.

The long-duration a.c. test is a special test for transformers rated above 72.5 kV but below 170 kV; it is however, often requested as a type test on new designs.

#### 33.13.2.2 Temperature test

Each new design of transformer should be subjected to a test to determine that the temperature rise at rated load will not exceed the guaranteed values. It is uneconomic, if not totally impossible, to test a large transformer at the maker's works with both full voltage applied and full-load current in the windings, as the total output would have to be supplied and dissipated in some way. On small transformers where the rating of the available test plant is equal to or greater than twice the rating of the transformer under test, it is possible to arrange two units connected back-to-back in the manner shown in *Figure 33.30*. If the ratio of both units is identical, no current will flow in the windings, but if the ratio is deliberately unbalanced (by connecting the two units on different tapplings), a circulating current will flow through the two units, of magnitude governed by the out-of-balance voltage and the total impedance of the two units in series. The current is largely reactive (since the reactance of a transformer is normally considerably greater than the resistance), and the net power taken from a supply is equal to the total power loss in the two transformers under test. If tapplings are not available, or are unsuitable to circulate approximately rated full-load current, it is possible to inject the requisite circulating current through a small

Figure 33.30 Method of connection for a back-to-back heat run

booster transformer connected in the leads running between the two main transformers.

The back-to-back connection, or direct loading, must be employed when making temperature tests on dry-type transformers, because the heat transfers from the core and windings to the cooling medium (air) are largely independent. The test conditions must therefore represent actual conditions in service when the core is heated by the magnetisation loss and the windings are heated by the load current. In oil filled transformers the heat generated in both core and windings is transferred to the oil, and the total heat then has to be dissipated from the oil to the cooling medium. Because the loss in the core is usually appreciably less than the loss in the windings, it is possible to employ the so-called short-circuit method of test.

Under short circuit the loss in the core is almost negligible and the current in the windings is adjusted to a value slightly above the rated figure, so that the total loss in the windings is equal to the sum total of the separately measured load and core losses. The procedure during a short-circuit temperature test is to load the transformer with this increased current until such time as the observed oil temperature rise becomes sensibly constant, or is not rising at more than 1°C/h. This part of the test proves that the cooling equipment of the transformer is adequate to dissipate the total losses under normal full-load conditions and the oil temperature rise is recorded accordingly.

The increased current obviously results in the temperature gradient between windings and oil being higher than when the current is at the rated value. The thermal inertia of the windings is relatively low, however, and any change in current is quickly followed by a corresponding change in the temperature gradient between windings and oil. After the oil temperature rise has been recorded, current is reduced from the increased to the normal rated value and maintained at this level for 1 h. The supply is then disconnected and the d.c. resistance of the windings measured in a manner similar to that employed prior to the loss measurement tests when the transformer was cold. By taking temperature measurements over a period of 10 min plotting a graph against time from shut-down and extrapolating back to the time of shut-down, the resistance of the windings at the instant of shut-down can be determined. The winding temperature rise is then calculated by comparing the cold and hot resistances, with an allowance being made for any fall in oil temperature during the last half-hour at rated current. Full details of the methods are given in IEC 60076.<sup>12</sup>

### 33.13.3 Special tests

Special tests consist of:

- (1) Dielectric special tests.
- (2) Determination of capacitances between windings and earth and between windings.
- (3) Determination of transient voltage transfer characteristics.
- (4) Measurement of zero-sequence impedances on three phase transformers.
- (5) Short circuit withstand test.
- (6) Determination of sound levels.
- (7) Measurement of harmonics in the no-load current.
- (8) Measurement of the power taken by the fan and oil pump motors.
- (9) Measurement of insulation resistances to earth of the windings, and measurement of the loss angle ( $\tan \delta$ ) of the insulation system capacitances.

Special tests are only carried out by agreement between purchaser and manufacturer. The most common special test carried out in Britain is the sound level test.

#### 33.13.3.1 Sound level measurement

Because of the importance of noise as an environmental factor, the specification of a sound level limit for power transformers is increasingly common. The British Electricity Board's Specifications for various sizes of transformer stipulate maximum acceptable sound levels for each size of transformer purchased. The sound level tests, normally carried out at the manufacturer's works, are usually made at times when factory noise (including that of running test plant) can be kept to a level well below that of the noise emitted by a transformer on test. When it is necessary to make sound level tests in a more noisy environment than the noise emitted by the transformer it is necessary to use the sound intensity measurement method. It is also important that the transformer on test is well clear of walls or other large areas which would reflect sound and cause a build-up of noise which would give a false reading.

Sound level measurements made using sound pressure, sound power or sound intensity methods have been standardised and are described in IEC 60076-10.

### 33.13.4 Commissioning tests at site

Commissioning tests vary considerably with the size and importance of the installation.

For a small or medium-sized distribution transformer the minimum requirements would be a visual examination for transport damage and an insulation test with a portable instrument. Preferably there should be a check of the ratio (by applying a medium voltage to the high-voltage terminals and measuring the induced voltage at the low-voltage terminals), and on the oil level and condition to confirm that ingress of moisture has not occurred. Measurements of ratio and of polarity are essential if a transformer is to be connected into a circuit where it will operate in parallel with other transformers.

On large units which are normally despatched either without oil or are only partially filled, checks must be made on the filling procedure and of the condition of the oil prior to filling, in addition to ensuring that the insulation has not become wet during transport.

After filling, a sample of oil may be taken for dissolved gas analysis (see Section 33.14.4) so as to provide a basis for comparison with similar samples taken as part of a routine maintenance procedure when the transformer is in service.

Auxiliary equipment such as on-load tap changing gear and any protective relays and current transformers associated with the main transformer must also be checked for correct operation.

In general, a repetition of high-voltage tests carried out at the works is not considered to be necessary. Where the transformer is subjected to retesting on site at high voltage, the test voltage level is normally restricted to 75% of that applied during tests at the works.

## 33.14 Maintenance

Maintenance can be described as the measures adopted to ensure that equipment is kept in a fully serviceable and reliable condition. Of necessity it is therefore mainly a routine involving attention at regular intervals to particular features

based on service experience and manufacturers' recommendations. In the former, the measures involved tend to be general, whereas the latter tend to cover, in addition to general points, particular measures depending on the constructional characteristics of the individual manufacturer's designs. Consideration here is limited to two particular issues, namely insulating oil and solid insulation.

### 33.14.1 Insulating oil

Oil forms part of the main insulation of most transformers, but it tends to deteriorate in service owing to (a) operating temperature, (b) atmospheric conditions (applicable to unsealed, non-conservator-type transformers) and (c) presence of moisture or fibres.

In (a) deterioration is accelerated by prolonged high operating temperatures leading to the development of acidity and sludging, which in turn have a deleterious effect on the solid insulation. Poor ventilation in a transformer chamber (b) results in condensation inside the transformer, which similarly is liable to promote acidity and sludging. The electrical strength of the oil is considerably reduced by included moisture or fibres and particularly by a combination of both (c).

Deterioration can be greatly reduced or even arrested by attention to operating conditions and by routine precautions. Samples of the oil should, therefore, be taken from the transformer at regular intervals and the characteristics checked. With large transformers, generally speaking, little trouble is experienced with acidity, mainly owing to the lower operating temperatures. Standard British practice is to specify conservator-type transformers, and apart from one experimental installation associated with a group of generator transformers, it has not been necessary to consider the use of 'inhibited' oil. Similarly, any form of 'sealing' has in the past been considered unnecessary, for the same reasons. More sophisticated oil preservation equipment is now being specified for 400 kV transformers.

In small transformers there is a greater tendency for the development of acidity, but with modern oil (and provided that reasonable precautions are taken) no serious inconvenience should be experienced in this respect. Discharge under oil may result in the flash point of the oil being reduced, although after a relatively short period of time it may recover. Similar reduction in flash point can occur as the result of abnormal local heating such as may be experienced during the development of an incipient fault, e.g. a core fault: involving circulating currents within the core itself due to a breakdown of interlamination resistance or failure of core bolt insulation.

### 33.14.2 Insulation

The standard method for checking the state of insulation is by measurement of the insulation resistance. It should be noted, however, that a transformer with relatively 'wet' insulation may have a high insulation resistance when the measurement is made with the transformer cold, but the value may drop rapidly as maximum operating temperatures are approached. A hot insulation resistance reading below 1 M $\Omega$  per 1000 V rating of the tested windings is generally indicative that drying out is necessary.

When suitable equipment is available, measurement of dielectric loss angle gives a reliable check on the state of the internal solid insulation. As the value of the loss angle will depend on the transformer design, a reference value taken on the actual transformer during works test is necessary

for comparison before any useful assessment can be made. A useful method mainly used in the factory for checking the state of dryness in solid insulation is the 'dispersion' test or 'recovery voltage' test, based on the fact that in dry insulation the distribution of elements is such that individual shunt paths of time constant greater than 3 ms are effectively absent and that the presence of moisture introduces time constant within the range 3–300 ms. The method of test involves the application of a 300 ms pulse followed by a 3 ms short-circuiting pulse. Any shunt paths having time constants greater than 3 ms retain their charge, which is measured as a voltage by a suitable measuring device, the measurement indicating the moisture content.

The windings of a transformer should be inspected at long-term intervals. Any slackness due to insulation shrinkage or to the falling out of packing can then be remedied either by the adjustable coil clamping screws or by packing out the winding. This operation is particularly advisable in the case of transformers subject to heavy load surges, such as furnace transformers. Large transformers are usually built with preshrunk windings, so that slackening in service is almost entirely eliminated.

### 33.14.3 On-load tap changing equipment

From an operational aspect, an important factor is the period of time that can be allowed to elapse before attention to the switch contacts becomes necessary. If practicable, this period should be such that it can be co-ordinated with other outages of plant. This is of particular importance with generator transformers, where outage of the unit means the non-availability of generating plant. Until comparatively recently it was normal practice to carry out maintenance after every 10 000 operations, reasonably corresponding to a normal 12-month period between generator overhauls. The modern high-speed resistor tap changer, however, requires diverter switch maintenance only after 100 000 or more operations, and tap changer maintenance is no longer a limiting factor from the operational point of view.

### 33.14.4 Reliability and condition monitoring in service

Ignoring short-term outages due to defects in components, the reliability of a transformer depends on the electric strength of the insulation being designed and maintained at an adequate level to withstand the stresses imposed on it by either steady-state or transient voltages.

Although rare, unexpected conditions can arise to cause insulation failure despite an apparently adequate margin of safety. Wagenaar *et al.*, refer to such incidents where discontinuities in the winding arrangement of a large generator step-up transformer responded to critical frequencies arising on the system.<sup>7</sup> Resonant voltages within the windings—particularly in the tapping zone—were significantly higher than those arising during impulse testing and insulation breakdown occurred. The supply authority has increased test voltage levels and introduced further tests to detect critical frequency response within the windings and to prove capability to withstand the consequent stresses.

In the long term, insulation failure can be caused by ageing. This may be due to overheating because of local cooling deficiency or overloading, or simply because of long periods of operation at or near full load. The economics of supply system operation dictate that maximum utilisation is made of installed transformer capacity, by normally loading well up to rated value and accepting some loss of life due to deliberate overloading in an emergency. In these circumstances

it is essential to be able to monitor the condition of important units at regular intervals to allow action to be taken to prevent a failure in service.

The simplest and cheapest diagnostic technique available for on-line tests is by laboratory analysis of dissolved gases (DGA) in samples of oil taken from the transformer while in service. DGA can be used to diagnose the type of fault causing gas to be produced, e.g. arcing, intense local heating of conductor joints or other metal parts, with or without involvement of cellulose insulation.

IEC 60599 gives guidance for fault diagnosis which involves determining the concentration of the various hydrocarbon gases and calculating the ratio of the concentration of different pairs of gases.<sup>14</sup>

Table 33.3 provides a useful summary of the key gases produced by different types of fault.

A very important development has been to determine the amount of furfuraldehyde present in the oil samples.<sup>15</sup> Furfuraldehyde is the liquid residue of the breakdown of paper by molecular chain scission and is the only non-destructive indication of the thermal ageing of paper. It enables an assessment to be made of the 'amount of life' left in the insulation before total ageing has occurred and can be used to determine whether a transformer should be replaced.

### 33.15 Surge protection

Any transformer connected to an overhead transmission line must be protected against surges resulting from lightning striking the line conductors. National and international standards exist for the insulation level of lines, switchgear and transformers at all usual transmission voltages, in the context of *insulation coordination*.

Transformers are protected against lightning surges by discharge gaps which may be in the form of simple arcing horns attached to the transformer bushings, or more sophisticated surge arresters. The minimum spacing of the gap electrodes, is chosen to ensure that a flashover will not occur under normal steady state or transient power-frequency operating conditions. The voltage at which the gap will flash-over following a lightning surge is known, and the insulation level of the transformer is chosen to withstand this gap voltage together with a margin of safety. (The nominal margin is 20%, but in practice it is somewhat higher, owing to the fact that the actual strength of the transformer insulation is necessarily greater than its specified level.)

Modern surge arresters are based on metal oxide technology. Under normal service conditions the arrester draws only a very small current, but under surge or overvoltage

conditions the non-linear characteristics of the material allow it to draw a much larger current to supply a discharge path to the surge or overvoltage.

Whether surge arresters are used instead of the simple discharge gap depends on such factors as the severity of lightning in the area and the importance of ensuring that the individual supply circuit remains intact. A lightning surge that causes a gap discharge with either form of protection is inevitably followed by a power arc sustained by normal operating voltage. With surge arresters the non-linear characteristic causes the resistance to rise immediately the lightning discharge current (which may amount to several kiloamperes) ceases to flow. With simple arcing horns, however, a flashover of the gap due to lightning is followed by a power arc which is not self-extinguishing and which forms a direct earth fault on the phase in question. This leads to disconnection by the normal earth fault protection, although if the associated switchgear is arranged for automatic reclosing, there is only a momentary interruption.

In Britain it has been found that, in general, surge arresters are unnecessary largely because of the relative freedom from severe lightning storms and the small statistical probability of a lightning strike close to a transformer. Open-type gaps (usually referred to as 'co-ordinating gaps') give perfectly adequate protection against lightning surges with relatively slow 'fronts' (of the order of 5  $\mu$ s or greater), although necessarily with the disadvantage described above in respect of continuity of supply following a gap flashover. In other parts of the world where lightning storms are intense, it is normal practice to provide surge arresters because of the better protection that they provide.

Lightning arresters are used in Britain on certain lower-voltage lines (as an alternative to the use of automatic reclosing circuit-breakers) and on some 132 kV wood pole lines without earth wires. Such lines have an inherently high insulation level to ground (compared with a steel tower line, in which a lightning surge is usually immediately discharged by a flashover of a line insulator on the nearest tower) which results in high-amplitude surges travelling along the line to the transformer.

Surge arresters are also used in certain special cases (e.g. in association with shunt inductors) where circuit characteristics are such that it is desirable to limit the magnitude of switching surges by installing an arrester to provide a discharge path. Conversely, some circuit configurations (e.g. the complex bus-bar system of a main switching station) are such as to reduce to an insignificant level any likelihood of a co-ordinating gap flashover being caused by lightning. In such cases surge arresters may be found unnecessary, even on such important installations as main generator step-up transformers.

**Table 33.3** Sources of 'key gases' from decomposition of cellulose and oil

Material	Condition and temperature	Key gases	Symbol
Cellulose	Overheated	Carbon monoxide	CO
	>150°C	Carbon dioxide (Water)	CO <sub>2</sub>
Cellulose	Excessive heat	Carbon monoxide	CO
	>1000°C	Carbon dioxide (Carbon/tar)	CO <sub>2</sub>
Oil	Overheated >150°C	Methane	CH <sub>4</sub>
		Ethane	C <sub>2</sub> H <sub>6</sub>
		Ethylene (Organic acids)	C <sub>2</sub> H <sub>4</sub>
Oil	Electrical stress (partial discharges and arcing to 1000 °C)	Hydrogen	H <sub>2</sub>
		Acetylene (Waxes and water)	C <sub>2</sub> H <sub>2</sub>

### 33.16 Purchasing specifications

The essential basic information to be given is the following:

- (1) standard (national or international);
- (2) rated winding voltages;
- (3) frequency;
- (4) cooling medium (external);
- (5) cooling medium (internal);
- (6) ambient temperature of cooling media;
- (7) transport limitations (weight, dimensions);
- (8) nominal rating;
- (9) number of phases;
- (10) phase connection;
- (11) phase relation;
- (12) terminal arrangement;
- (13) altitude (if >1000 m);
- (14) impulse levels for lightning and switching surges (if applicable);
- (15) impedance (with acceptable minimum or maximum values for limitation of fault level or voltage regulation);
- (16) characteristics of transformers with which parallel operation is required;
- (17) tapping range (number and size of steps, whether on-load or off-load, restriction of impedance variation over tap range);
- (18) performance requirements for cyclic or emergency overloading; and
- (19) special requirements (fittings, paint finish, etc.).

In addition to the technical information, listed above, the manufacturer should be advised on the basis of purchase (minimum first cost, maximum efficiency or capitalised loss). If a loss-capitalising formula is to be used, details should be provided to minimise the work of preparing and evaluating bids.

A working group within CIGRE Study Committee 12 has prepared a guide for customers' specifications for transformers 100 MVA and 123 kV and above.<sup>16</sup>

Specifications should set down a clear definition of technical requirements and operating conditions, and exclude detailed clauses on constructional points better left to the maker. The highly competitive transformer market, together with the normal practice of buying on the lowest tender that complies with the specification, means that the manufacturer must put forward the minimum-cost design

with no extra capability not specified. It is thus important to specify every abnormal requirement.

'Switchgear' is a term used to refer to combinations of switching devices and their interconnection with associated control, protective and measurement systems. It facilitates the interconnection of different parts of an electricity supply network by means of cable or overhead-line connections in order to allow the control of the flow of electricity within that network. Switchgear is also designed to be capable of safely clearing any fault which may occur on any part of the electricity network in order to protect the network itself, connected equipment and operational personnel. It also provides the facility, by means of disconnectors, for segregating parts of the network and, with the application of earth switches, allows safe access for maintenance or repair to component parts of the electricity supply network. Switchgear connected into an electricity supply network via transformers, overhead lines and/or cables, together with its mounting structures, housings, protective fencing and ancillary equipment and connections is referred to as a 'substation'.

These terms generally apply to switchgear of all voltage ratings ranging from, for example, supplies to domestic consumers at say 240 V with nominal short-circuit currents of up to 16 kA, to equipment used on major transmission networks at say 420 kV or higher with short-circuit currents of typically 55 kA. Switchgear may also be used for direct connection of main generators having rated short-circuit currents of typically 200 kA at 24 kV with normal rated load currents of 24 kA.

Switchgear is used to provide supplies to major items of plant such as motors, arc furnaces, reactors, capacitors or other machinery as well as supplies to commercial, industrial and domestic consumers. In doing so it must also provide for the safe operation of connected items of plant and limit the effects on connected equipment of transient overvoltage phenomena caused, for example, by lightning or other surges generated by operation of the switching devices themselves. In order to perform these varied functions, switching devices used within switchgear assemblies have evolved in different ways to suit particular applications. They may be mounted separately in an outdoor fenced area and be interconnected by means of air-insulated bus-bars, this arrangement generally being referred to as an 'open-type substation'. Alternatively, they may be coupled together by the switchgear manufacturer to form an assembly within a metal enclosure. The insulating media may comprise combinations of air, solid insulating material, insulating oil, bitumen compound or, with more recent equipment, an inert dielectric gas known as sulphur hexafluoride ( $\text{SF}_6$ ).

The major components of the switchgear are described in the following sections.

## 34.1 Circuit-switching devices

### 34.1.1 Disconnectors (isolators)

A disconnector is a device comprising movable contacts capable of being mechanically closed to form an electrical circuit to other equipment or of being mechanically opened to physically disconnect one part of the electrical network from an adjacent part and at the same time providing an isolating distance. This provides circuit segregation for operational purposes or, with appropriate earthing equipment and application of safety procedures, provides facilities to allow work to be safely undertaken on disconnected and earthed primary electrical equipment.

Disconnectors are generally hand operated but may have power operating mechanisms if remote operational facilities are required. Disconnector moving contact systems are generally slow in operation as a disconnector is not intended to interrupt circuit currents. It will, however, be required to interrupt the small capacitive current flowing in the associated disconnected equipment. When air-insulated disconnectors are operated a short duration 'buzz' is generally heard when this capacitive current is interrupted. High-frequency currents are generated during such an operation. These can result in primary circuit overvoltages, which in turn can be coupled into earthed circuits or secondary connected equipment resulting in electromagnetic interference. In its closed position a disconnector must be capable of carrying the full rated load current of the associated circuit and of safely withstanding the rated short-circuit current of the system for the maximum circuit-breaker clearance time which may be between 1 and 3 s.

Disconnection may be achieved in metal-enclosed switchgear of voltage ratings typically up to 36 kV by physical withdrawal of the circuit-breaker either horizontally or vertically. No separate disconnector as such is provided, as the separation of the plug in contacts of the circuit-breaker provides an isolating distance. Earthed metallic shutters are commonly provided to segregate both sides of the circuit, but this is not an essential requirement for a disconnector. For higher voltage metal-enclosed equipment or for open-type substations separate disconnectors are used. Depending on the substation electrical layout, disconnectors are generally provided to isolate either side of each circuit-breaker and all circuits connecting into a substation. In addition, they are generally used on overhead rural distribution networks to segregate parts of the network in the event of a faulted section.

Disconnectors can take a number of different physical forms depending on particular applications and substation layout. Typical arrangements are shown in *Figure 34.1*.

The isolating distance of a disconnector is generally visible, but this is not an essential requirement. With open-type equipment, visible indication is readily achieved, but with metal-enclosed equipments windows may be provided. These may induce additional problems. Very many disconnectors are in use which do not provide visual indication of the isolating gap and with this type of equipment the operator must be able to rely fully on the external operation indicators accurately representing the positions of the main contacts.

### 34.1.2 Switches

A switch is a mechanical switching device that, unlike a disconnector, is capable of closing against, and interrupting, circuit load currents. In its closed position it must be capable of carrying the rated short-circuit current of the system for the rated time, i.e. 1–3 s. An additional optional design feature is the ability to close satisfactorily against the rated short-circuit current of the system. A switch is not capable of breaking short-circuit currents. A further optional design feature is the ability to close and open satisfactorily against specified overload conditions as may occur, for example, when switching motor circuits.

In view of the need to make and break specified circuit conditions, consistency of operation is an essential requirement. As direct manual operation cannot achieve this, power operation is necessary. Power operation of the switch is invariably achieved by the use of a spring operating mechanism whereby the spring is compressed during the

Figure 34.1 Typical disconnector arrangements

early part of the operation by manual means and then travels over centre to release its stored energy to operate the moving contact system independently of the operator. Switches normally are either air or oil insulated, with more recent designs being SF<sub>6</sub> insulated and they usually have some rudimentary method of controlling the arc during a breaking operation. Although the major application of switches is in low-voltage networks they are also widely used on distribution networks at voltages of up to about 20 kV. Use at higher voltages is minimal and at transmission voltages very few current designs exist and these have very limited specific applications.

### 34.1.3 Switch disconnectors

A switch disconnector is a switch which in its open position provides the isolating facilities required of a disconnector. Interlocking and padlocking facilities are generally provided. In LV applications switch disconnectors are not always employed, whereas at higher voltages switch disconnectors are almost invariably employed. The oil switch and SF<sub>6</sub> switch shown in Figure 34.2 normally provide an isolating distance and are thus defined as switch disconnectors.

For open-type equipment at distribution voltages a switch may be built into a disconnector. This usually comprises an air-insulated interrupter as shown in Figure 34.3. Such a switch disconnector provides the facility for switching a downstream length of overhead line without the need to de-energise the whole of the line as would be required for a disconnector.

Switch disconnectors were also commonly used at transmission voltages some years ago but they now show little

economic advantage over the use of a circuit-breaker and their application has declined. A typical 420 kV switch disconnector is shown in Figure 34.4.

### 34.1.4 Earth switches

An earth switch is not a switch as described in Section 34.1.2 because it does not have to make or break load current. An earth switch is a mechanical switching device used to connect the disconnected and de-energised primary conductors of a circuit to earth and to allow work to be undertaken on the earthed part of the circuit. An earth switch does not have to be capable of making or breaking current on its contacts and, consequently, earth switches are usually dependent manual operated. In its closed position it must be capable of carrying the rated short-circuit current of the system for the rated time. This requirement is necessary to safeguard against the circuit being inadvertently re-energised at its remote end. Earth switches are usually interlocked by mechanical or electrical means with the associated disconnector such that they can only be operated to apply an earth to the system when that part of the system has been de-energised and isolated. However, when applying an earth to an outgoing circuit comprising a cable or overhead line, interlocking with the remote end of the circuit is not feasible and safety instructions and permits must be relied upon. These may not always be foolproof and some authorities insist that line-end and cable-end earth switches must, in addition, be capable of safely closing onto an energised circuit. Such earth switches are generally referred to as 'fault-making earth switches' and power-operated mechanisms are an essential requirement.

Figure 34.2 Arrangement of (a) an oil switch and (b) an SF<sub>6</sub> switch disconnectors

Figure 34.3 Pole-mounted switch disconnector

At low voltages earth switches are seldom applied, as circuits can readily be tested to check whether they are live. Once proven to be de-energised, temporary earth connections can then be fitted. At distribution voltages many accidents have occurred over the years with operators inadvertently applying an earth to a live circuit and current practice is for fault-making earth switches to be provided for all applications. At transmission voltages, where instruction and permit systems can more readily be relied upon, and particularly for open-type substations where visible isolation is readily available, non-fault-making earth switches are nearly always used. For gas-insulated earth switches at transmission voltages where isolating distances may not be readily visible, the practice of using the safer fault-making earth switch is now becoming more common.

### 34.1.5 Fuses

A fuse is a 'one-shot' device capable of carrying the rated load current of the circuit in which it is situated, defined circuit overload conditions for predetermined times and of clearing overcurrents or short-circuit currents associated with faults which may occur on the system. Once operated on short-circuit, the fuse link, a component part of a fuse, must be replaced. (A fuse comprises all the parts which form the complete device and incorporates terminations for connecting into a circuit.)

A fuse is a thermally operated device. It comprises some form of conductor which, when subjected to predetermined currents for predetermined times, melts or blows to clear the circuit. The simplest form of fuse link comprises a wire held between terminations in air.

#### 34.1.5.1 Rewirable fuses

For LV applications a wire fuse is generally described as a 're-wirable' or 'semi-enclosed' fuse. These are commonly used in domestic applications for protecting radial and ring circuits, their main advantage being that they are readily repairable by the layman, providing appropriate fuse wire

Figure 34.4 A 420 kV switch disconnector

is available. However, they can readily be abused. Their rated short-circuit breaking capacity is low, typically 2–3 kA at 240 V, although some designs may achieve a rating of 10 kA. As they break in air they require the passage of a current zero in order to clear, hence the total let-through energy of such a fuse is high and the 'downstream' circuit must be designed to cater for this passage of short-circuit current and associated energy. In addition, the fuse holder, which contains the wire fuse element tends to carbonise with repeated fault operations and the fuse may eventually fail to clear. A further shortcoming is that for the fuse to operate, the fuse element must reach a temperature which will cause it to melt; depending on the element material, this may be of the order of 1000°C or more. Also, for long-duration overloads over-heating may well occur.

Notwithstanding these potential limitations re-wirable LV fuses are very economical and are still widely used in domestic applications, although latterly the tendency has been to use the inherently better performance of the cartridge fuse or miniature circuit-breaker.

Re-wirable fuses are also used at distribution voltages up to 33 kV, but in some countries they may be used at even higher voltages. Such a re-wirable fuse is generally referred to as an expulsion fuse. This comprises a fuse element, i.e. that part of the fuse designed to melt when the fuse operates, which is generally enclosed within a small insulated tube. Each end of the element has a flexible tail for connecting to the terminals of the fuse carrier. The fuse carrier also generally comprises an insulating tube through which the fuse element is inserted. The fuse element is then held under tension by spring-loaded contacts into which the fuse carrier is fitted. These contacts are secured to the fuse base which comprises one or more insulators and a metallic base for installation on to an overhead-line pole.

The assembly, as described, is placed up a pole and connected onto the overhead line. It operates in atmospheric air and may be subjected to all types of weather conditions. When the fuse operates the fuse-carrier assembly usually hinges about its bottom contact and drops down, thus providing a visible indication of operation. Such a fuse

assembly may also be designed to provide isolating facilities and thus can be used as a disconnection point.

When an expulsion fuse operates an arc is formed at the appropriate point of the fuse element, gases are produced from the small insulated tube surrounding the element; for small overloads these gases may be sufficient to build up pressure to extinguish the arc. For higher overloads or short-circuit currents the rapid pressure build up will cause the inner tube to burst and gases will then be generated by the arc impinging on the inner wall of the fuse-carrier tube. When sufficient pressure is built up the arc is extinguished and this pressure expels the ends of the fuse element. During such an operation a loud detonation or bang will be heard and hot ionised gases will be expelled from both ends of the fuse-carrier tube. A typical expulsion fuse is shown diagrammatically in *Figure 34.5*.

Like the semi-enclosed LV fuse, the expulsion fuse also requires the passage of a zero current in order to clear and thus the let-through energy is high. This results in the breaking capacity being relatively low, typically 8 kA at 12 kV. Expulsion fuses are very economical devices and are particularly effective at protecting overhead-line spur connections. However, replacement of an operated expulsion fuse can be costly in terms of the manpower required to be sent to the appropriate location. The problem can be alleviated to a large extent by the use of an electronically operated sectionalising link which fits into an expulsion fuse base. The link differentiates between transient and permanent faults and operates to isolate a permanently faulted circuit during the open period of the feeding auto-reclosing circuit-breaker.

#### 34.1.5.2 Current-limiting fuses

The most widely used type of fuse for industrial applications is the current-limiting cartridge fuse. The main advantage of a cartridge fuse over the re-wirable fuses described is that they are perhaps the most effective circuit-protecting device available in that they will operate very rapidly during

**Figure 34.5** Typical expulsion fuse

Figure 34.6 Fuse cut-off current

the initial part of the power frequency short-circuit current to clear the current at a low level before it reaches its peak value. Such a phenomenon is referred to as 'cut-off' and is shown in *Figure 34.6*.

In consequence, the downstream circuit will never see the full short-circuit current of the system and economies in circuit design can be achieved. A further advantage of this rapid cut-off of current is that energy fed through to the faulted point is also considerably limited; this is shown diagrammatically in *Figure 34.6*.

A cartridge fuse exhibiting these properties is known as a 'current-limiting fuse'. Current-limiting fuses are generally available from LV up to about 72.5 kV. Their major application in HV distribution being for voltages in the range 10–20 kV. Typical short-circuit breaking currents at LV are normally up to 80 kA and in the HV range up to 20 kA. However, short-circuit ratings as high as 200 kA at 415 V can be achieved and recent development of a HV fuse at 200 kA, 20 kV has been successfully achieved. In general interruption of high short-circuit currents does not constitute a difficult problem to a current-limiting fuse since the current and resultant energy is kept to a very low level by the phenomenon of cut-off.

The construction of LV fuses is somewhat different from HV fuses, but both operate in a similar manner. The current-limiting fuse is always in the form of a cartridge comprising a specially designed and proportioned element or number of parallel elements enclosed within an insulating barrel, usually of a ceramic material. The barrel is fitted with end caps to which the fuse elements are attached, additional end caps may then be fitted to carry the terminations for connecting to the fuse holder. Before the outer caps are fitted the inner assembly of fuse link is filled with fine-

Figure 34.7 Construction of a typical LV fuse link

grained silica sand. The general construction of a typical LV fuse link is shown in *Figure 34.7*.

The fuse element may take a number of different forms, but the basic design criterion is to achieve melting of the element at defined points to create a number of arcs in series along the length of the fuse element. Restrictions are incorporated in the element to ensure a greater current density at these points and, for high short-circuit currents, there is little time for heat to dissipate along the length of the element and the element thus melts at these restrictions. An arc is formed at each point and energy is removed from the arc by the fine granules of sand which melt and fuse together to form a glass-like substance known as 'fulgurite'. The rate of extraction of energy must be greater than the rate of build up of energy in order for the arc to be extinguished. In practice this process is very rapid and will only last for some 2–3 ms or less and it is this phenomenon which gives the cartridge fuse its rapid current-limiting capabilities. Typical fuse-element forms are shown in *Figure 34.8*.

The fuse-element material is generally silver, but copper is now widely employed for LV applications.

In order to avoid overheating problems as might occur with small, long-duration overcurrents, the fuse element

Figure 34.8 Typical fuse-element forms

often employs a small deposit of low-melting-point alloy at some point across its width. The alloy solder deposit causes an eutectic effect whereby the melting point of the base material is considerably reduced, e.g. from 960°C for silver to about 230°C for the alloy. This is often referred to as the 'M' or 'Metcalf' effect.

For HV current-limiting fuses it is necessary to employ a significantly longer fuse element comprising a larger number of restrictions along its length. A greater number of arcs in series must be generated in order to produce a back-e.m.f. capable of overcoming the applied voltage to ensure arc extinction. A typical 11 kV fuse link may require an element length of approximately 1 m. Clearly, a fuse link of this length would be impracticable and costly. The problem is overcome by winding the fuse element or elements in a spiral form around an inner ceramic star core support. This enables the element of an 11 kV fuse to be accommodated in a fuse barrel length of some 250 mm. Since the spacing between adjacent sections of the spirally wound elements must be sufficient to ensure that flashover does not occur across this gap, only a limited number of parallel elements can be employed. This limits the normal current rating to typically 80 A for a fuse link of some 250 mm length and 50 mm diameter. Higher current ratings at the same voltage can be achieved by increasing the barrel length, a typical length being 350 mm for which ratings of some 125 A may be achieved at 11 kV. Even higher current ratings can be achieved by connecting a number of fuse links in parallel. This requires more space, becomes more costly and is seldom applied at HV.

A typical HV fuse construction is shown in *Figure 34.9*.

A further feature of a HV current-limiting fuse is that it can generally be fitted with a fuse-striker device which ejects when the fuse operates. The striker can be used as an indication device or, more generally, to cause an associated switch to trip so that for single-phase faults all three phases can be disconnected by operation of the striker activated switch. This approach prevents two phasing of HV circuits and alleviates consequential problems that might occur for example on three-phase motors.

Striker assemblies are of two basic types, being either activated by an explosive charge or compressed spring. The former is generally used within the UK where three-phase tripping is a requirement. This tends to necessitate the larger output of an explosively operated striker. Where indication or three-phase tripping is not required or where very light

loaded switch trip mechanisms are used the lower energy spring-operated striker can be applied. Spring-activated strikers are commonly used in continental European fuse designs. Both types of striker are operated by a very thin fuse wire running the length of the fuse, generally located within the centre section of the star core assembly.

The striker wire may only require a few amperes to operate. When it does so it activates and ignites the gunpowder charge in the explosive design of striker or allows the release of the precharged spring in the spring striker assembly. Once the striker has operated to cause an associated switch to trip it must not be possible to reclose the switch until the operated fuse has been replaced. Thus a fundamental requirement is that it must not be possible to push the operated striker back into its housing. This is normally achieved by employing a ratchet-type serration on the striker pin which engages with a flat spring washer.

Typical explosive and spring-operated striker assemblies are shown in *Figure 34.10*.

With a HV fuse link it may not be possible to generate sufficient arc energy and consequent back-e.m.f. when operating under very low overload conditions to ensure that clearance will be achieved. It is thus common for HV fuses to have a specific minimum breaking capacity below which fuse operation cannot be guaranteed. Some other form of circuit-overload-protection device should be employed to cater for long-term overcurrents which may be of values between the fuse rated current and the fuse minimum breaking current. Such a type of fuse is referred to as a 'back-up' fuse and the fuse manufacturer will specify its minimum breaking current so that the user can ensure that coordination is achieved throughout the required operating range of the circuit-protecting devices.

HV fuses having very low minimum breaking currents can be produced, and are referred to as 'general-purpose' fuses. By definition, a general-purpose fuse is one that will operate at all values of short-circuit current or overload current down to a value of current which will cause the fuse to operate in 1 h. Even such fuses may have limitations in attempting to clear values of overload current between the rated current and the 1 h melting current. In consequence, there are now designs available which will clear all values of current to which the fuse may be subjected, even values below the rated current, if for example the fuse link is situated in a very high temperature environment. Such a fuse link is generally referred to as a 'full range' fuse link.

Figure 34.9 HV fuse construction

Figure 34.10 Typical explosive (a), and spring-operated (b), strikers

However, means of adequately verifying the performance of such a fuse is still under discussion within the appropriate international standards committees.

### 34.1.5.3 Fuse characteristics

A fuse exhibits a number of different performance characteristics of which the user needs to be familiar in order to ensure its correct application. The main advantage of a current-limiting fuse link is, as described, its ability to limit very rapidly the flow of fault current. Hence, in order to ensure adequate 'downstream' circuit design, it is necessary to know its cut-off current performance. This will vary depending on the current rating of the fuse and the value of prospective short-circuit current. A typical fuse cut-off characteristic is shown in Figure 34.11.

As the prospective short circuit is decreased for a given fuse rating, the proportional value of cut-off current to prospective peak current will increase until such a time as the cut-off current equates to the peak prospective current. Below this value of prospective current the fuse link will no longer exhibit cut-off.

A further important characteristic for 'downstream' circuit design is the total let through energy of the fuse link.

However, since energy is dependent on the total circuit resistance, an additional quantity is normally referred to, this being the 'joule integral', i.e. the square of the current over a given time interval:

$$I^2t = \int_{t_0}^{t_1} i^2 dt$$

Specific values are quoted for each fuse rating and these are given as  $I^2t$ . The values generally quoted are pre-arcing time  $I^2t$ , i.e. the  $I^2t$  integral over the pre-arcing time of the fuse, and the arcing  $I^2t$ , i.e. the  $I^2t$  integral over the arcing period of the fuse. The sum of these two characteristics is referred

Figure 34.11 Cut-off characteristics

to as the 'total operating  $I^2t$ '. Typical  $I^2t$  characteristics are shown in Figure 34.12.

The total operating  $I^2t$  is important in designing the 'down-stream' circuit because its energy-handling capability must be in excess of this. Also, in order to achieve discrimination it is important to ensure that the total operating  $I^2t$  of the 'down-stream' fuse does not exceed the pre-arcing  $I^2t$  of the main fuse.

The  $I^2t$  characteristics are important parameters when assessing the circuit performance under high values of short-circuit current. With values of short-circuit current below the value which will cause the fuse to exhibit cut-off, it is then necessary to examine the fuse characteristics for these lower values of current. These characteristics are known as time-current characteristics and are usually presented in graphical form on log-log paper. Typical time-current characteristic zones are shown in Figure 34.13.

Each manufacturer's time-current characteristics will differ slightly for a given current rating, depending on the specific design features used. Thus specific time-current

Figure 34.12  $I^2t$  characteristics

**Figure 34.13** Time-current characteristic zones

characteristics cannot be used as the basis for circuit design as the designer may wish to be able to employ any particular manufacturer's fuse link. In order to overcome this problem, time-current characteristic bands are specified for LV fuse current ratings in the appropriate international fuse specifications.

#### 34.1.5.4 Fuse applications

From examination of the fuse characteristics, it is evident that fuses are suitable for very many applications. Fuse designs have evolved around idealised characteristics for the protection of specific circuits. For example, recent changes within the international committees dealing with wiring regulations now require a close degree of protection of downstream cable circuits and protection against electric shock. The new regulations call for a discrimination ratio between major and minor fuses of 1.6 : 1. This requirement is met by modern LV fuses based on pre-arcing  $I^2t$  at a time of 10 ms.

Many fuses are used to protect motor circuits. With this application it is imperative that the fuse does not operate with the current surge present when starting a motor. For direct on-line starting this may require a possible current of six times the motor full-load current for some 10 s. For motor protection a steep time-current characteristic is desirable such that the fuse will clear quickly for high values of short-circuit current. For overload, these characteristics would not be ideal and it is common practice for separate overload protection to be provided. Such a characteristic is shown in *Figure 34.14*.

The motor fuse characteristics would not be ideal for protection of a transformer circuit where the fuse must be able to withstand the transformer in-rush current, typically  $10 \times I_{FL}$  for 0.1 s. It must also quickly clear faults within the transformer circuit and may have to discriminate with fuses on the LV side of the transformer. A shallow-sloped characteristic is more ideal (see *Figure 34.15*).

For HV fuses there are now separate international specifications covering both motor- and transformer-protection requirements. Specially developed LV fuses are available for protecting semiconductor devices. These must have a low  $I^2t$  let-through, low cut-off current and very low over-voltage on operation. In order to achieve the low  $I^2t$  such fuses tend to run very hot and the 'M' effect is generally not applied. They are not suitable for use in enclosed fuse holders and must be mounted so as to allow adequate air circulation. They generally have substantial terminations to assist in heat dissipation.

#### 34.1.6 Fuse switches

A fuse switch is a switch which is connected in series with a fuse or, more precisely, the fuse is mounted on the moving contact system of a specially designed switch. An alternative device, a switch fuse, has the switch electrically connected to a series fuse to form a composite unit. This arrangement has disadvantages in that when changing a fuse the electrical circuit to which it is connected may still be live. Furthermore, if the switch is connected to the live side of the circuit the switch may not be capable of closing against

Figure 34.14 Motor starting fuse characteristics

Figure 34.15 Transformer fuse characteristics

a fault between the switch and fuse. A fuse switch is inherently a safer device and is now widely used.

The advantage of the fuse switch is that it is an economical switching device that can safely make and break, by means of the fuse, short-circuit currents that may occur on the 'down-stream' system. Fuse switches are usually manually operated by means of an over-centre spring-operating mechanism which ensures a consistent and adequate opening and closing speed.

Fuse switches are perhaps the most commonly encountered mechanical switching device on industrial switchboards using three-phase LV circuits. A typical LV fuse switch is shown in *Figure 34.16*.

HV fuse switches operating at voltages of up to some 20 kV are widely employed on urban secondary distribution networks. In such an application three-phase operation of the fuse switch is necessary for any single-phase fuse operation and this is achieved by means of the fuse striker pin (see Section 34.1.5.2) operating the HV switch-trip bar. In addition, co-ordination is applied between the switch and fuse to ensure that for currents below the minimum breaking current, for a back-up fuse, the switch will trip satisfactorily, by fuse-striker operation, to clear an overloaded circuit. HV fuse switches use fuses mounted either in air or under oil, the latter being the more widespread application. When a fuse is mounted under oil the fuse design must incorporate appropriate sealing to ensure that oil does not enter the fuse

body as this may result in fuse maloperation. A cross-section of an oil-filled fuse switch is shown in *Figure 34.17*.

### 34.1.7 Contactors

A contactor is capable of performing much the same switching duty as a switch and may also be capable of closing against a downstream short circuit when protected by an appropriate fuse. Its main difference is that it is capable of performing very frequent switching operations such as may occur, for example, with industrial processes where frequent stops and starts are required. In consequence it is necessary that it is capable of being remotely operated and, therefore, a spring-operated mechanism, for example, is unsuitable. The majority of contactor designs use a solenoid operating mechanism. This may be a continuously energised coil which holds the contactor closed, i.e. 'electrically held', or a short-time rated coil which closes the contactor via a mechanical operating mechanism and causes the mechanism to latch to hold the contactor in the closed position, i.e. a 'latched contactor'. Opening of a latched contactor requires the provision of a trip coil to operate a trip bar to release the latched mechanism. Most contactor-operating coils are energised from the source of supply; on loss of supply, all electrically held contactors would open and, unless appropriate protection were provided, would re-close on reinstatement of supply. For many industrial processes

**Figure 34.16** L.v. fuse switch

**Figure 34.17** Cross-section of an oil-filled fuse switch

this feature may prove to be unsatisfactory, in which case latched contactors would be used.

A contactor, like a switch, needs to break inductive load currents and in order to achieve this within compact dimensions some form of arc control system is employed. This usually comprises a number of parallel disposed metallic plates separated by small gaps into which the arc is forced. These plates cause a number of separate arcs to be formed and at the same time they cool and extract energy from the arc to achieve arc extinction.

Early designs of contactors comprised a large open-clapper-type single-break construction. These have now largely been replaced by more modern, compact and economic double-break block construction contactors.

### 34.1.8 Circuit-breakers

A circuit-breaker is a more sophisticated mechanical switching device in that, in addition to making and breaking load and overload currents of the circuit, it is also capable of both making and breaking the full-rated short-circuit current of the system.

In order to break the full short-circuit current of the system, very sophisticated arc control mechanisms have been evolved over the years. The techniques of arc extinction were developed originally on a trial-and-error basis, and were considered to be more of an art than a science. However, with modern knowledge and experience, interrupter performance can more readily be predicted using advanced theory and computer techniques. Nevertheless, it is still necessary to perform actual short-circuit tests to verify the performance of a circuit-breaker.

In order to be able to clear a faulted circuit some means of detection of the fault is necessary and that information must be transferred into a signal to cause tripping of the circuit-breaker. For LV systems direct-acting overload coils may be employed or more sophisticated relays used. For HV systems it is necessary to ensure that the tripping

signal is at LV, i.e. it must safely be segregated from the HV system. This is achieved by the use of current and voltage transformers. The output from these devices is fed into appropriate relays which operate under predetermined conditions to cause their contacts to make and energise the circuit-breaker tripping circuit.

Tripping supplies are usually obtained from continuously charged batteries operating at a nominal 125 V d.c. The most common method of satisfactorily achieving low tripping energy is to use mechanically held or latched operating mechanisms. This type of mechanism requires some form of prestored energy which can be released when required to cause the mechanism linkages to operate to close the circuit-breaker. Once the circuit-breaker has been closed and the stored energy dissipated, the mechanism must hold the circuit-breaker in the closed position by virtue of its interconnecting linkages, usually by some form of mechanical latching. The mechanism can then only be released to open the circuit-breaker by operation of a low energy trip bar operated from a trip coil plunger.

The most common circuit-breaker operating mechanism is the spring charged mechanism whereby the springs are charged either manually by means of a detachable spring charging handle or by means of an electric motor and geared drive system. The latter offers the advantage of remote charging. The charged springs can then be released by means of a small solenoid coil to close the circuit-breaker. An alternative closing energy source may be derived from a large solenoid coil but, whilst again this offers the facility for remote closing, it has the disadvantage of requiring a large d.c. supply.

This supply can either be fed from substation batteries or from a rectified supply derived from a voltage transformer. Either source of d.c. supply can be expensive and the motor rechargeable spring is now more widely employed.

For lower fault rated circuit-breakers the over-centre spring-operating mechanism, as used in most switches, is sometimes employed. Higher fault rated circuit-breakers, particularly at transmission system voltages, use either

pneumatic or hydraulically operated mechanisms. These may take a number of different forms. For example, compressed air may be used to close a conventional mechanical operating mechanism to achieve mechanical latching with tripping being achieved by release of the latched linkages. Alternatively, the compressed air may be released through a series sequence of valves to operate a piston which in turn operates through direct mechanical linkages to the circuit-breaker contacts. A further alternative is where the compressed air is used directly to operate the circuit-breaker contacts.

Similarly with hydraulic mechanisms, a hydraulic pump may be used as a method of remotely charging the operating mechanism spring. This arrangement is seldom employed nowadays. Alternatively, the hydraulic system itself may be used to transmit the drive via a piston to operate the circuit-breaker moving contacts directly. With such an arrangement the stored energy required to operate the circuit-breaker is derived from an accumulator. This comprises a cylinder with a central 'floating' piston, one side of the cylinder being filled with a suitable compressed gas, usually nitrogen, and the other side of the cylinder being filled with hydraulic oil which is connected to the hydraulic pump. The pump operates to pressurise the system, the stored energy being contained within the pressurised nitrogen compartment of the accumulator. A series sequence of valves is then used to allow the stored energy to be released, via the hydraulic pipework to operate a piston to close the circuit-breaker.

Circuit-breakers have evolved in a number of different ways to suit particular applications and use a number of different arc interruption techniques. The types of circuit-breaker typically encountered are described in the following sections.

#### 34.1.8.1 Miniature circuit-breakers

Miniature circuit-breakers are only used at LV, mainly in domestic or light-industrial or commercial applications. In general they are used in the same applications as semi-enclosed or cartridge fuses and offer an alternative for protecting radial or ring circuits. They are usually only single-phase devices and have a typical rated load current range of up to 100 A with a maximum short-circuit rating of 16 kA at 240 V. Manually operated over-centre spring-operating mechanisms are used. Miniature circuit-breakers usually employ a series overload coil for rapid short-circuit tripping and a bimetallic element for tripping on overloads. All miniature circuit-breakers operate on the air-break principle where an arc formed between the main contacts is forced, by means of an arc runner, and the magnetic effects of the short-circuit currents, into metallic arc splitter plates. These cause a number of series arcs to be formed and at the same time extract energy from the arc and cool it to achieve arc extinction. With some designs of miniature circuit-breaker this arc interruption process can be so rapid that current cut-off can be achieved in much the same way as described for a current-limiting fuse. The principle of a typical miniature circuit-breaker is shown in Figure 34.18.

Miniature circuit-breakers do not, however, provide rapid operation for low values of earth leakage current. Modern day wiring regulations require that very rapid operation is achieved in the event of an earth fault to minimise the dangers from electrocution. This requires operation for earth fault currents as low as 30 mA in a time of some 2–3 ms.

Figure 34.18 Principle of miniature circuit-breaker

A variation on the basic construction of the miniature circuit-breaker is used to achieve this requirement. Such a device is commonly known as an 'earth-leakage circuit-breaker', although the correct terminology is 'residual-current device'. Tripping at such low values of earth leakage current is achieved by passing both the feed and return conductors through an integral current transformer. Under normal conditions the resultant flux in the current-transformer core is zero. Under earth-fault conditions the feeding and return currents will not be of the same value and the current difference causes a flux to be generated within the current transformer core producing an output voltage at its secondary winding terminals which is used to energise the tripping circuit of the residual-current device.

Residual-current devices may be permanently wired into an installation or used as plug-in devices to protect domestic electrical appliances.

One feature of the miniature circuit-breaker and residual-current device is that their contacts are not maintainable and after a limited number of operations replacement of the device may be necessary. However, in practice, this is seldom a significant limitation and eroded contacts can usually be detected by overheating causing nuisance tripping of the device.

#### 34.1.8.2 Moulded-case circuit-breakers

Moulded-case circuit-breakers are also only used for LV applications. They are basically an upgraded version of the miniature circuit-breaker and are invariably three-phase devices. They have typical current ratings ranging from 100 to 2500 A and may have rated short-circuit ratings up to 50 kA at 415 V. Some designs also exhibit cut-off similar to the current-limiting fuse and all are provided with inherent short-circuit and thermal overload protection devices. They may also be provided with earth-leakage protection.

There are two categories of short-circuit performance: P1 and P2. Category P1 requires the circuit-breaker to be capable of performing two short-circuit operations, an open (O), operation followed by a close/open (CO) operation. Subsequent to this duty the circuit-breaker may not be capable of performing its normal requirements and should be replaced. Category P2 requires the circuit-breaker to perform a further CO duty and subsequent to this test there must be no reduction in its current carrying performance.

In applying moulded-case circuit-breakers care must be taken to ascertain the circuit prospective short-circuit level and probable frequency of occurrence of faults. For circuits where the frequency of faults is high a category-P1 moulded-case circuit-breaker is likely to be inadequate.

Whilst some designs offer facilities for contact maintenance others do not, in which case erosion of contacts will only be detected by nuisance tripping resulting from overheating.

As the name implies, moulded-case circuit-breakers are invariably completely enclosed in a premoulded casing. There is usually an on/off operating toggle on the front of the unit with the three-phase terminals at the top and bottom of the unit. As for the miniature circuit-breaker, an over-centre spring-operating mechanism is usually employed.

Moulded-case circuit-breakers are generally used in similar applications to fuse switches, i.e. protection of large three-phase LV loads and for motor-starting applications. They do not, however, have the facility for remote or frequent operation and cannot be used to replace a contactor where frequent starting is likely to be a requirement. A typical moulded-case circuit-breaker is shown in *Figure 34.19*.

#### 34.1.8.3 Air circuit-breakers

An air circuit-breaker uses atmospheric air as its interrupting medium. The arc is drawn between its contacts and extended via arc runners on to an arc chute where it is presented with a large cooling surface of arc splitter plates. These break the arc into a number of series arcs, the principle being to increase the resistance of the arc and extract energy from it via the metallic splitter in much the same way as described for LV switches, contactors and miniature circuit-breakers. A typical arc chute is shown in *Figure 34.20*.

**Figure 34.19** A typical moulded-case circuit-breaker

**Figure 34.20** Arc chute interrupter used for air circuit-breakers

Free-air circuit-breakers are used for LV applications and HV applications up to some 20 kV. They can have very high rated currents of typically up to 4000 A and very high short-circuit interrupting capabilities of typically up to 90 kA at 12 kV. Their main application at LV is where an onerous performance is required in terms of load, number of operations and fault level. Mainly due to economic considerations, moulded-case circuit-breakers have replaced many LV applications where previously air circuit-breakers were used but where high performance, maintainability and long-term reliability are essential requirements air circuit-breakers are still used. A typical application is in generating-station LV auxiliary supplies.

The main application of HV air circuit-breakers has been in applications where the exclusion of flammable materials is a fundamental requirement. Again a typical application being generating-station HV auxiliary supplies. Such large high-rated air circuit-breakers are, however, extremely costly and their use is now tending to diminish in favour of high performance vacuum or SF<sub>6</sub> circuit-breakers.

A further application of air circuit-breakers is for use with d.c. supplies, this method of interruption still being the most suitable for d.c. circuits. D.c. circuit-breakers are widely used in traction applications where ratings of up to some 3 kV may be employed.

#### 34.1.8.4 Air-blast circuit-breakers

Air-blast circuit-breakers use a blast of compressed air at a pressure of 25–75 bar which is directed across the arc path to cool and remove the ionised gas. Air-blast circuit-breakers are fast in interruption, which occurs usually at the first or second zero current, and arc lengths are short. The compressed air needs to be stored locally at the circuit-breaker within its own air receiver. Subsequent to operation the compressed air local storage needs to be replenished from a compressor system. This is usually a central system feeding all circuit-breakers via a suitable ring-main network.

Air-blast circuit-breakers are of two basic types, one where the interrupter contacts reclose subsequent to the blast of air, usually referred to as a 'sequentially isolated circuit-breaker' and the other where the interrupter contacts remain in the open position after the passage of the air blast and are continually pressurised to maintain the dielectric strength. This latter type is referred to as a 'pressurised-head circuit-breaker'.

With the sequentially isolated type, air is admitted via a blast valve at the bottom of the vertical support insulator. A high pressure ceramic blast tube is necessary to transfer this blast of air up to the main interrupter contacts to cause them to open against a return spring. This type of

circuit-breaker also incorporates a free air disconnector in series with its interrupters. During the period in which the circuit-breaker contacts are held open by the blast of air and, after arc extinction, the disconnector is automatically operated to open the circuit. Once the sequential disconnector is fully open the main blast valve recloses to cause the main contacts to reclose under their own return spring pressure. For closing, the circuit is made on to the contacts of the sequential disconnector. These contacts must be very robust as they must close against the full short-circuit current of the system.

Sequentially operated air-blast circuit-breakers are used typically at voltages of up to 420 kV. Their main application is at transmission voltages. Their application at distribution voltage is minimal. Ratings of 50 kA at 420 kV with normal current ratings of 4 kA are possible. The interrupting capability per interrupter is limited and it is necessary to employ a number of series interrupters per phase, 12 breaks being typical at 420 kV. It is necessary to ensure that the interrupting duty is shared equally across each break and parallel capacitors or resistors are often employed for this purpose. Sequentially operated air-blast circuit-breakers invariably employ pneumatic operating mechanisms.

With pressurised-head circuit-breakers the arc is extinguished in much the same way as for the sequentially operated air-blast circuit-breaker. The main difference is that this type employs a main operating valve on the exhaust side of the interrupter such that once interruption is complete the open contact system is pressurised, at the full pressure of the compressed-air system, to maintain the dielectric strength across the open contacts. The contacts are held open permanently whilst the circuit-breaker is in its 'open' position. Interrupter contacts are generally driven mechanically via insulated pull rods from the main mechanical operating mechanism normally operated from a compressed-air-driven piston. The circuit-breaker is usually held closed by mechanical latching of the mechanism and opened by operation of a mechanical release trip bar, although some designs employ a compressed-air mechanism which is held open or closed by pneumatically operated valves.

Whilst the pressurised-head circuit-breaker alleviates the need for sequential isolation its main advantage is that, because the pressurised air is already at the interrupter contacts, very rapid arc extinction can be achieved, typical total break times being of the order of 40 ms. Such fast operation is necessary in order to ensure stability of the supply system when subjected to major faults. The very severe duties encountered often require the application of an interrupter in parallel to the main interrupter. When the main interrupter opens a resistor is then inserted in series with the parallel interrupter. This has the effect of damping the very severe transient overvoltage that might arise on circuit interruption, thus ensuring satisfactory fault clearance.

Such circuit-breakers may be used up to 800 kV with fault currents of some 80 kA or more. A number of series interrupter heads is necessary to achieve this rating—at 420 kV, for example, 10 or 12 interrupter heads may be required per phase. In addition to the resistor interrupters, parallel capacitors are also necessary to ensure equal voltage distribution across the interrupter heads during operation.

One phase of a typical pressurised-head air-blast circuit-breaker is shown in *Figure 34.21*. Such circuit-breakers are both mechanically and electrically very complicated and are very costly. Nevertheless, until the advent of SF<sub>6</sub> circuit-breakers, they were the only satisfactory means of interrupting very high values of fault current at the highest system voltages.

**Figure 34.21** One phase of a pressurised-head air-blast circuit-breaker

Since all air-blast circuit-breakers expend, in a very short period of time, a large quantity of compressed air, they are very noisy in operation. To overcome this problem it is common to fit silencers to the exhaust systems of the circuit-breaker. The application of a silencer will reduce the noise level from approximately 120 to 90 dB.

Since the action of all air-blast circuit-breakers is dependent on arc extinction by a blast of compressed air, consistent fault-clearance times are achieved which are independent of the value of current interrupted.

#### 34.1.8.5 Oil circuit-breakers

Oil circuit-breakers were the earliest devices used for satisfactorily achieving arc interruption. It was found that when an arc is drawn in hydrocarbon oil the arc energy decomposes the oil to form hydrogen (80%), acetylene (22%), methane (5%) and ethylene (3%), and the arc takes place in a bubble of gas surrounded by cooler insulating oil. The effect is that energy is extracted from the arc by chemical decomposition of the oil. Arc cooling is achieved mainly by the hydrogen gas which has a high thermal diffusion ratio; the surrounding oil also cools the arc plasma and the oil itself has a high dielectric strength when it flows into the arc path at zero current. Its good insulation properties also allow electrical clearances to be minimised.

The chief disadvantage of oil is that it is flammable. When expelled gases, formed due to decomposition of the oil on arc formation, mix with air these can be ignited as a result of a circuit-breaker maloperation to cause an explosion. For these reasons oil circuit-breakers are not used in generating stations where fire hazards are of paramount importance.

Early designs of oil circuit-breakers were of the plain-break design where contacts separated in oil without any specific means of controlling the arc. Performance was rather unpredictable, particularly under single-phase operating conditions and when drawing long inductive low-current arcs. For these reasons many plain-break circuit-breakers have now been withdrawn from service.

The problem was resolved in the late 1930s when the arcing process was controlled within an arc-control device. This device has the effect of constricting the arc, allowing a high pressure to be built up, which in turn assists in arc extinction. The gas, formed by the decomposition of the oil by the arc, is expelled through vents in the side

of the arc-control device, allowing cool oil to flow across the arc path and cause rapid arc extinction (*Figure 34.22*).

Careful design of the arc-control device is necessary to allow the arc-interruption features to operate effectively. Each manufacturer has their own design of arc control device. All oil circuit-breakers now employ some form of arc-control device.

There are two basic forms of oil circuit-breaker: the bulk-oil circuit-breaker and the low-oil-content circuit-breaker. Both are widely applied with the former being traditionally used in the USA and the UK and the latter in Continental Europe.

The bulk-oil circuit-breaker comprises an earthed tank which contains the contacts and arc-control system. Connections are taken into and out of the tank by means of through-bushing insulators.

Operating mechanisms are external to the tank with drive linkage to the moving contacts taken via an oil-tight seal. For voltages up to 72.5 kV all three phases are contained in a common tank; above this voltage separate phase isolated tanks are usually employed. Up to 72.5 kV single-break contact systems per phase are used, although the major application uses double-break contact systems per phase.

Above 72.5 kV multibreak contact systems are necessary with six series breaks being used at 300 kV. Parallel resistors are usually employed to ensure equal voltage sharing across the breaks. Above 300 kV bulk-oil circuit-breakers become dimensionally unsatisfactory and uneconomical and are seldom employed.

Low-oil-content, or live tank minimum oil, circuit-breakers have only sufficient oil to surround the contact and arc control device and use phase segregated insulated enclosures. The main advantage of this design is that less oil is used and compact, economical designs can be achieved. The main disadvantage is that the small quantity of oil used per interrupter can soon become contaminated with carbon under frequent fault operations and the dielectric withstand capabilities across the oil and oil/insulator interface can deteriorate. More frequent maintenance is thus required than for an equivalent rated bulk-oil circuit-breaker. Low-oil-content circuit-breakers offer a convenient form of construction for transmission voltage open type switchgear in that the interrupters can be contained within a vertical hollow porcelain insulator and the assembly can be mounted on a support insulator.

Multiple interrupters can be connected in series using a modular construction to achieve short-circuit ratings of some 50 kA at 420 kV.

With dead-tank bulk-oil circuit-breakers, current transformers can be placed around the circuit-breaker entry bushings to provide an economical mounting arrangement. With low-oil-content circuit-breakers separate current

transformers are required which must contain their own primary insulation. When current transformers are required on both sides of the circuit-breaker the low-oil-content concept can become a more costly arrangement than a dead-tank bulk-oil circuit-breaker with integral current transformers.

#### 34.1.8.6 $\text{SF}_6$ circuit-breakers

Virtually all current designs of circuit-breaker for use at transmission voltages now use sulphur hexafluoride ( $\text{SF}_6$ ) gas both as an arc-interrupting and a dielectric medium. At distribution voltages  $\text{SF}_6$  designs of circuit-breaker are also used, but here the market is still shared with vacuum and bulk-oil circuit-breaker alternatives.

Three basic types of  $\text{SF}_6$  interrupter are commonly employed. The gas-blast interrupter, the puffer interrupter and the rotating-arc interrupter.

The gas-blast interrupter tends to have a higher performance capability than the other interrupters and is more commonly applied to transmission circuit-breakers. All gas-blast interrupters cause a flow of pre-pressurised gas across or along the opening circuit-breaker contacts. These interrupters may take a number of forms. Early designs used a store of high-pressure  $\text{SF}_6$  gas kept separate from the main  $\text{SF}_6$  used for dielectric purposes. On opening of contacts a valve operates to allow the flow of the high-pressure gas around the contacts to extinguish the arc. The gas is then re-compressed following an opening operation. Such a two-pressure system was used on early designs of  $\text{SF}_6$  circuit-breaker. However, it has the disadvantage that the high-pressure gas, typically stored at some 15 bar gauge, liquefies at normal ambient temperatures and it is then necessary to apply heaters to the gas in the high pressure storage cylinder to ensure that it is retained in its gaseous state. Heater failure would require the circuit-breaker to be removed from service until the heater could be reinstated. In addition, the provision of a high pressure storage chamber makes the two-pressure circuit-breaker very expensive.

The problem was resolved by the development of the 'puffer' circuit-breaker. Here the gas is compressed during the initial part of the opening stroke and prior to separation of the circuit-breaker arcing contacts. This requires the circuit-breaker to have a long operating stroke and a powerful operating mechanism to precompress the gas. Nevertheless, it is this arrangement that is most commonly used on transmission  $\text{SF}_6$  circuit-breakers. There are a number of variations of the puffer principle which determine the way in which the gas flows around the opening arcing contacts. These may be referred to as 'mono-blast', 'partial duo-blast' or 'duo-blast'. A typical partial duo-blast interrupter is shown in *Figure 34.23*.

Attempts have been made to overcome the necessity for the provision of a large powerful operating mechanism on puffer circuit-breakers by using the heat of the arc itself to pressurise the surrounding gas and induce arc extinction. This principle is commonly referred to as the 'self-pressurisation interrupter'. Whilst clearance at high values of fault current can readily be achieved, it is usually still necessary to apply a small piston to assist in arc extinction at very low values of fault current. This design of circuit-breaker is commonly used in distribution circuits and is now being employed in circuit-breakers for use at transmission voltages.

A further alternative, widely used at distribution voltages, is the use of the rotating-arc principle. Here the arc is induced to rotate very rapidly under the influence of magnetic fields set up by a series coil inserted into the current

**Figure 34.22** Arc-control device

Figure 34.23 A typical partial duo-blast SF<sub>6</sub> interrupter

path during the opening of the circuit-breaker contacts. Very rapid movement of the arc causes a flow of cool SF<sub>6</sub> gas across the arc to achieve arc extinction.

The rotating-arc principle is shown in Figure 34.24. With this design more economical operating mechanisms can be achieved but, unlike the puffer circuit-breaker, the arc duration is largely dependent on the size of current being interrupted.

At transmission voltages, SF<sub>6</sub> circuit-breakers mainly use either pneumatic, hydraulic or spring operating mechanisms, whilst at distribution voltages spring operating mechanisms are now invariably used.

With SF<sub>6</sub> circuit-breakers it is imperative to ensure a leak-proof assembly. The number of enclosure joints needs to be kept to an absolute minimum and the main drive for the circuit-breaker moving-contact system should preferably be taken through only one point in the enclosure. Either rotary or axial drives may be used, but special provisions must be made to ensure adequate gas sealing. Maximum gas-leakage rates are typically specified as being not greater than 1% per annum in order to ensure adequate gas retention within the anticipated maintenance periods of the circuit-breaker.

Low-gas-density alarms are usually fitted to give indication of loss of gas and, in the event of rapid loss of gas, circuit-breaker immediate tripping or trip lockout systems are usually employed.

Figure 34.24 One type of SF<sub>6</sub> rotating-arc principle

The development of the SF<sub>6</sub> interrupter has been such that the interrupter capability has increased rapidly and it is now common practice to use only two interrupters per phase for a typical circuit-breaker rating of 55 kA three-phase at 420 kV. A single interrupter can achieve a typical rating of 40 kA at 420 kV.

The transient recovery voltage withstand capabilities are such that parallel resistor interrupters, as used on air-blast circuit-breakers, are not required. All that is necessary is simple capacitive voltage grading across both interrupters to ensure uniform sharing. Comparison with an equivalent air-blast circuit-breaker shows that the number of interrupters at 420 kV has been reduced from 10 to 2, parallel resistor interrupters and high pressure ceramic blast tubes are no longer required because standard porcelain insulators can satisfactorily operate at the SF<sub>6</sub> gas pressures required for interruption. This considerably reduces the number and complexity of components used and has enabled significant cost reductions to be achieved in the application of transmission switchgear.

#### 34.1.8.7 Vacuum circuit-breakers

The possible use of vacuum as an interrupting medium has been studied since the 1920s. The major difficulty has been to produce a sealed device capable of retaining the full vacuum over an anticipated life span of some 25 years. It was not until commercially available high integrity vacuum devices, such as cathode-ray tubes, appeared that suitable techniques for ensuring adequate sealing evolved. This then opened up the way for vacuum interrupters which became available in the late 1950s. Early designs were costly to produce and could not compete economically with the then widely used oil circuit-breakers. It was not until the late 1960s that mass produced economical designs became readily available.

In a vacuum interrupter, as the vacuum chamber is evacuated and the available ionisable molecules are reduced, the dielectric strength for a given gap rapidly increases. Pressures of some  $10^{-8}$  T are typically used in vacuum interrupters. Pressures up to some  $10^{-4}$  T would be satisfactory, but above this value ionisable atoms become available and the dielectric strength rapidly reduces to give the typical Paschen voltage-vacuum breakdown characteristic. Thus, at the end of the life of a vacuum interrupter, a pressure of some  $10^{-4}$  T is still necessary. A typical contact gap in

11 kV vacuum interrupters would be some 15 mm. A major advantage of a vacuum circuit-breaker is that the very small contact travel required and the low mass of contacts have enabled very economical low output operating mechanisms to be used.

Very careful choice of contact material is necessary for vacuum interrupters. At high-current interruption, metal vapours are produced which assist in arc extinction and, therefore, for long contact life a hard contact material is the ideal choice. However, under low-current interruption conditions, hard contacts produce very little metallic vapour and very rapid arc extinction and 'chopping' of the current waveform results, which can produce high overvoltages. A softer contact material is better for low-current interruption, but erodes too rapidly at high currents. Contact material therefore must be a compromise between these two extremes and contact designs have evolved to ensure that the arc is kept in motion to minimise contact erosion. Important contact material criteria are vapour pressure, electrical conductivity, heat conductivity and melting point. Commonly used contact materials are copper–bismuth or copper–chrome alloys. Since the arc burns in an ionised metal vapour this vapour must condense on arc extinction and a vapour shield is usually provided for this purpose. This prevents the vapour from depositing on the insulating envelope and reducing its dielectric withstand capabilities. The shield also protects the envelope from thermal shock.

At or near zero current the arc extinguishes, vapour production ceases and very rapid re-combination and de-ionisation of the metal vapour occurs. The metal vapour products are deposited on the shield thus ensuring the clean conditions necessary for withstanding transient recovery voltage across the open contacts.

Means must be provided to allow moving-contact travel within the vacuum envelope. This is usually achieved by the provision of a stainless-steel bellows assembly. Design, construction and quality-control checks of the bellows are vitally important to ensure long term vacuum integrity.

Vacuum interrupters, by virtue of their construction, are single-phase devices. They are usually mounted in air in a three-phase circuit-breaker with air and solid insulation between phases. The maximum voltage rating of a vacuum interrupter is some 36 kV and maximum short-circuit currents may, in extreme cases, be as high as 100 kA, with rated currents of up to 4000 A.

The main use of vacuum interrupters is in circuit-breakers for use on distribution systems. More recently, with the

higher ratings now achievable and for economic reasons, they are also being used in generating station auxiliary supply applications instead of free-air circuit-breakers. Vacuum circuit-breakers are seldom used at transmission system voltages as their maximum voltage limitation would require a large number of series connected interrupters which would be uneconomical.

The vacuum interrupter can also be used, in a much lighter construction, as a contactor for motor switching applications at voltages of up to 12 kV. A typical vacuum interrupter construction is shown in *Figure 34.25*.

## 34.2 Materials

### 34.2.1 Insulating materials

Many insulating materials are used in switchgear, they may be required just to provide insulation or to provide insulation and mechanical support, or to provide insulation and also assist in the arc interruption process. Where this happens some disassociation occurs and chemical recombination may be required.

They must also be capable, in addition, of withstanding temperature variations which may occur in service under both normal load and fault conditions. Under the latter they must withstand the extreme mechanical and electromagnetic forces that might result and sometimes also extreme pressure rises.

With insulation systems exposed to the atmosphere they must also be designed to withstand all anticipated environmental conditions of extreme temperature, rapid temperature changes, ice, snow, sun, wind, severe rain, solar radiation and lightning. All insulation systems must be designed to withstand transient overvoltages associated with lightning, switching surges and power frequency overvoltages. In some cases they may also experience d.c. trapped charges on circuit de-energisation or possibly d.c. with superimposed a.c. voltage.

Insulation systems must thus withstand many varied criteria and often with simultaneous combined phenomena, in addition, they must perform satisfactorily for many years with minimum of maintenance.

For outdoor insulation of overhead lines at transmission voltages for example, glass insulators have been commonly used, glazed porcelain insulators are also occasionally used. Whilst porcelain insulators are somewhat more expensive

**Figure 34.25** Cross-section of a vacuum interrupter

than glass insulators they generally show improved performance under polluted conditions. Porcelain insulators are widely used for distribution overhead lines and have almost universally been used for exposed terminations of substation equipment. In more recent years polymeric overhead line insulators have been used, these usually being in the form of EPDM or silicone rubber. Their performance is somewhat more complex than both porcelain and glass and very careful design is necessary. In addition, the composition of polymers is very critical and minor changes of constituents can cause significant performance changes.

Epoxy resin polymers have occasionally been used for outdoor insulation although these tend to deteriorate from solar radiation. Epoxy resin insulators are widely used in switchgear applications not exposed to external atmospheric conditions. These resins can be readily moulded to form complex insulator shapes which may not be possible with many other insulating materials. Such insulators have both exceptionally good dielectric and mechanical strength. Epoxy resin insulators will be encountered in most types of distribution switchgear and in gas insulated switchgear at transmission voltages.

A more economic form of insulation which is widely used in low-voltage switchgear is commonly referred to as dough moulding. This is a mixed polymer that rapidly sets at high temperature and pressure and is usually impregnated with numerous glass fibre strands to provide increased mechanical strength. Its mechanical and dielectric performance is usually inferior to epoxy resin systems and it is rarely found in distribution or transmission switchgear.

A further form of insulator which has been used for many years in switchgear is known as the 'Synthetic Resin Bonded Paper' insulator, often referred to as SRBP. This can only be used for straight insulators as may be required for example for circuit breaker bushings. The basic constituent is a thin, flat, electrical quality paper, commonly known as 'Kraft' paper. The paper, on a roll, is cut to the required length and then wound onto a mandrel, at the same time, a special electrical grade varnish is allowed to run in between the layers of paper. The mandrel may either be a metallic tube or in the form of a copper rod. Stress control throughout the section of insulator is important, this is usually achieved by winding in very thin aluminum foils known as stress control shields. The length of these shields tends to reduce from the HV conductor to the external earthed electrode to ensure uniform stressing both across the insulator section and along its length. On completion of winding the assembly is placed in an oven, often under vacuum, to allow the varnish to cure. The final insulator is mechanically very strong. Such a form of insulator is commonly used where an HV conductor has to pass through an earthed electrode i.e. a circuit breaker tank. The atmospheric side of the insulator is usually enclosed in a porcelain housing to protect it from the environment. The annular gap between the SRBP insulator and inner porcelain wall is filled with high quality insulating oil.

A somewhat similar form of insulator is referred to as the 'Oil Impregnated Paper' insulator, commonly known as OIP. This form of insulator is usually utilised where more complex insulation profiles may be required. The same type of paper as used for SRBP insulators is employed, but in a narrower strip form, such that it may be wound either by machine or by hand, over a complex profile. In some cases a crepe paper is used to give greater flexibility where even more complex profiles are required. Aluminum foils are also embedded for stress control purposes. On completion of winding the insulated assembly is placed in a vacuum chamber with gradual increasing temperature to remove

both moisture and air which will be trapped within the winding. Finally, high grade insulating oil is slowly introduced into the chamber to fully impregnate the paper. Once impregnated in its final assembly the oil should not be removed otherwise moisture and air might be re-introduced and re-processing would again be required. OIP insulation is commonly used as the insulation system for transmission system current and electromagnetic voltage transformers.

Where insulated screens may be required, for example between the phases in air insulated distribution switchgear, these may be of either bakelised paper form, made in flat rigid sheets in a similar manner as described for SRBP bushings, or in the compressed fibre board form which comprises bonded layers of oil impregnated fibrous paper. Compressed fibre board has the advantage that it can be bent to form enclosures. Such bent assemblies of compressed fibre board are usually found, as insulating barriers, within the tanks of bulk oil circuit breakers.

A further form of solid insulating material which is commonly used for insulated mechanical drive rods within switchgear is compressed and impregnated plywood, the impregnation again being with a high grade electrical varnish. This material has a high breaking strength under both tensile and compressive loading.

For transmission circuit breakers where a much higher mechanical loading is required the drive rods usually take the form of wound, epoxy impregnated, fibreglass matting, either wound as a tube or a rod. Metallic end fittings can usually be attached either by crimping or by epoxy bonding.

For cable terminations to distribution switchgear bitumen compound has been used for many years to provide the main insulation between phases and to earth. This material has a low affinity to moisture and becomes fluid at temperatures of around 120°C such that when heated it can readily be poured into the cable box and sets hard on cooling. Care is necessary however to use the appropriate grade of compound as shrinkage, embrittlement and cracking may occur to produce voids which may latter result in dielectric breakdown. Bitumen compound is also commonly found in current transformer chambers of distribution switchgear.

In more recent years, heat shrinkable polymers have been used for insulation of cable terminations. The application process is somewhat critical as entrapped air can lead to dielectric failure. Correct stress control is also vitally important. As cable jointing is, by necessity, a site function, it is important that site personnel are appropriately trained in the techniques and that appropriate Quality Control procedures are applied.

Insulating mineral oil has been used for many years as a dielectric media and also as an arc interrupting media in oil circuit breakers. It is usually of a Naphthenic or Paraffinic base dependent upon its source. Both have been used successfully in switchgear but in more recent years paraffinic based oils have been more widely used due to, limitations of supply of naphthenic oils.

One disadvantage of insulating oils is that they absorb moisture which can lead to dielectric degradation. Hence it is necessary to ensure that moisture entry is severely limited by equipment design. A further major disadvantage is that oils are flammable and, dependent upon class, have flash points varying between 95°C and 140°C. When disassociated due to arcing, hydrogen is formed and under equipment failure conditions the hydrogen can ignite to result in severe explosion and subsequent oil fire. Whilst the failure rate of oil filled switchgear is extremely low, the number of equipment's in service is very large (some hundreds of thousands

of equipment's in the UK alone). Unfortunately failures and explosions do occasionally occur. It is for this reason that the application of oil filled switchgear has significantly diminished in recent years in favour of SF<sub>6</sub> insulated equipments.

In order to eliminate fire risks, synthetic insulating oils have been previously used, these were generically referred to as 'Askerals', these were based on polychlorinated biphenyls (PCBs). These have no flash point and are considered non-flammable. However, they are hardly bio-degradable and accumulate along the food chain, for this reason their production was banned in Europe in 1985. Strict regulations now apply to their use and most have in fact now been eliminated from service. Over the last 20 years considerable work has ensued on the production of less flammable liquids, the main alternatives are silicone and ester liquids, these are expensive and other performance parameters are limited. They are not generally used in switchgear.

Over the last 30 years or so the use of sulfur hexafluoride (SF<sub>6</sub>) as an insulating and interrupting medium has slowly increased whereby today it has virtually replaced the use of oil in modern designs of switchgear.

Pure SF<sub>6</sub> is odourless and non-toxic but will not support life. It is 4.7 times heavier than air and tends to accumulate in low areas with the possibility of causing drowning. It has unique features which are particularly suited to its application in switchgear. It has a high electron attachment coefficient which allows it to have a high dielectric withstand characteristic. Its alternating voltage withstand characteristic at 0.9 bar(g) is comparable with that of insulating oil. A further advantage is that its arc voltage characteristic is low, hence the arc energy removal requirements are low. When subjected to the extremely high temperatures associated with arcing it tends to fragment into numerous constituent gases some of which are toxic, however, these recombine very quickly as the temperature falls and dielectric strength rapidly recovers. This process can occur in microseconds to allow several fault interruptions in quick succession. Solid arc products may be produced, these comprise mainly metal fluorides and sulphides, these are acidic and must not be inhaled. The gas performance is not impaired by the presence of these solids provided that it is maintained in a very dry state. At typical operating pressures of 4.5 bar(g) at 20°C SF<sub>6</sub> will remain in its gaseous form down to about -40°C, below this temperature it will liquefy and the equipment's performance may be impaired.

SF<sub>6</sub> is a very stable gas and if released into the atmosphere it may take over 3000 years to dissociate. It also has a high reflective index in the infrared spectrum which means it contributes to greenhouse warming. In fact it is the worst known greenhouse gas but at present the quantity in the outer atmosphere is small and its contribution to greenhouse warming is negligible. Nevertheless, it must no longer be deliberately released into the atmosphere and leakage and handling losses must be minimised. Contaminated gas can readily be re-processed to restore it to a state whereby it can safely be reused. It can also be safely disposed of at the end of its useful life.

### 34.2.2 Contact materials

Low-voltage high current contacts are used in LV distribution switchgear. They are usually of the bolted form or are intended to open and close to provide either circuit isolation, load interruption, motor switching duties or fault interruption.

Bolted contacts used to connect bus-bars for example are usually of silver or tin plated copper. The silver or tin

plating being used to inhibit long term oxidation of pure copper contacts. Usually more than one fixing device is employed to minimise the possibility of a loose contact which could lead to over-heating or failure. The contact must also be capable of withstanding short circuit through current in the event of a system fault. A typical fault withstand capability being 43 kA for three seconds.

Disconnectors may be provided to facilitate a circuit open point, these are switched with the load removed such that their contacts have only to interrupt a few milliamperes. They are infrequently switched and copper contacts are usually silver plated to prevent oxidation of the copper surfaces. Switches or switch disconnector contacts have to break load current and may have to close against the system short circuit current. Such switches may be operated relatively frequently and contacts are generally unplated as the wiping action during closing or opening generally cleans the contacts and tends to remove any oxide formation. When fault closing is required pure copper contacts may well weld due to the softness of the copper. Such contacts usually contain a hardening additive within the copper, typically additives are beryllium or tungsten. For low-voltage circuit breaker applications where high fault current breaking is required the point of arc root during interruption must be of a very hard material and typically tungsten tips are welded to the ends of the contact fingers. It is important that the arc transfers to the contact tip and does not root on the normal current carrying surface of the contacts, failure would rapidly result if this should occur, i.e. the normal current carrying surfaces of the closed contacts should not be eroded as a result of fault interruption.

Circuit breakers at distribution voltages usually employ copper contacts with a hardening agent to prevent either cold welding in the normally closed position and high current welding resulting from the passage of through fault current. Copper/tungsten contact tips are invariably employed for arc rooting during short circuit interruption. Such contacts may be of the rod and multi-finger type, wedge and multi-parallel finger type or butt type contact.

Distribution switchgear bus-bar contacts are usually of multi-fixing point silver plated copper joints. Sometimes however, for lower rated current circuits, aluminum bus-bars may be employed. Jointing aluminum however requires more care than for copper as aluminum readily oxidises and it is necessary to wire brush joint surfaces with a stainless steel wire brush with a layer of grease applied to prevent re-oxidation. The joint is usually made with the application of a fine layer of jointing grease. Where aluminum bus-bars are used in outdoor substations it is necessary also to apply a proprietary jointing compound to inhibit moisture ingress.

For transmission circuit breakers similar contact materials are used but the copper contact fingers may have an additional additive, e.g. molybdenum, to provide spring resilience. In view of the generally higher current ratings of transmission circuit breakers cylindrical type contacts are often used to minimise the skin effects induced by the very high current.

For gas insulated switchgear (GIS) aluminum tubular bus-bars are invariably used. This is to provide a large diameter to minimise the surface dielectric stresses. Copper surfaces may be embedded onto the aluminum tube where bus-bars are jointed.

## 34.3 Primary-circuit-protection devices

Primary-circuit-protection devices are necessary to ensure that any system malfunction is quickly detected and steps

taken to minimise its consequences. The main primary-circuit-protection devices encountered are current transformers, voltage transformers and surge arresters.

### 34.3.1 Current transformers

A current transformer is a current transducer that will give a current signal directly proportional in magnitude and phase to the current flowing in the primary circuit. It also has another very important function in that the signal it produces must be at earth potential relative to the HV conductor. The primary circuit of the current transformer must be insulated to the same level of integrity as the primary insulation of the system. For current transformers used on HV systems the primary-circuit insulation represents a very large proportion of the cost of the transformer.

The current transformer is the only current transducer widely used in HV networks. Recent developments of fibre-optic HV current transducers show promise but high cost and questionable reliability have limited their application. There is little doubt, however, that future current transducers will use fibre-optic technology.

A current transformer, as its name implies, is a transformer. It is almost invariably in the form of a ring-type core around which is wound a secondary winding.

The primary winding usually consists of a straight bar through the centre of the core which forms one turn of the primary winding. For low primary currents, typically below 100 A, multiturn primary windings consisting of two or more turns may be used in order to achieve sufficient ampere-turns output to operate the secondary connected equipment. For use at distribution voltages the core and secondary winding, together with the secondary terminations, are usually placed over a straight HV conductor bushing insulator which forms the segregation between the HV conductor and earth. An earthed screen is usually provided on the outer surface of the bushing and the current transformers are placed over this earth screen to ensure the limitation of HV partial discharge activity in the air gap between the bushing and the current-transformer winding. Current transformer secondary windings are generally connected to electromagnetic relays. These tend to require a high operating input which necessitates high-output (typically 15 V-A) current transformers. More modern protection is of the solid-state form and requires a much lower operating signal, thus enabling current-transformer designs and costs to be reduced. The secondary windings of current transformers tend to be rated at either 1 or 5 A, although other ratings are used at times.

Where long secondary connections are required between the transformer and the relay, 1 A secondary windings are advantageous in reducing the lead burden. Cold-rolled silicon-iron is usually used as the core material for protective current transformers but, where high-accuracy metering requirement is necessary, a very high grade alloy steel is used which is commonly referred to as 'Mumetal'.

For use at higher transmission voltages it is necessary to build integral insulation into the current transformer between HV conductors and secondary windings. This insulation is nearly always in the form of oil-impregnated paper, although SF<sub>6</sub> gas is occasionally used. The cost of providing the pressurised SF<sub>6</sub> gas enclosure usually makes SF<sub>6</sub> insulated current transformers uneconomical.

There are two basic forms of construction of transmission voltage oil-impregnated-paper insulated current transformers: the live-tank and dead-tank forms.

In the live-tank form the core and winding are placed at the same level as the primary conductor which passes through the centre of the assembly. The core and windings clearly need to be at earth potential. They are usually enclosed in some form of metallic housing which has a long vertical metallic tube through which the secondary winding leads pass to the base level. This housing and vertical metallic tube then have very many layers of paper wrapped around them to form the main primary insulation. Aluminium foil stress-control layers are wound in between the paper layers to ensure a uniform stress distribution from earth potential at the bottom end of the assembly to line potential at the top end.

The insulated current transformer assembly is then placed within an insulator housing having a metallic top assembly through which a primary conductor is passed. This conductor is electrically connected to the top assembly on one side and insulated on the other to prevent a current transformer short-circuited turn.

Before assembling the top cover, the whole transformer assembly is placed under vacuum for several days to ensure thorough extraction of moisture from the paper. The assembly is then filled under vacuum with a high grade insulating oil to prevent the formation of air bubbles. After filling the transformer to the top it is sealed. Some form of expansion assembly is incorporated to allow for expansion and contraction of the oil within its sealed compartment. This may comprise a bellows assembly or sealed nitrogen cushion. The current transformer may also incorporate an oil-level indicator to allow checking for loss of oil and a gas-detection system to allow monitoring for the production of gaseous products resulting from partial dielectric breakdown.

In the dead-tank version the current transformer core and windings are placed at the bottom, earth, end of the assembly and the insulation between the primary and secondary is in this case placed around the HV primary conductor rather than core and winding assembly. The centre section of the insulated HV primary conductor at which the core and windings are placed must be at earth potential. The HV primary conductor insulation must be graded on either side of the core and windings. Aluminium-foil wraps are inserted between the paper layers to provide the necessary grading from earth potential at the centre section to line potential at either end. To enable the HV primary conductor assembly to be accommodated in a vertical insulator, the assembly is bent in a 'hairpin' fashion. The insulated paper is in fact wound on to a conductor already formed to this hairpin shape. The legs of this insulated assembly are then opened up to allow the core and windings to be slipped over.

The completed assembly is vacuum processed and oil filled in a similar manner to that described for the live-tank current transformer.

Both live-tank and dead-tank forms of construction are very widely used. Both constructions are shown in *Figure 34.26*.

### 34.3.2 Voltage transformers

Voltage transformers are also, as the name implies, voltage transducers giving an accurate representation in magnitude and phase of the voltage of the primary conductors. They also require insulation to segregate the primary and secondary circuits. At transmission voltages they are always single-phase assemblies, whereas at distribution voltages they may be three-phase or single-phase assemblies. At distribution voltages the primary winding is always star connected with its neutral point generally insulated and unearthed.

Figure 34.26 Cross-section of (a) live-tank and (b) dead-tank current transformers

The secondary windings are usually connected in a star arrangement to provide a standard phase-to-phase secondary voltage of 110 V, the individual phase secondary windings being rated at 63.5 V.

For certain applications a further secondary winding is sometimes provided which is connected in open delta. Under normal balanced voltage conditions the voltage across the open delta is zero. However, for earth-fault conditions balance will no longer be achieved and a voltage will occur across the open-delta winding. A three-phase residual voltage transformer uses a five-limb core to allow the zero sequence resultant flux to circulate. Such a system is generally used for residual earth-fault protection.

Three-phase assemblies at distribution voltage traditionally were of the oil-filled construction. More recent designs of three-phase voltage transformer employ a dry type cast epoxy resin insulated assembly enclosed in a metallic tank. Three single-phase cast epoxy insulated voltage transformers may also be mounted within an enclosure and connected to form a three-phase assembly.

Designs of electromagnetic voltage transformer usually employ an earthed electrical shield between the HV and the secondary winding. In the event of an HV breakdown, fault currents will flow to earth via the shield rather than through the secondary winding. A further useful feature of the shield is that it prevents h.f. coupling between primary and secondary windings as h.f. coupling in secondary windings and circuits could cause maloperation of secondary connected equipment. Such high frequencies may, for example, be generated by disconnector operation.

At distribution voltages, voltage transformer HV windings are usually protected by means of fuses to limit the energy that is fed into a faulted voltage transformer to prevent possible external disruption of it.

At transmission voltages, early designs of voltage transformers were also of the electromagnetic construction with the core and winding built in a conventional transformer

manner and enclosed within a large oil-filled tank at earth potential. The HV connection was taken into the transformer via a large external bushing. Whilst some of these designs are still in service and are reliable, in the rare event of failure a large amount of energy would be expended within the transformer tank.

Since it is impracticable to protect such voltage transformers with fuses, to alleviate the problem a gas-detection device is usually fitted which will trip the associated circuit-breaker in the event of rapid build up of gas.

Electromagnetic voltage transformers for use at transmission voltages are also very costly and a more inherently reliable and economical device was developed which is referred to as a 'capacitor-voltage transformer'. This concept uses one or more HV capacitor assemblies, each of which is enclosed within its own porcelain housing. The individual units are mounted on top of each other to form a series assembly of HV capacitors. The complete assembly is usually mounted on an earthed tank which encloses a further capacitor and an electromagnetic transformer/reactor assembly. The bottom capacitor forms the lower leg of a capacitor divider assembly and a voltage signal (typically 12–25 kV) is taken from the interface of the HV and LV capacitors. This signal is then fed via a reactor to a transformer which has a secondary winding giving an output of 63.5 V at the system rated voltage. The secondary winding may have tapplings to enable correct setting and thus minimise the voltage-ratio error.

The reactor also usually has tapplings to allow for minimum setting of the phase-angle error. The LV capacitor is usually of a large value, typically 20 000 or 30 000 pF. The value of the reactance connected to this capacitor is such as to allow resonance to occur at the required system frequency, e.g. 50 or 60 Hz. This arrangement allows a significantly larger secondary output to be taken from the capacitor-voltage transformer than would be available if it were purely a capacitor divider. Ratings of 200 V-A can

readily be achieved by this means. Capacitor-voltage transformers are tuned devices and their accuracy and output will fall considerably at frequencies other than the tuned frequency.

Maloperation of a capacitor-voltage transformer is usually detected by variation in secondary output voltage and explosive failures are extremely rare. Unless a very high value of HV capacitor is used, external moisture or pollution contamination on the insulation can cause variations in the HV field around the insulator which will result in slight variations in output. These variations are of little significance for capacitor-voltage transformers used for protective purposes, but for high accuracy tariff metering such variations can be significant.

For these reasons capacitor-voltage transformers are seldom suitable for use in high accuracy tariff metering applications and it has been necessary to revert to the electromagnetic transformer for these applications. Early designs used a cascade arrangement of separately connected transformers in order to reduce physical size and to alleviate the consequences of dielectric breakdown. These arrangements have been used at both 420 and 300 kV and comprise three separate electromagnetic units vertically mounted on top of each other and enclosed within a large-diameter oil-filled insulator assembly. Cascade electromagnetic voltage transformers have proved to be very reliable, but are also extremely costly. Where large numbers of high-accuracy voltage transformers are required, for example at interconnections between adjacent electricity supply companies, then the cascade voltage transformer is no longer economical and it has been necessary to revert to a single electromagnetic unit enclosed within its own porcelain housing.

Because of the considerable reduction in output achieved by the use of solid state secondary equipment, smaller electromagnetic units can now be used. These designs nevertheless still comprise paper-insulated oil-filled units and are prone to the dielectric-breakdown problems of the earlier designs. Very careful design and strict manufacturing quality-control procedures are necessary to ensure the long-term integrity required of these equipments. It is still normal practice for gas-detection alarms to be provided which may also offer the facility for circuit-breaker tripping on sudden build up of gas.

### 34.3.3 Combined-instrument transformers

Where high-accuracy instrument transformers are required to be fitted retrospectively, space limitations in existing substations often present significant problems. The situation has been alleviated by the combination of both a current transformer and an electromagnetic voltage transformer into a common insulator housing. These devices are referred to as 'combined instrument transformers'. They are used at transmission voltages up to some 300 kV, but for higher voltages where very limited numbers would be required they are not economically viable and separate units are still used.

Figure 34.27 shows typical arrangements of a capacitor-voltage transformer, cascade electromagnetic voltage transformer and combined-instrument transformer.

### 34.3.4 Surge arresters

Electricity supply networks extensively use overhead lines to transmit the power from generating stations to major load centres. These allow interconnection of different parts of the system and, in rural networks, supply isolated consumers. All of these overhead-line circuits are prone to atmospheric disturbances. These may be physical in nature (i.e. wind, rain, snow, ice and pollution) or electrical (as may occur during lightning activity). Should an overhead-line circuit be struck by lightning the overvoltage surge generated on the line may be of the order of megavolts. This surge will travel down the line, possibly causing flashovers en route, and its magnitude and shape will be attenuated by the electrical parameters of the line. When it arrives at the terminations of electrical equipment it may cause the equipment to flashover externally or fail internally. The surge will be triangular in wave shape having a steep wavefront with a rate of rise of possibly up to  $3 \text{ MV}/\mu\text{s}$  and a long duration tail of typically 20–200  $\mu\text{s}$ .

In addition, transient overvoltages can be generated by the switching devices themselves. These will also be triangular in shape but with a much less steep wavefront (250  $\mu\text{s}$ ) and much longer wave tail (2500  $\mu\text{s}$ ) than the lightning surge. Switching surges can also result in dielectric failure of connected electrical equipment. It is thus necessary to

**Figure 34.27** Arrangement of (a) capacitor-voltage transformer, (b) cascade electromagnetic voltage transformer, and (c) combined-instrument transformer

protect electrical equipment against these transient over-voltages. This is normally achieved by application of a surge diverter or, more correctly, surge arrester. The surge arrester is a device which is electrically connected between the conductor and earth and in close proximity to the equipment that it is to protect. Under normal power frequency conditions the current which flows to earth is negligible, but under transient overvoltage conditions it will detect the change in voltage magnitude and divert the surge to earth. Surge currents may be as high as 100 kA or more and of a few tens of microseconds in duration. Once the surge has passed, the surge arrester will very quickly reinstate itself to immediately withstand the power frequency system voltage and prevent power frequency fault current flow. The duration of the passage of surge current is so short that the system protection does not operate to cause circuit-breaker tripping.

Rod gaps are sometimes provided across insulators, or electrical apparatus also to divert the surge to earth but, in doing so, cause power frequency fault current to flow and result in circuit-breaker tripping.

Surge arresters provide the required characteristics by the use of non-linear resistor blocks which have a high resistance at LV and a very low resistance at HV. Traditionally, silicon carbide blocks have been used as being the most suitable non-linear resistor material. However, they suffer from the disadvantage that even at LV a significant current will still flow which will lead to overheating and eventual failure. This problem was resolved by incorporating a number of series gaps in the arrester. The capacitance of these gaps causes insignificant current to flow through the blocks under normal voltage conditions and thus alleviates overheating problems. For transient overvoltages, the series gaps will break down and the resistor blocks will effectively be switched into circuit. These gaps will quickly reinstate after the passage of surge current.

Many lightning strikes comprise multiple strokes which occur within a few milliseconds of each other. For example, a low-probability strike might comprise six strokes within 100 ms. The application of each transient overvoltage to the terminals of the surge arrester will require the dissipation of a large amount of energy which will result in heating of the silicon carbide blocks. The arrester, however, must be capable of dissipating multiple lightning strokes without deterioration and the resistor blocks must be sized accordingly. The disadvantage of the silicon carbide gapped arrester is that, in order to overcome the high leakage current problems, series gaps are required and these make the arrester large and costly. Nevertheless, these arresters can readily withstand temporary power frequency overvoltages for long periods of time since the series gaps are unlikely to operate.

The problem of size, complexity and cost of the silicon carbide gapped arrester has been resolved in recent years by the development of the zinc oxide arrester. These arresters use resistor blocks manufactured from zinc oxide and a combination of a number of other additives and have the advantage that their resistance is such that, at normal operating voltages, only a milliampere or so of leakage current will flow. They have a sharp knee point at higher voltages which rapidly allows the flow of high current resulting in the very rapid dissipation of the surge.

A comparison of the characteristics of silicon carbide and zinc oxide resistor blocks is given in Figure 34.28.

Since the leakage current for zinc oxide blocks is very low, series gaps are no longer required. In addition, the zinc oxide blocks are physically smaller for a given rating. This technology has allowed the rapid development of very

Figure 34.28 Comparison of (a) silicon carbide and (b) zinc oxide resistor characteristics

economical high-performance designs of surge arrester and the virtual elimination of silicon carbide designs.

A further innovation has been the recent introduction of a polymeric housed, rather than a porcelain housed, arrester. This has significantly increased the mechanical strength of the arrester and elimination of the problem of shattered porcelain in the event of arrester internal failure. A typical porcelain housed silicon carbide gapped arrester and a polymeric house of zinc oxide arrester construction for the same voltage rating are shown in Figure 34.29.

## 34.4 LV switchgear

### 34.4.1 Fuse cut-outs

'Fuse cut-out' is a term commonly applied to the equipment placed at the interface between the supply authority system and a domestic consumer's system. It comprises facilities for terminating the main incoming cable, for incorporating a fuse link and for terminating outgoing conductors to the supply authority's meter. Since the consumer may have physical access to this equipment, safety is of paramount importance. All live connections must be enclosed to prevent danger and fuse holders containing the fuse links are sealed within the cut-out assembly.

Many thousands of these units are installed by the supply authorities and reliability is of paramount importance. Elaborate specifications and extensive type testing are necessary to ensure the suitability of the device. The cut-out must be rated for the consumer's load which is normally supplied from a single-phase circuit typically having current ratings of up to 100 A.

For higher loads three-phase assemblies must be supplied. The consumer's load can vary rapidly over short periods of time and the cut-out must be designed and tested under a very large number of repetitive cyclic loading conditions in order to ensure that long-term deterioration is unlikely to occur.

The fuse cut-out must also be capable of clearing a short-circuit across its terminals. This may be of the order of 16 kA at 240 V. The main purpose of the cut-out is to protect the supply authority's circuits in the event of malfunction of the consumer's installation. However, in performing this function it will also limit the energy fed into

**Figure 34.29** Construction of silicon carbide and zinc oxide surge arresters

a consumer's faulted equipment. Removal of the cut-out fuse links will provide physical isolation between the supply authority's and consumer's equipment to allow work to be safely undertaken on the consumer's installation. As the cut-out fuse holders are sealed within their base their removal can only be undertaken by the supply authority.

A typical three-phase domestic fuse cut-out is shown in Figure 34.30.

#### 34.4.2 LV fuse cabinets

For commercial or light-industrial consumers the connected loads are in excess of those that can be provided by the domestic fuse cut-out. Three-phase loads are generally required with possible current ratings of up to 1600 A at 415 V. Multiple circuit loads may also be required. These are usually provided by means of a LV fuse cabinet supplied directly from a HV transformer having ratings typically of up to 1000 kVA.

Fuse cabinets may be bolted directly to the LV terminals of the transformer. They comprise an incoming directly connected circuit from the transformer to three single-phase manually operated disconnectors. These disconnectors then control and supply each phase of a main three-phase bus-bar system from which up to five outgoing circuits can be taken. Each phase of the outgoing circuit is protected by a bus-bar-mounted LV fuse with terminations for the outgoing circuit cables provided on the outgoing fixed contacts on the fuse.

Fuse cabinets are generally of weatherproof construction suitable for installation outdoors. They are incorporated within the supply authority's substations and only authorised personnel can gain access. Since live manual fuse replacement may be necessary special training and

**Figure 34.30** Domestic fuse cut-out

**Figure 34.31** LV fuse cabinet

equipment is provided for authorised operators. Short-circuit ratings may be up to 43 kA at 415 V three-phase.

*Figure 34.31* shows a typical LV fuse cabinet.

### 34.4.3 LV switchboards

For LV supplies to large commercial and industrial consumers a LV switchboard is often used whereby the incoming circuit-breaker is owned by the supply authority and is connected by cables to the LV of a suitable transformer. The incoming circuit-breaker will then feed on to a bus-bar system from which the load circuits can be fed. The load circuits may be protected by moulded-case circuit-breakers or fuse switches. The equipments are generally built into a metal-enclosed housing which provides glanding for terminating outgoing circuit cables. Similar switchboards are also used for LV distribution applications in large industrial complexes.

Various configurations of switchgear can be applied depending on the equipment importance. For example, all bus-bars, bus-bar tee-off connections, and circuit-protecting equipments may be enclosed in a common metal-enclosed housing. This arrangement has the disadvantage that any one faulted component within the switchboard will allow the fault to spread to other equipments within the switchboard such that for a major fault the complete switchboard could be rendered inoperative. For high-integrity switchboards, where reliability of supply is of utmost importance, metallic segregation is provided whereby the incoming circuit-breaker will be in its own metal-enclosed compartment as will the bus-bars and bus-bar feeder circuits, the outgoing feeder equipment and the cable terminations, thus preventing the spread of a fault from any one compartment to adjacent

compartments. This latter construction is normally applied to high integrity industrial equipments such as may be used, for example, within generating stations. The switchboard can also incorporate combinations of fuse switches and contactors to form motor starter assemblies. A high-integrity LV switchboard is shown diagrammatically in *Figure 34.32*.

## 34.5 HV secondary distribution switchgear

### 34.5.1 Urban networks

Supplies to large numbers of consumers in urban conurbations are usually taken from a primary switchboard at between 10 and 20 kV. The switchboard usually comprises two sections of bus-bar with a central, normally open, bus-section circuit-breaker. The supplies are taken from a circuit-breaker on one section of the bus-bar via a ring cable circuit to a circuit-breaker on the adjacent section of bus-bar. The ring circuit may be some kilometres in length and secondary distribution substations can be situated at various points around the ring. The ring may be normally run open at some suitable point along its length.

The secondary distribution substation comprises a HV cable connected switchgear unit normally referred to as a ring-main unit, a HV/LV transformer having typical ratings up to 1000 kVA and a LV fuse cabinet of the type described in Section 34.3.2. The ring-main unit may be physically mounted on the HV terminals of the transformer with the LV fuse cabinet mounted on its LV terminals to form a complete transportable secondary distribution substation. Alternatively, the three items of equipment may be separately mounted and all cable connected. Secondary distribution substations are normally of weatherproof construction and used in outdoor environments. Such a substation is usually protected from the public by means of suitable fencing. The equipments may also be housed in a weather-proof, vandal-resistant housing in which case individual items of equipment may not be weatherproofed.

Very many thousands of secondary substations of the type described are in service and have, over a long period of time, given economical and reliable performance. The ring-main unit usually comprises two manually operated ring switches and a centrally disposed tee-off fuse switch, also manually operated. In addition to the ring switch, fault-making earth switches and suitable cable test facilities may be built into the cable side of each switch to allow the cable to be safely earthed, repaired if necessary, and re-tested. The ring switches, earth switches and test facilities may incorporate interlocking and padlocking facilities to prevent an operator from undertaking an incorrect switching sequence.

As described in Section 34.2, switches are not fault-breaking devices. However, there have in the past been occasions when a switch has inadvertently been closed on to a fault and the operator's reaction, on realising his error, is immediately to attempt to open the switch. In order to prevent this happening most switches now have a delay incorporated such that, subsequent to closing, the switch cannot be opened for a period of at least 3 s. This allows time for the protection at the primary substation to operate to trip the associated circuit-breaker to clear the fault.

The tee-off fuse switch may also incorporate a fault-making earth switch on its HV terminations as a safety precaution against possible LV back-feeds.

Careful selection of the fuse rating in the fuse switch is necessary as the fuse needs to fulfil a number of functions. It must operate to clear a fault within the HV winding of the transformer and in the HV cable circuit to the transformer.

**Figure 34.32** Construction of a high-integrity LV switchboard

It must be sized to discriminate with the LV fuses such that it does not operate for a downstream LV fault and it also must discriminate with the HV ring feeder circuit-breaker protection. It must not operate on transformer in-rush current and it must be sized to carry the rated current of the transformer or overload current of the transformer, which may be up to 150% of the transformer rating, for limited periods of time. It must also not deteriorate with age.

Most currently used designs of ring-main unit are oil-filled and use fuses under oil, although some may have fuses mounted in air.

SF<sub>6</sub> insulated designs of ring-main unit are now becoming available, their main advantage being the limited fire hazard in the event of a fault. However, they are relatively costly to produce since the enclosure must be gas tight. Relays or pressure gauges may be incorporated to give an indication of loss of gas pressure. HV fuses cannot be readily accommodated within the SF<sub>6</sub> insulated chambers and are usually mounted in air. Some manufacturers now use suitably rated vacuum or SF<sub>6</sub> circuit-breakers in place of the tee-off fuse switch. Whilst SF<sub>6</sub> insulated ring-main units can be made weatherproof for outdoor use, the general tendency now is to place them within a weather-protected housing. *Figure 34.33* shows an SF<sub>6</sub> insulated ring-main unit installed within a housing.

Modern safety legislation now requires equipment to be designed such that, even in the event of maloperation, it will present no danger to an operator. It is becoming common practice for new designs of equipment to be tested with a deliberately connected internal fault in order to demonstrate that any arcing products which may be expelled are directed away from where an operator may be standing whilst performing his normal duties. This is particularly pertinent for manually operated ring-main units.

Operating mechanisms which can be controlled remotely are available and provide the possibility for remote switching. However, pilot cable connections are seldom available

for secondary distribution substations and this provision together with remote operational facilities can add significantly to the cost of a secondary distribution network where fault ratings are invariably low.

**Figure 34.33** SF<sub>6</sub> insulated ring-main unit

### 34.5.2 Rural networks

Rural networks are usually fed from overhead-line systems operating at voltages of 10–36 kV. They may entail line lengths of some tens of kilometres which may only be lightly loaded.

The lines are fed from a primary switchboard and may comprise either a ring formation or radial network. The disposition of the load may be such that ring networks are not geographically practicable and the majority of circuits are radial with tee-off branches to consumers. The tee-off circuits traditionally have been protected by pole-mounted three-phase or single-phase expulsion fuse assemblies or, more recently, by automatic pole-mounted sectionalisers (see Section 34.1.5.1). The main line circuit is usually protected by a circuit-breaker incorporating an auto-reclosing facility.

Many overhead-line faults are transient in nature due, for example, to wind activity or lightning. The circuit-breaker will trip on fault initiation and the fault will then clear to allow the circuit-breaker to re-close automatically. Three or more reclosures may be permitted before it is assumed that the fault is permanent in nature when the circuit-breaker will then remain open. Under these conditions the whole of the overhead-line circuit will be out of commission with all consumers off supply until the faulted section can be located and repaired.

This situation can be alleviated by the use of pole-mounted auto-reclosing circuit-breakers, normally referred to as ‘auto-reclosers’, situated at suitable positions along the overhead line. The protection settings and number of permissible reclosures to lock-out can be pre-set such that only consumers downstream of a faulted section will be affected. Early auto-reclosers were operated by a falling-weight mechanism which needed to be re-charged subsequent to completion of a predetermined number of reclosures. More modern designs use solenoid coils operated directly from the HV feeding supply.

Auto-reclosers were traditionally oil-filled devices, but more recently SF<sub>6</sub> auto-reclosers have been available. A typical SF<sub>6</sub> auto-recloser is shown in Figure 34.34.

Sometimes a pole-mounted switch, often referred to as a ‘sectionaliser’ is used in conjunction with auto-reclosers, to allow manual reinstatement of circuits.

Rural consumers tend to suffer more and longer outages than urban consumers since the overhead line is more vulnerable to faults and longer distances are involved in operator travel to locate and repair the faulted section.

Where ring circuits can be employed, these offer the advantage of possible automation whereby a faulted section of line can automatically be isolated and all remaining sections up to the faulted section automatically reinstated. Signalling can be incorporated to allow the control engineer to direct the personnel directly to the circuit. Such systems are now technically viable and in use in some countries, but financial viability needs to be demonstrated.

## 34.6 HV primary distribution switchgear

HV primary switchgear feeding urban systems usually comprises cable-connected metal-enclosed switchboards housed within a brick-built substation. For feeding rural systems it may be in the form of open-type switchgear equipments, interconnected by air-insulated bus-bars, feeding overhead-line circuits. The metal-enclosed switchboard comprises disconnectors, bulk oil, SF<sub>6</sub> or vacuum circuit-breakers connected to a common bus-bar system and feeding via current transformers and voltage transformers on to a

Figure 34.34 Pole mounted SF<sub>6</sub> auto-reclosing circuit-breaker

cable network. The bus-bars, circuit-breakers, current-transformer chambers and cable-box terminations may each be segregated within metal enclosures. Such equipment is referred to as being ‘metal clad’. Live components within the enclosures may be air insulated or, more generally, insulated with solid material, usually cast epoxy resin, although more recently many different forms of cast resin materials have become available to the designer.

Bus-bars are usually segregated into two or more sections which can be coupled together by means of a bus-section circuit-breaker. A double bus-bar system may be provided for important installations where outages from a possible bus-bar fault cannot be tolerated. However, switchgear reliability is such that double bus-bar arrangements are now seldom employed at distribution-system voltages.

Outdoor substations at distribution voltages usually employ dead-tank oil, SF<sub>6</sub> or vacuum circuit-breakers incorporating ring type current-transformers around their bushings.

Manually operated disconnectors are usually employed. They are interconnected by copper or aluminium tubular bus-bars which are air insulated and supported on post insulators. The live equipment is mounted at a height of some 2 m above ground level to allow safe personnel access. Surge arresters may be employed at overhead-line entries into the substation.

## 34.7 HV transmission switchgear

HV transmission switchgear is used within substations to control the flow of large quantities of electric power within an electrical network. It may operate at rated voltages of 145–800 kV, with normal load currents of up to 4 kA and short-circuit currents of up to 80 kA.

The switchgear may be connected in the substation in various arrangements, the most common being the double bus-bar arrangement. Other commonly found alternatives are 1½ switch or mesh-connected arrangements. These are shown diagrammatically in *Figure 34.35*.

The switchgear may be of the open-type air-insulated construction basically similar to that described for open-type distribution switchgear or it may also be in the metal-enclosed form. The metal-enclosed form is a relatively recent innovation made possible by the use of SF<sub>6</sub> gas and is now widely employed, it is generally referred to as 'gas-insulated switchgear'. All live parts to earth are insulated with SF<sub>6</sub> and circuit-breakers also use it as their interrupting medium. Typical clearances between live parts and earth for 420 kV equipments might be some 250 mm which allows very compact substations to be built. A gas-insulated-switchgear substation, for example, may occupy only one-fifth of the ground area of an open-type substation. It will also have a low physical profile and is ideal for installation in urban networks where land availability and space is at a premium. Gas-insulated switchgear usually consists of phase-isolated assemblies at 420 kV and above but below this voltage the three phases may be housed in a common SF<sub>6</sub> enclosure. Cable compartments, bus-bars, disconnectors and circuit-breakers are generally segregated within their own gas enclosures. A typical 145 kV gas-insulated substation is shown in *Figure 34.36*.

In view of the very small electrical clearances involved between live conductors and earth, internal cleanliness is of utmost importance. For example, a small particle of a few millimetres in length can induce dielectric breakdown. Strict quality-control and inspection procedures are necessary during assembly. Such particles can induce partial discharge activity and most users now require monitoring for this activity in order to alleviate the consequences of dielectric breakdown. Partial discharges within gas-insulated switchgear excite resonances within the chambers. These resonances can be detected by the use of integral capacitive couplers and by examination of the frequency spectrum which may be generated. They are typically of the order of 1000 MHz. This recently developed technique is referred to as the 'ultra-high frequency partial discharge technique'.

### 34.8 Generator switchgear

It had long been the desire to be able to switch generator circuits directly at generator voltage, but circuit-breaker technology and testing techniques had not developed sufficiently to allow this. This situation changed some years ago and a few manufacturers now produce generator circuit-breakers capable of switching and clearing faults on the

**Figure 34.35** Typical substation arrangements: (a) double bus-bar; (b) mesh; (c) 1½; circuit-breaker

**Figure 34.36** A 145 kV gas-insulated-switchgear substation. (FMES, fault making earth switch)

largest of generator circuits. Typical ratings may be 200 kA at 24 kV with rated load currents of 24 kA.

Early designs of generator circuit-breaker used air-blast technology, but more recent designs use SF<sub>6</sub> technology. The cross-section of a typical generator circuit-breaker is shown in *Figure 34.37*.

## 34.9 Switching conditions

Switching equipment must clearly be suitable for switching normal and, where required, abnormal conditions of the circuit in which it is situated. All circuits consist of series/parallel arrangements of resistance, reactance and capacitance and during switching these components will produce resonances of different forms. The switching equipments must therefore be capable of safely withstanding these resonant conditions during the switching operation. The switching conditions described in the following sections are regularly encountered.

### 34.9.1 Normal switching conditions

#### 34.9.1.1 Shunt capacitor bank switching

When switching a shunt capacitor bank the load is purely capacitive. The source side of the circuit-breaker will include bus-bar capacitance to earth, this being small

compared with the load capacitance, and series reactance. Since the capacitive current will be small compared with the circuit-breaker's rated short-circuit current, clearance of this current will often occur at the first available zero current. At this point of clearance a 1 pU charge will be left on the load-side capacitance. The source-side power frequency voltage will then swing to its opposite polarity to create a voltage across the opening circuit-breaker contacts of 2 pU. The circuit-breaker contact gap may be insufficient to withstand this voltage and breakdown across the gap might occur.

Thus the energy stored in the load capacitor is discharged to the bus-bar shunt capacitance and series inductance to cause a high-frequency oscillation. Large currents will flow across the opening contact gap and damage to arc control devices may occur. The term 're-ignition' is applied if this breakdown occurs within 0.25 cycles of arc extinction and 're-strike' if it occurs subsequent to this.

Circuit-breakers suitable for switching shunt capacitor circuits ideally should be designed and proven by test to be re-strike free.

#### 34.9.1.2 Overhead-line and cable switching

Both overhead-line and cable switching conditions present problems similar to those of capacitor switching.

In the case of the overhead line there will be distributed capacitance between the phases, and to earth along the line,

**Figure 34.37** Cross-section of a typical generator circuit-breaker

interspersed with distributed line inductance. The load current is again small and its interruption is probable at the first available current zero. This will leave a charge on the line which may result in a travelling wave propagating along the line to the far end where it will reflect and return to the circuit-breaker.

The wave is generally attenuated when it reaches the circuit-breaker, but the circuit-breaker contact gap may be insufficient to withstand the voltage now appearing across its contacts and a re-ignition or re-strike may occur. Overhead-line switching may be a regular switching condition for a circuit-breaker and international specifications now require a circuit-breaker intended for overhead-line switching duties to be re-strike free.

A further problem may occur when switching an overhead line which is terminated at an unloaded transformer. The combination of line capacitance and transformer reactance then may cause high-frequency oscillations with phase to earth overvoltages in excess of 3.0 p.u. Overhead-line switching regimes usually prohibit the switching of such circuits. If remote-end switching is necessary the over-voltage at the transformer can be limited by the application of surge arresters, but these would need to be rated to be capable of dissipating the energy associated with this switching condition.

With cable switching, the condition is similar to overhead-line switching except that capacitance values significantly

higher than those associated with the overhead line will be encountered.

#### 34.9.1.3 Transformer magnetising current switching

The arc-extinction methods described in Section 34.1.8 for circuit-breakers indicate that circuit-breakers generally clear on cessation of flow of current, i.e. at a natural zero current. When interrupting very low values of current this may not always be the case and the arc-extinction mechanisms may force the arc to extinguish before the current reaches its natural zero. This phenomenon is referred to as 'current chopping'. Since the voltage appearing across the circuit is proportional to the rate of change of current times and inductance of the circuit, very high overvoltages may occur as a result of current chopping. This phenomenon occurs when switching low inductive currents, as for example may occur when switching the magnetising current of a transformer. The transient voltage will in fact oscillate at a frequency determined by the transformer magnetising inductance and winding capacitance. The oscillation will be damped by eddy and current hysteresis losses in the transformer. Overvoltages of the order of 3 p.u. may be generated.

Whilst vacuum circuit-breakers are particularly good at rapidly extinguishing low values of current, current

chopping can occur when used for switching inductive currents such as transformers or motors.

#### 34.9.1.4 *Shunt-reactor switching*

Shunt reactors are often used to compensate for the capacitance of lightly loaded lines. They may be frequently switched depending on the line-loading regimes. Shunt-reactor switching presents onerous switching conditions for a circuit-breaker and frequent maintenance may be necessary. At transmission voltages, shunt-reactor currents may be of the order of 400–600 A. The associated circuit-breaker will thus have to switch a very large reactive current with little parallel capacitance on the load side and very steep rates of rise of transient recovery voltage may result across the opening circuit-breaker contacts. These may cause multiple re-ignitions and, depending on the circuit-breaker type, may cause long arc lengths and arc durations. The dielectric withstand properties of the interrupter may rapidly deteriorate under these switching conditions.

#### 34.9.1.5 *Series-reactor switching*

Series reactors are sometimes used to limit the short-circuit fault capacity between two connected sections of a supply system. Should a fault occur on the circuit side of the reactor this would cause a relatively high-frequency transient on the reactor side of the circuit-breaker and a low-frequency oscillation on the bus-bar side. A double frequency recovery voltage will thus appear across the opening contacts of the circuit-breaker and may result in a very high rate of rise of transient recovery voltage being imposed as the circuit-breaker contacts are opening. Thus circuit-breakers for series-reactor switching duties need to be tested for these specific conditions.

#### 34.9.1.6 *Disconnecter switching*

Whilst disconnectors generally have only to switch the small capacitive currents associated with a section of bus-bar between the disconnector and circuit-breaker, this can cause certain problems. Firstly, the disconnector must be capable of satisfactorily switching the maximum value of capacitive current likely to be encountered without causing contact or dielectric deterioration.

Secondly, the contacts of a disconnector are generally slow in operation and, when switching very low values of capacitive current, very many re-ignitions may occur. These will result in very high-frequency transients propagating along the bus-bar and may result in overvoltages of the order of 2.6 p.u. The disconnected section of bus-bar may be left with a d.c. trapped charge which, in gas-insulated switchgear, may remain for some weeks. If, however, an electromagnetic voltage transformer is connected to the disconnected section of bus-bar, the trapped charge may dissipate through the primary winding of the voltage transformer and, depending on the relative circuit parameters, overheating or physical damage to the voltage transformer may occur.

When synchronising generators, a disconnector may be used to energise a short section of bus-bar from the generator circuit to an open synchronising circuit-breaker with the generator already excited to system voltage. If the open circuit-breaker has capacitive voltage grading, the voltage of the bus-bar between the open circuit-breaker and open disconnector may be very close to the system voltage since capacitance to earth will be small. This means that the open disconnector contacts have, on one side, a voltage fed from the system which is close to the system voltage, and on the

generator side a voltage close to the system voltage fed from the generator. The generator frequency will not align with system frequency and the voltage across the disconnector contacts can rise to 2 p.u. As the contacts close the contact gap may flashover at this 2 p.u. voltage which will leave a d.c. trapped charge superimposed on the a.c. voltage on the section of bus-bar between circuit-breaker and disconnector. The voltage across the disconnector contacts then may rise to as high as 3.5 p.u.

The three disconnector switching conditions described above need to be proven by test, and international specifications covering these requirements are in preparation.

Disconnectors are also commonly used to transfer load current from one bus-bar to an adjacent parallel connected bus-bar. Under these conditions the disconnector may have to make and break full-load current with a voltage across its contacts equal to the impedance drop around the parallel circuit. Whilst this may only be some tens of volts, contact burning can result. Disconnectors require to be designed such that this type of operation does not adversely affect the dielectric properties of an open disconnector.

International specifications now call for disconnectors to be proven for switching this condition.

#### 34.9.1.7 *Earth switch/switching*

Since earth switches are only applied to a de-energised circuit they should not, under normal conditions, be required to make or break current. However, when an overhead line is taken out of service and where work is required on the line, it is necessary to earth the line at both ends. In the case of a double circuit overhead line with one circuit earthed, the earthed line will have currents induced into it by means of magnetic coupling from the adjacent loaded line and inductive currents will circulate around the closed loop of the earthed line. The first earth switch to open will then have to break this inductive current which, at 420 kV, may be of some hundreds of amperes and the voltage appearing across the earth switch contacts may also rise to a few kilovolts. With the line then earthed at one end only, a current to earth will be induced in the line equal to the capacitive current flowing between the two parallel lines. When the second earth switch opens it will have to clear this capacitive current, which again for 420 kV may be some tens of amperes, but the voltage across the open contacts may now increase to some tens of kilovolts.

New international specifications will incorporate tests to verify earth-switch performance when operating under these conditions.

### 34.9.2 **Abnormal switching conditions**

The main difference of a circuit-breaker compared with other mechanical switching devices is its ability to satisfactorily clear abnormal circuit conditions as may occur, for example, when a short-circuit occurs on the downstream side of the circuit-breaker. Under these conditions the circuit is mainly inductive and the short-circuit current lags the system voltage by almost 90°. This means that when the current passes through a zero point the voltage across the opening circuit-breaker contacts is at or near its peak value. The arc-extinguishing process must therefore be such as to ensure that, at a suitable current zero, sufficient dielectric strength has built up to withstand this peak voltage. For an air-blast or gas-blast SF<sub>6</sub> circuit-breaker this will usually occur at, or before, the second available current zero. For oil circuit-breakers several current zeros may pass before

arc extinction occurs. Unfortunately the process is more complicated than that described since during the arcing period the voltage across the circuit-breaker contacts is small and, at clearance, it must change from this small value to the peak of the system voltage in a very short period of time. In doing so the voltage across the contacts will tend to rise to twice the peak voltage which will set the downstream circuit into a damped oscillation at its natural frequency. This transient voltage is known as the 'transient recovery voltage'. For a given circuit the value of the fault current will depend on the impedance of the circuit up to the point of a fault, and fault currents will clearly be lower for longer distance faults. This means that a greater length of the circuit will be available to resonate on fault clearance. This has the general effect that the rate of rise in the transient recovery voltage, and its peak value, tend to be higher for lower values of fault current. This situation is covered in international specifications by calling for short-circuit tests at 100%, 60%, 30% and 10% of the circuit-breaker current with the transient recovery voltage parameters being specified for each value of short-circuit test current.

An additional complication arises where the ratio of inductance to resistance can be high, for example, for faults close to transformer terminals. This causes the a.c. current to contain a large decaying d.c. component of current. When the circuit-breaker contacts open, this decaying d.c. current may not have reached zero and the circuit-breaker will be required to clear an a.c. current off-set from the zero line. This is referred to as an 'asymmetrical short-circuit current'. This has the effect that, depending on the circuit-breaker type, clearance, for example at a minor loop of current, might be less onerous than clearance at a major loop of current. Again international specifications detail precise parameters to be met by a circuit-breaker when clearing these conditions.

A similar situation might arise when a circuit-breaker is required to close against a short-circuit when the system reactance to resistance ratio ( $X/R$ ) is high. A large d.c. current in the initial part of the a.c. current wave may occur and the d.c. current peak may, in theory, reach  $2 \times \sqrt{2} I_{rms}$ . For typical  $X/R$  ratios the peak current is, in practice, nearer to  $1.8 \times \sqrt{2} I_{rms}$  and it is this value which the circuit-breaker must satisfactorily close against. As large mechanical forces will result from the electromagnetic effects of the peak short-circuit current, the circuit-breaker operating mechanism must have sufficient energy to overcome these forces.

As described previously for disconnectors, a circuit-breaker may be required to close, and open, under conditions where it ties together two large power systems the frequencies of which may differ by up to  $180^\circ$  prior to circuit-breaker closure or during opening. Under these conditions the current that flows may be of the order of 25% of the rated short-circuit current of the system, but the recovery voltage across the circuit-breaker contacts may, in the extreme, be as high as 3 p.u.

A further onerous condition may occur for a fault a short distance along an overhead line whereby the line impedance is such as to reduce the short-circuit current to some 75–95% of its rated value. This is termed a 'short-line fault condition'. At a current zero the voltage on the line-side terminal of the circuit-breaker is equal to the impedance drop along the faulted section of line. When the circuit-breaker opens to clear the fault this impedance voltage drop will cause a transient voltage to propagate up and down the short section of faulted line. This will result in a decaying 'saw tooth' wave on the line side of the circuit-breaker. The voltage across the circuit-breaker contacts will be the sum of this

line-side voltage and the source-side power frequency voltage. This will result in a very steep rate-of-rise of the initial part of the transient recovery voltage wave thus presenting a very onerous clearance condition for the circuit-breaker. Again specifications require transmission circuit-breakers to be tested for this condition.

## 34.10 Switchgear testing

During short-circuit fault clearance an interrupter of a circuit-breaker will be required to dissipate a very large amount of energy. For example, higher rated circuit-breakers may be required to safely dissipate, over a very short period of time, something in excess of 1000 MW. The circuit-breaker must be capable of satisfactorily performing such a rated short-circuit duty at least three times, without danger to operators, or without danger to the system. Whilst present day theory can significantly assist in the development of interrupter design, it can still not satisfactorily ensure the safe operation of the complete circuit-breaker. It is thus necessary for the circuit-breaker performance to be proven under very specific short-circuit test conditions in order to verify its safe performance.

Whilst tests can be, and sometimes are, performed on actual systems, the system parameters cannot readily be modified to achieve the required test conditions. In addition, such testing may induce significant risk to system operation and is rarely undertaken nowadays.

Short-circuit testing is thus performed in specially designed short-circuit testing stations. These may entail the use of 1–4 large, specially designed, generators for producing the necessary output. The supply to the generator is usually disconnected immediately prior to the application of a short-circuit and a large flywheel may be attached to the generator shaft to maintain its inertia. The output of the generators may be paralleled to produce the necessary short-circuit ratings and they may also be connected via transformers so that a wide variation of test settings can be achieved. Reactors, resistors or capacitors may be added to both the source and load sides of the circuit-breaker in order to ensure the achievement of the specified test parameters. Such short-circuit testing is generally referred to as 'direct testing' and may be either single phase or three phase. For distribution circuit-breakers, for example, three-phase direct testing can nearly always be achieved. However, for large circuit-breakers the output of the short-circuit test station may be insufficient to allow direct testing of the complete three-phase circuit-breaker. Under these conditions a section or 'unit' of a circuit-breaker may be tested, i.e. one interrupter of a two-interrupter circuit-breaker. Test parameters on this 'unit' must be such as to reproduce the worst conditions that would apply to the interrupter when the circuit-breaker was operating to clear the specified three-phase fault condition. This method of testing is referred to as 'unit testing'.

Even with unit testing, however, the output of the short-circuit testing station may still be insufficient to meet the specified short-circuit levels. It is then necessary to revert to a more recently developed method of short-circuit testing known as 'synthetic testing'. With synthetic testing the current is still obtained from a short-circuit generator, but the recovery voltage is obtained from a separate supply circuit and is injected across the opening circuit-breaker contacts at an appropriate current zero. The recovery voltage circuit usually comprises a large precharged capacitor bank assembly which is switched, at the precise moment in time, via

a combined inductance, capacitance and resistance network to produce the correct transient recovery peak voltage and frequency. Synthetic unit testing is now the standard method used for testing large transmission circuit-breakers.

International specifications have been produced which detail precise test requirements and methods of tests covering all the normally required short-circuit test conditions for circuit-breakers.

In addition to short-circuit testing there are other 'type tests' to which a circuit-breaker must be subjected in order to demonstrate its performance. These comprise a mechanical endurance test, generally of 1000 operations without maintenance, a temperature-rise test at rated current, a HV test and, for outdoor circuit-breakers, an environmental test.

The HV tests verify the dielectric performance of the circuit-breakers and generally comprise a power frequency overvoltage test, a lightning impulse voltage test, to simulate the effects of a lightning strike, and for higher voltage transmission circuit-breakers a switching surge on the system.

A further test is usually performed at a specified power frequency overvoltage to check for any partial dielectric-breakdown activity that might be occurring in faulted insulation. This is referred to as a 'partial discharge test'.

Environmental testing on outdoor circuit-breakers entails subjecting the circuit-breaker to cyclic variations in ambient temperature, from its maximum working temperature of, say, 35°C to its minimum working temperature of, say, -25°C. It may also entail the application and verification of mechanical operations at various points during the temperature cycling and of checks for leakage of insulant.

The above tests are usually performed as type tests on one equipment of a specific design and are intended to demonstrate the suitability of that design of equipment.

Further works tests must be performed on production equipment and these are referred to as 'routine tests'. These usually comprise a power frequency overvoltage test, measurement of resistance of primary circuits and a mechanical operations test. Similar tests are generally repeated once equipment has been erected on the site. Site tests would, in addition, include primary circuit injection tests to verify circuit-breaker operation via protective relays.

Whilst clear and precise erection instructions are necessary for all switchgear equipments this is particularly important for gas-insulated switchgear where even very small particles may, for example, induce dielectric breakdown. Site quality-control checks are of paramount importance and many users of gas-insulated switchgear now require the measurement of partial discharge activity as a site commissioning test and some also require on-line monitoring for partial discharge activity as an essential operational criterion.

### 34.11 Diagnostic monitoring

The concept of using maintenance-free switchgear whereby maintenance would not be required during the lifetime of the equipment is an ideal user objective. Indeed, with modern SF<sub>6</sub> switchgear, this ideal objective is now becoming more of a reality. On the other hand, current legislation may require equipments to be regularly maintained to be in a serviceable condition and, therefore, there is a need to be able to verify that equipment remains in a serviceable state without the need for physical dismantling. The application of techniques to monitor externally the internal state of equipment can reveal many incipient problems and such diagnostic monitoring techniques are currently being devel-

oped and applied. Continuous on-line monitoring and self-diagnosis using fibre-optic technology is now becoming a practical reality. Parameters that can be readily monitored are, for example, contact speed, contact engagement, moving system damping, circuit-breaker operating times, summated interrupted fault current, operating mechanism pressures/times, conductor temperatures, dielectric gas pressures, liquid levels and, for gas-insulated switchgear, partial discharge activity. In addition, system-fault currents and associated voltages can now readily be recorded and these data, in conjunction with the above on-line monitoring, can assist in ascertaining the internal condition of a circuit-breaker.

### 34.12 Electromagnetic compatibility

'Electromagnetic compatibility' refers to the susceptibility of electrical equipment to any electromagnetic interference phenomena to which it might be subjected as well as to electro-magnetic interference signals which the equipment itself may emit. Levels are currently being specified for maximum emissions from electrical equipment and also for levels of interference below which the equipment would not be affected. Switchgear equipment will be required to comply with the criteria.

Such interference phenomena may be caused, for example, by lightning, switching surges, high-frequency-discharge activity, voltage dips, signalling on lines, harmonics, and superimposed d.c. on an a.c. system. Some of the phenomena may be generated by the switchgear itself and may cause malfunction of associated electrical equipment, e.g. alarm circuits and relays. Typical phenomena in a metal-enclosed gas-insulated-switchgear substation may, for example, be disconnector induced transient over-voltages, these may be coupled either by conduction or by radiation into secondary connections and other associated equipments causing flashover or dielectric breakdown. It is then necessary for steps to be taken to limit the coupling of these signals. Typical steps might, for example, be: the provision of an earth screen between HV and LV windings of voltage transformers; short direct earth connections to a high-frequency earth mat; the use of screened secondary cables with the screening earthed at both ends of the cable; cables should be run together, preferably within a trench and parallel with main earth connection; and flow and return conductors should be within the same screened cable.

With ever-increasing use of modern electronic equipments this subject is gaining significant importance to the extent that in some countries not only are limiting values specified but legislation is being introduced to make compliance mandatory.

### 34.13 Future developments

In the last ten years or so since deregulation the Electrical Power Industry has been through major re-organisational changes. In the main, the way in which electricity is produced, transported and delivered to customers is much the same as it has always been. There is one significant change however, and that is the advent of combined cycle power plants which can be located nearer to load centres, within very short time scales, at lower costs and with reduced emissions compared with conventional coal fired plants. All of this minimises the requirements for transmission. If this trend continues, as it is likely to, then the way in which

transmission systems operate will significantly change. In addition, there is also a trend for more and more generation to be embedded in the distribution systems so the way in which they operate will also significantly change. These factors mean that the requirements for switchgear will also have to adapt to the changing power systems. For distribution systems the switchgear will need to be re-locatable such that as new systems evolve it can be positioned to the most appropriate system node. It will also have to cater for power flows in both directions which means that protection systems will need to be modified. The switchgear should have improved reliability, require the minimum of maintenance and be capable of complete operation from a remote source. It must also be cost effective and in fact, may be leased to the utility and operated by an independent owner.

Similarly transmission switchgear will follow the system trends and many of the functions described for distribution switchgear will also be required.

Fortunately, many new technology developments are becoming available. There is a major breakthrough in polymers, for example, these can now be designed on a computer to formulate the appropriate molecular structure to meet the performance requirements. Similarly, there are major developments in magnetic materials, both conducting and insulating ceramics, superconductivity and solid state thyristors such that conventional power transformers may become a thing of the past. Developments in hard materials utilising diamond technology and carbon C60 will undoubtedly assist in the practical development of current limiting/solid state/superconducting circuit breakers. Already prototype equipment's are being developed and the concept of switchgear equipment's embodying all these new technologies, together with fundamental changes in the ways electricity is produced and provided to the customer presents many new and exciting challenges for younger engineers.

## 35.1 Overcurrent and earth leakage protection

The main effects of fault current in a power system are:

- (1) disturbance of the connected load;
- (2) overheating at the fault point and in associated plant;
- (3) electromagnetic forces of abnormal magnitude, with consequent mechanical damage; and
- (4) loss of synchronous stability.

The function of the protective equipment is to isolate the faulty plant from the running system by initiating tripping signals for appropriate circuit-breakers. It should therefore discriminate between faulty plant and sound plant carrying through-fault current. The whole process must be effected with the minimum of delay and disturbance.

Exceptionally, some faults may be allowed to persist: an example is an earth fault on a system earthed through an arc suppression (Petersen) coil, or one having an isolated neutral, where the fault may be located and alternative feeds provided before the fault is isolated.

Faults are due to insulation breakdown by deterioration, overvoltage, mechanical damage or short-circuit effects; they may be simple or complicated, and involve conductor breakage or short-circuited turns on transformers or generators.

The incidence of faults on cables and lines depends on the installation and the climatic conditions. For a typical system in a temperate zone the distribution of faults as percentages of the total is approximately: overhead lines, 60; cables, 15; transformers, 12; switchgear, 13. The causes of overhead-line faults, and the number of faults per 100 km of line per year, are, typically: lightning, 1.0; gales, 0.15; fog and frost, 0.1; snow and ice, 0.06; salt spray, 0.06. The total is 1.37 faults per 100 km per year: in tropical countries lightning faults may be markedly more numerous. In general, the higher the voltage the lower the number of lightning faults.

### 35.1.1 Fault conditions

Below are given circuit and phasor diagrams relevant to the behaviour of protective equipment under the simpler fault conditions.

#### 35.1.1.1 Three-phase fault

A three-phase fault usually develops first as a phase-earth fault, and it may be unbalanced. Even when a circuit-breaker closes on to a three-phase fault, one phase may momentarily be faulted before the other two, a matter of importance in high speed protection. Figure 35.1 shows the

Figure 35.1 Three-phase fault

Figure 35.2 Phase-to-phase fault

relevant phasor diagram. At the fault the voltages to neutral are zero; and if AN, BN, CN are the phase-to-neutral pre-fault voltages, the voltages at some distance from the fault (e.g. at a relay controlling a circuit-breaker) are A'N, B'N, C'N. With a symmetrical short-circuit the conditions are independent of the system earthing arrangements.

#### 35.1.1.2 Phase-to-phase fault

Two phases are faulted clear of earth, an unusual kind of fault even less likely on cables than on overhead lines. Figure 35.2 shows AN, BN and CN as the normal voltages at the site of the fault. On occurrence of the fault, the voltages there are XN, XN and CN, and the voltages at some specified distance are A'N, B'N and C'N, with the locus of A'N and B'N on the line AB. The voltage to earth of the sound phase is not affected. The conditions are independent of the system earthing, but the fault current will be reflected into the further sides of associated transformers in accordance with their connections.

#### 35.1.1.3 Single phase-to-earth fault

This type of fault is considered for a system with the generator or transformer having its neutral earthed (a) solidly, (b) through a reactor, (c) through a resistor.

**Neutral solidly earthed** The voltages to earth at the point of fault with phase A earthed are zero, B'E and C'E, as in Figure 35.3, and at some distance away the voltages are A'E', B'E' and C'E'. The locus of A'E' of the line AN, and the voltages to earth of the sound phases are slightly changed to B'E and C'E by reason of the currents in these phases between the two infeeds. With the system earthed at one point only (apart from the fault), the total earth fault current divides between the two infeeds. If there are two (or more) system earth points and the infeeds are  $I_A$  and  $I_A'$ ,

Figure 35.3 Single phase-to-phase earth fault (solid earthing)

there may be currents in the sound phases of direction decided by the preponderance of zero-over positive- and negative-sequence impedance of one infeed compared with the other. In this case the residual or earth current on each side will be  $I_A + I_B + I_C = I_E$ ; the residual voltage will be  $0 + B'E + C'E$  at the fault, and  $A'E' + B'E' + C'E'$  some distance away.

**Earthed through reactor** With a low-valued phasor (small compared with an arc suppression coil), the earth point potential on the occurrence of a fault will be E (Figure 35.4(a)), and the drop in the reactor will be  $E'N$ . The fault position voltages are zero; voltages to earth of the sound phases are increased. If the reactor is an arc suppression coil, point E is raised to A, the sound phase voltages to earth become  $\sqrt{3}$  times normal, and the residual voltage at the fault will be 3 times the normal phase-to-neutral value.

**Earthed through resistor** The conditions (Figure 35.4(b)) are essentially similar to those for reactor earthing except that there is unbalance in the voltages to earth of the sound phases. The volt drop across the resistor is  $E''N$ .

#### 35.1.1.4 Double phase-to-earth fault

With *solid earthing* at one point only, the voltages to earth at a double phase-to-earth fault will, as shown in Figure 35.5, be zero, zero and  $C'E$ , and at some distance away will be  $A'E'$ ,  $B'E'$  and  $C'E'$ . The voltage to earth of the sound phase may be increased at the point of fault. The angle  $\alpha$  between the phase currents  $I_A$  and  $I_B$  (or  $I_A$  and  $I_B'$ ) may be less than  $60^\circ$ , depending on the ratio of balanced to zero-sequence impedance; the angle varies considerably, according to the earthing arrangements, and in the limit with the neutral

Figure 35.4 Single phase-to-earth fault: (a) through reactor; (b) through resistor

Figure 35.5 Double phase-to-earth fault

Figure 35.6 Variation of residual quantities at fault point

point isolated it becomes  $180^\circ$ . The residual current (i.e. the earth current) is the vector sum of the currents in the faulted phases and that (if any) in the sound phase. The residual voltage at the point of fault is the normal phase-to-neutral voltage, and it decreases with distance from the fault position.

With the system neutral earthed through a low-valued reactor, the drop across the latter is  $NE'$  and the voltage to earth of the sound phase is  $CE$ , increasing to a possible maximum of 1.5 times normal value if the reactor is an arc suppression coil.

With system earthing through a *resistor*, the point E in Figure 35.5 is no longer on the line  $CX$ .

The system  $Z_0/Z_1$  ratio is defined as the ratio of zero sequence and positive sequence impedances viewed from the fault. It is a variable ratio dependent on the method of earthing, fault position and system operating arrangement. When assessing the distribution of residual quantities through a system, it is convenient to use the fault point as the reference, as it is the point of injection of unbalanced quantities into the system. The residual voltage is measured in relation to the normal phase-neutral system voltage, and the residual current is compared with the three-phase fault current at the fault point. It can be shown that the character of these quantities can be expressed in terms of the ratio  $Z_0/Z_1$  of the system; see Figure 35.6. The residual current in any part of the system can be obtained by multiplying the current from the curve by the appropriate zero sequence distribution factor. Similarly, the residual voltage is calculated by subtracting from the voltage curve three times the zero sequence drop between the measuring point in the system and the fault.

#### 35.1.2 Protective equipment

The satisfactory operation of protective equipment (which extends from simple domestic subcircuit fuses to sophisticated electronic system devices) depends largely on *co-ordination*. The influencing factors include the network layout

and characteristics, fault megavolt-ampere levels, earthing, the availability of pilot cables and the physical extent of the system. Generally, the higher the voltage and fault levels the more necessary is quick-acting discriminative protection covering lines and plant.

Protective equipment may be broadly classified into: (a) *restricted zone*, giving full discrimination; (b) *semi-restricted zone*; and (c) *unrestricted zone*, with no discrimination. Type (a) can be considered as applying to a network of such magnitude that the disconnection of each item of plant is necessary if an internal fault develops. Types (b) and (c) apply to less important installations and also as 'back-up' in restricted-zone schemes.

### 35.1.2.1 Modes of operation

An alternative classification based on the operating mode is as follows.

*Overcurrent equipment* operates if the current exceeds a pre-set value. Restrictions regarding the direction of the overcurrent are often included to improve discrimination.

*Balanced (differential) equipment* operates if an out-of-balance occurs between currents or voltages which under normal conditions are balanced.

*Distance (impedance) equipment* operates if the impedance (proportional to distance), as viewed at a circuit-breaker supplying a feeder, falls below a specified value.

*Miscellaneous equipment* is designed for special purposes.

### 35.1.2.2 Equipment elements

The chief items of plant making up a complete protective installation are as follows.

*Current and voltage transformers* These provide convenient levels of current or voltage proportional to the system values. Rated secondary values are normally 1 or 5 A (current transformer (c.t.)), and 110 V (voltage transformer (v.t.)).

*Relays* These, operating from c.t. and v.t. detect the presence of faults and energise the trip circuits of the appropriate circuit-breakers. Electronic (solid state) devices are now generally available as alternatives to the electromagnetic types, and give improved performance.

*Pilot circuits* These carry signals between points in the system for comparison, for feeder protection and other purposes. The circuits may be provided in a variety of ways:

- (1) conductors specially installed for the purpose;
- (2) rented telecommunication lines; the current and voltage limitations are 60 mA and 130 V peak, and the pilots must be insulated from all power system equipment for 15 kV;
- (3) power transmission lines, using carrier signals at frequencies between 70 and 700 kHz;
- (4) radio links using microwave transmission between line-of-sight terminals; and
- (5) optical links, usually embedded in the earth wire.

The choice requires very careful consideration, particularly for long distances. Even apparently simple conductors, for which the resistance and capacitance between ends can be measured, often act as a transmission line operating in conjunction with relay equipment. The performance of the pilot circuit may be complex, and in operation is made even more so by inductive interference effects.

It is possible to obtain high-speed feeder protective schemes using voice frequencies of 600–3000 Hz, which are suitable for pilot-wire channels, or pilot-line carrier or radio channels.

The overall fault clearance time is made up of the signalling time, and the operating times of the protection relay, trip relay and circuit-breaker opening. This total time must be less than the maximum for which the fault can remain on the system for minimum plant damage, loss of stability, etc. In recent years practical minimum times have been achieved in reducing protection times from 60 to 20 ms, trip relay times from 10 to 3 ms, circuit-breaker times from 60 to 40 ms, leaving protection signalling times to be reduced from 70–180 ms down to 15–40 ms in the UK, and to 5 ms in certain parts of the world where system stability is critical.

Protection current transformers may have to maintain accuracy up to 30 per unit overcurrent, although often the error is less important than that c.t. characteristics should match.

*Current transformers* The errors are due to the exciting current, and they vary with the phase angle of the secondary burden. An increased burden demands a corresponding increase in core flux, and as the exciting current is a non-linear function of the flux, it is subject to a more than proportional rise accompanied by a greater harmonic content, so that the composite error is increased.

Protective equipment is intended to respond to fault conditions, and is for this reason required to function at current values above the normal current rating. Current transformers for this application must retain a reasonable accuracy up to the largest relevant current, known as the 'accuracy limit current', expressed in primary or equivalent secondary terms. The ratio between the accuracy limit current and the normal rated current is known as the 'accuracy limit factor'. Standard values are 5, 10, 15, 20 and 30. Protective c.t. ratings are expressed in terms of rated burden, class and accuracy limit factor (e.g. 10 V-A class 10P 10). Classes 5P and 10P are useful only for overcurrent protection; for earth fault protection, in particular, it is better to refer directly to the maximum useful e.m.f. which can be obtained from the c.t. In this context the 'knee point' of the excitation curve is defined as that point at which a further increase of 10% secondary e.m.f. would require an increment of exciting current of 50%. Such current transformers are designated class X.

Current transformers may have primaries wound or of bar ('single-turn') form for mounting on bushings. For high-voltage systems the c.t.s may be separately mounted with oil or SF<sub>6</sub> insulation.

*Voltage transformers* The main requirement in protection is that the secondary voltage should be a true reflection of the primary voltage under all conditions of fault. It is usual with electromagnetic v.t.s to apply additional delta-connected windings (*Figure 35.7*) to give a measure of the residual voltage at the point of connection. The three voltages of a balanced system summate to zero, but this is not so when the system is subject to a single-phase earth fault. The residual voltage in this case is of great value for protective gear practice as a means of detecting or discriminating between earth fault conditions. The residual voltage of a system is measured by connecting the primary windings of a three-phase v.t. between the three phases and earth, and connecting the secondary windings in series or 'open delta'. The residual voltage is three times the zero sequence voltage. To measure this component it is necessary for a zero sequence flux to be set up in the v.t., and for this to be

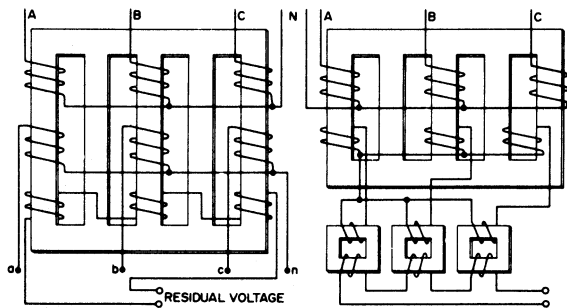

Figure 35.7 Voltage transformers with residual-voltage windings

possible there must be a return path for the resultant summated flux: the v.t. core must have unwound limbs linking the yokes (Figure 35.7). If three single-phase units are used (as is common for e.h.v. systems), each phase unit has a core with a closed magnetic circuit, so that the above consideration does not arise.

An alternative, avoiding the cost of a HV voltage transformer, is to use the secondary voltages from a.v.t. on the LV side of a power transformer, the voltage drops in which are compensated by the addition or subtraction of voltages developed by c.t.s in the delta of the power transformer. The v.t.s and c.t.s must be provided with tapplings if the power transformer is equipped with tap-changing gear, and arranged for automatic selection with the main tapplings.

For high-voltage systems the *capacitor voltage divider* gives a cheaper (but less accurate) device than its electromagnetic counterpart. A typical divider for 400 kV has a total capacitance of 1500–2000 pF, with about 34 000 pF between the tapping point and earth, to give about 13.5 kV across the primary of the intermediate transformer, the secondary of which gives 63.5 V (phase to neutral).

### 35.1.3 Relays

Relays may be classified according to the number of current inputs and their operating function. Types and constructional forms are available as follows:

- |                        |                        |
|------------------------|------------------------|
| (1) attracted armature | (7) magnetic amplifier |
| (2) moving coil        | (8) thermionic         |
| (3) induction          | (9) semiconductor      |
| (4) thermal            | (10) photoelectric     |
| (5) motor-operated     | (11) digital           |
| (6) mechanical         |                        |

Of these main group types, (7)–(11) are commonly known as 'static' relays.

#### 35.1.3.1 Single-input relays

In the simple *repeater* type a small signal can be multiplied by  $10^3$  or more to operate one or more secondary devices, e.g. the trip coil of a circuit-breaker. Operation is rapid (within 20 ms), although a time delay can be incorporated. The *magnitude indicator* type operates instantaneously (or after a fixed time delay) when the magnitude of the signal exceeds or falls below a specified value. In the *time-dependent* relay the operating time depends on the magnitude of the signal; the most usual characteristic gives an operating time inversely proportional to the magnitude.

#### 35.1.3.2 Double-input relays

In the *amplitude comparator* one input,  $I_1$ , tends to operate the relay, while the other,  $I_2$ , tends to restrain it. Operation takes place when  $I_1/I_2$  is less than the specified value. When drawn on a complex plane R–X, the characteristic is a circle (Figure 35.8(a)). Operation is independent of the phase angle between the currents and occurs within the shaded area.

In the *phase comparator* operation takes place when the phase angle between the currents lies within specified limits (Figure 35.8(b)).

#### 35.1.3.3 Multiple-input relays

By using more than two inputs, various forms of operating zone can be obtained, as required for distance feeder protection.

#### 35.1.3.4 Types of relay

**Attracted armature** This single-input relay comprises a small coil carrying the signal current: it attracts a magnetic armature with one or more pairs of contacts which control the secondary circuits, and is suitable for both d.c. and a.c. operation. The setting may be based on minimum pick-up or maximum drop-out current, with ranges usually selected by tapplings to secure a constant value of operating m.m.f. Tapping changes the impedance and, therefore, the burden on associated c.t.s. The speed of operation is a function of the m.m.f., the length of armature travel and the inertia of the moving parts. The latter may be partly offset by counterweighting. When the relay coil is intermittently energised, it may be uprated to increase the operating speed: a set of contacts may be provided which, when energised by the operation of the initiating relay contact, gives a holding effect. The current in the coils of tripping relays is then usually broken by an auxiliary switch on the circuit-breaker. Magnetic sticking of the armature in attracted-armature relays is prevented by stops of non-magnetic inserts on the working face.

**Rotary** This is a rotary version of the foregoing. The armature is usually mounted on a vertical spindle, the rotating parts are light and well-balanced, and the relay is sensitive at a relatively low burden. Adjustment and accurate setting is by torsion head and helical spring control. In some types the armature carries a light silver contact, the coil operated contacts being energised when the silver contacts close. The relay can be made to operate with a few milliamperes, and both linear and rotary forms of the attracted-armature relay can be arranged for double-input working.

**Induction** The time-dependent induction protective relay is probably the most widely used of all. It employs essentially

Figure 35.8 Comparator relay characteristics: (a) amplitude; (b) phase

Figure 35.9 (a) Induction and (b) beam relays

the same construction as an integrating a.c. energy meter. For a single-input relay (*Figure 35.9(a)*) torque is produced by a phase difference between the flux of the main coil on the central limb of the upper magnet and that in the lower (secondary) magnet, an effect secured by impedance compensation in the secondary. The torque is proportional to the square of the exciting current and is unidirectional. The speed of the disc may be governed by a control spring and a permanent-magnet brake. Slots are cut in the disc to modify the operating time–current characteristic, and the shape of this curve at higher currents can be made almost flat if the magnetic circuit is arranged to saturate at two or three times the setting.

The driving disc usually has a vertical spindle, but one make of relay has a horizontal drum driven about its axis, the time–current characteristic being similar to that of the disc type.

The *single-input* relay is widely used for overcurrent protection. By feeding a separate signal to the secondary coil the relay becomes a *double-input* device with a torque proportional to  $I_1 I_2 \sin \alpha$ , where  $\alpha$  is the phase angle between the currents. In this form it can be given directional properties, and is also applicable to certain forms of distance protection.

**Directional** Directional relays operate in a manner similar to that of an electrodynamic wattmeter or, more commonly, an induction energy meter. In the latter the torque on the disc is proportional to  $VI \cos \beta$ , where  $\beta$  is the phase angle between the voltage and current inputs.

The maximum-torque angle is the angle by which the current applied to the relay must be displaced from the applied voltage to produce maximum torque. Although the relay may be inherently wattmetric, its characteristic can be varied by the addition of phase shifting components to give maximum torque at the required phase angle. Several different connections have been used, and examination of the suitability of each involves determining the limiting conditions of the voltage and current applied to each phase element of the relay for all fault conditions, taking into account the possible range of source and line impedances.

**Beam** A balanced beam with two electromagnets can be used as a simple double-input device and has been widely applied to distance protection (*Figure 35.9(b)*). It can also serve as a directional relay.

**Definite time** Devices employing a clockwork escapement released by the operation of an attracted-armature relay, or an escapement driven by a disc or drum, are available.

More usually, however, induction relays are used because of the long periods of inactivity in service.

### 35.1.4 Solid-state equipment

Thermionic valve equipment has been in use for a half-century in carrier current protective signalling. The advent of solid-state devices (transistors and thyristors) has made possible alternatives to electromagnetic relays.

The exploitation of integrated circuits and microprocessors has made a major impact on protection in recent years.

Solid-state equipment differs markedly from conventional electromagnetic equipment in several ways, particularly in the reduction in overall size.

The flexibility and characteristics enable schemes to be devised that are difficult to achieve conventionally, such as the distance relay with a quadrilateral characteristic (*Figure 35.15(f)*). For most applications the transistor has the advantage of high speed, high sensitivity and simple amplifying and switching properties. Where heavier currents are necessary, e.g. in a tripping circuit, the thyristor is required. Solid-state devices can, if desired, readily be associated with electromagnetic relays if the time delays (10–20 ms) associated with the latter can be accepted; however, the lighter and faster (1–2 ms) reed relay is applicable in many cases.

Components are subject to damage by moisture, but encapsulation can obviate the trouble.

Static components have some resilience and very low mass; they can withstand mechanical shock and vibration, significantly reducing risk of damage during transport and erection.

All components, are sensitive to transient voltages, even of only a few microseconds duration. Such transients arise from switching, and can be injected into the protective equipment directly through current and voltage transformers, or by electric or magnetic field induction. Equipment must be impulse tested, e.g. by a 5 kV 1/50  $\mu$ s impulse wave.

The burden imposed by static relay equipment on c.t.s is much less than that of comparable electromagnetic equipment. As the cost of instrument transformers is 20–40% of that of the complete protective scheme, smaller and improved types are being developed which may offset the higher cost of the static relay itself.

Even with conventional equipment, the use of 1 A secondary currents (instead of 5 A) is sometimes desirable, especially where long interconnecting leads are necessary. With static equipment even smaller currents can be used. The ultimate in this respect is a very small line mounted high-voltage current transformer feeding a laser system; the electromagnetic power (about 2 W) is converted to light power and transmitted to earth potential equipment by light-guides, the resulting power (a few microwatts) then being amplified and fed to static relay equipment.

The range of solid-state relays now available covers many applications hitherto dealt with by electromechanical devices. The static equivalent generally offers greater flexibility in the design to meet given protection functions. Typical characteristics are shown in *Figure 35.10* for static protection, which needs no auxiliary supply and provides a high reliability and accuracy.

### 35.1.5 Overcurrent protection

The most common overcurrent relay is the induction type, typical characteristics of which are given in *Figure 35.11*. The standard characteristic follows no simple law, but the

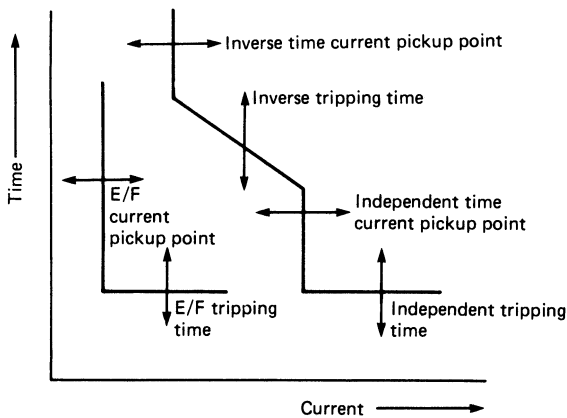

Figure 35.10 Static protection unit characteristics

Figure 35.11 Overcurrent relay characteristics

very-inverse-time characteristic is  $(I-1)t = \frac{k}{I}$  and the extremely-inverse-time law is  $(I^2-1)t = \frac{k}{I}$ .

The relay has two adjustable settings. The *plug setting* (current setting) comprises a tapped winding for the current coil, theappings being brought out to a plug bridge on which, by insertion of the plug, current settings of 50, 75, 100, 125, 150, 175 and 200% of the full-load output of the current transformer (5 A) can be obtained; removal of the plug automatically short circuits the current transformer terminals. A *time setting* is achieved by varying the amount of travel of the contacts, giving time multipliers between 1.0 and 0.1. The times on Figure 35.11 are for a time setting of 1.0 and the currents are multiples of the plug setting current.

### 35.1.5.1 Discrimination

**Graded time lags** On simple radial distribution systems, discrimination by graded time lags is effective, the lags of the relays being set successively longer for relays nearer to the supply source. The minimum time difference at all parts of the relay characteristic may be estimated as: error of

relay 1 (near to fault), 0.1 s; circuit-breaker operating time, 0.1 s; over-shoot of relay 2 (nearer to supply), 0.04 s; error of relay 2, 0.1 s; total, 0.34 s. The greater low-current times of the extremely inverse time characteristic may be suitable for grading with fuses, and also are less likely to cause tripping on switching-in after a supply interruption, when there may be heavy overloads resulting from plant left connected.

**Graded time lags and directional relays** If the overcurrent relays embody a directional feature (DOC), discrimination on more complicated networks can be obtained. Figure 35.12(a) shows a *ring main*: the arrows indicate the current direction for which the relays will operate, and the figures show typical time settings. The directional feature ensures that time grading can be obtained in each direction around the ring.

For the two *parallel transformers* in Figure 35.12(b) directional overcurrent relays are employed at the transformer ends on the LV side to detect phase faults on the line. Thus, a fault at F would be cleared by relays at C, while those at D would restrain. For a fault on the LV system both relays at C and D would restrain.

A more complicated network is shown in Figure 35.13. Suppose that the interconnector and feeder 6 are open and that there is a fault F on feeder 5. Fault current will then flow from the supply infeed direction into feeder 5 through 2. Now if feeder 2 is provided at each end with current

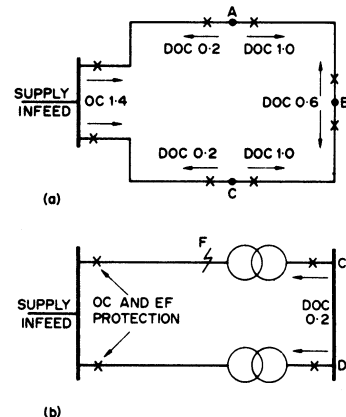

Figure 35.12 Directional overcurrent protection

Figure 35.13 Network time-grading

any change of state that might affect its electrical performance. This property of 'non-deterioration' requires that the fusible element be both thermally and chemically compatible with the ambient media. It must also respond thermally to overcurrents by melting and subsequently interrupting its circuits.

The melting of an element is followed by a period of arcing during which the electrical energy input can be very high, its magnitude and the duration of arcing being dependent on the protected circuit. Successful fault interruption implies that the arcing is wholly contained within the fuse-link and the level at which this can be achieved is termed the breaking or rupturing capacity of the fuse-link.

The operating time of a fuse-link varies inversely with the level of an overcurrent and discrimination is obtained in networks by choosing fuses with the necessary time/current characteristics and current ratings.

The time/current characteristic is determined by the design of the fuse itself, in particular but not exclusively, the fuse material and the physical geometry of the fuse link(s). In practice, the fuse/current characteristic is chosen to ensure adequate discrimination with other fuses and/or overcurrent relaying devices around the network. *Figure 35.16* for example shows how, in general terms, a fuselink 'f' situated between protective devices 'u' on the source side and 'd' on the load side could be arranged to provide discriminative tripping on a radial feeder.

#### 35.1.6.2 Fuse links with short operating times

All modern high-breaking-capacity fuse-links contain elements, usually with restrictions, of small cross-sectional areas connected between relatively massive end connections which act as heat sinks. To obtain rapid operation this principle is employed to a high degree. The extent to which the mass of the heat sink can be increased while reducing the length of the relatively thin element is determined by the requirement that the fuse should withstand the system voltage after the current has been interrupted i.e. it must not restrike. Considerable ingenuity has reconciled these two mutually incompatible requirements.

#### 35.1.6.3 The M effect

The M effect, deriving from an exposition by Metcalf, refers to exploiting the thermal reactions of dissimilar metals in

**Figure 35.16** Use of fuse time/current characteristic to provide discrimination on radial feeder

**Figure 35.17** (a) Fuse element (English Electric); (b) Dual-element fuse

the control of time/current characteristics. The thermally most stable fuse element is a simple homogeneous metal. Such an element provides the highest degree of non-deterioration and reliability with adequate breaking capacity at higher overcurrents, but it may be insensitive to lower overcurrents. A lower melting temperature metal with high resistivity and, therefore, greater thermal mass, can be made to respond more sensitively to lower overcurrents but may be unreliable at higher currents.

The M effect is a means by which these extremes can be combined to produce a desired characteristic, but it needs to be used with care in design to avoid compromising non-deterioration properties. An element incorporating the M effect is shown in *Figure 35.17(a)*.

#### 35.1.6.4 Composite or dual-element fuses

Satisfactory operation throughout the overcurrent and short-circuit ranges is sometimes obtained in the same package by combining what are, in effect, two fuses connected in series in the same cartridge (*Figure 35.17(b)*). Typical of these is the so-called dual-element design common in the USA. The short-circuit zone is similar to the homogeneous element used in single-purpose HRC fuses. The overload zone may take the form of a massive slug of low-melting-point alloy, or some electromechanical device, e.g. two copper plates soldered together and stressed by a spring, so that when the solder melts the plate springs apart to interrupt the current.

### 35.1.7 Earth leakage protection

A current-to-earth on an HV system invariably indicates the presence of a fault: if large enough, it will operate the o.c.

**Figure 35.21** Balanced protection principles: (a) discriminating delta; (b) summation transformers

12 and 12a which, being now additive, circulate a current in the operating coils 13 and 13a and in the two pilot wires. Both upper and lower magnets are energised, and if the fault current exceeds the scale setting, the relays operate to trip their associated circuit-breakers. A fault between phases Y and B energises section (2) of windings 11 and 11a, while a fault between phases R and B energises both sections (1) and (2), the fault setting being one-half of that in the former cases.

In the event of an earth fault on line R, the resultant secondary current from the phase R c.t. flows through sections (1), (2) and (3) of windings 11 and 11a. A Y phase earth fault energises sections (2) and (3); and a B phase fault, only section (3).

**Pilot wires** It is often desired, especially for feeder protection, to reduce the number of pilot wires to two. One method is the *discriminating delta* connection (Figure 35.21(a)) in which the c.t.s have different ratios (e.g. N,  $3N/4$  and  $N/2$ ). A more common method employs a *summation transformer* (b). If the primary turns of the summation transformer are in the ratios 1 between A and B, 1 between B and C, and  $n$  between C and N, then the relative sensitivities for various types of fault are in the following relative proportions as secondary outputs:

Fault	A-N	B-N	C-N	A-B	B-C	C-A	A-B-C
Proportion	$2+n$	$1+n$	$n$	1	1	2	$\sqrt{3}$

**Stability ratio** High *sensitivity* is desirable to ensure operation of the relays on minor or incipient faults, while high *stability* is required to prevent operation on heavy through-faults. These requirements are in conflict and it is usual to restrain ('bias') the relays by an additional winding carrying a current proportional to the fault current, thus desensitising the response to heavy fault conditions. The ratio (maximum through-fault stable current)/(minimum fault operating current) can thus be made as great as 100.

**Distance (impedance) protection** This type of protection, used chiefly for overhead lines, involves the measurement of the impedance of the circuit as 'seen' from the relay location; if this impedance falls below a specified value, a fault is present. The impedance observed is approximately proportional to the distance of the fault from the relay and

discrimination is obtained by introducing time delays for the more distant faults. Two schemes are available, *impedance time* and *stepped time*, the latter being more widely used on lines above 33 kV, on account of the shorter operating times obtainable.

### 35.1.8.3 Impedance time scheme

Relays having a directional characteristic give an operating time proportional to the impedance presented, i.e. proportional to the distance to the fault from the relay. By locating such relays at each circuit-breaker on a succession of feeders the characteristics of Figure 35.22(a) are obtained. It can be seen that should a relay, e.g. that at B, fail to operate, it will be backed up by that at A after a time interval. With feeders of different lengths the slopes of the characteristics must be adjusted to give correct discrimination; thus, the relay at A must have characteristic X (dotted) rather than Y, as the latter would give incorrect back-up discrimination for a fault near the end of section CD. The relays cater for fault currents flowing from left to right; a similar set would be required to cater for fault currents from right to left.

### 35.1.8.4 Stepped time scheme

Three separate relays are required for each direction of fault current at every circuit-breaker location. The relays are of the induction or (more rarely) of the beam type. In Figure 35.22(b) relay 1 of the group at circuit-breaker A is set to give 'instantaneous' operation for faults occurring within the nearest 80% of feeder AB, i.e. over distance  $X_1$ . Relay 2 operates, after a time lag, for faults occurring up to a point just beyond circuit-breaker B; it thus acts as a back-up for relay A over the distance  $X_1$ . Relay 3 operates with a still longer time lag for faults beyond the cut-off point of relay 2; it thus acts as a further back-up for relay A, and also for relay 2 over the last 20% of feeder AB.

### 35.1.8.5 Fault impedance

The impedance 'seen' by a relay depends upon the type of fault. Two sets of relays, differently connected to the system, are required (although a single set with a switching device is also practicable).

**Earth fault** For a simple earth fault fed with current  $I_e$  and phase-to-neutral voltage  $V_a$  of the faulted phase, the earth loop impedance presented to the relay is

$$V_a/I_e = Z_1 + Z_e = Z_1(1+k) \leftarrow$$

where  $Z_1$  is the normal positive-sequence line impedance from the relay to the fault,  $Z_e$  is the corresponding impedance of the earth path, and  $k = Z_e/Z_1$ .

**Figure 35.22** Distance (impedance) protection principles

**Phase-phase fault** The relay is fed with the phase-phase voltage and with the difference ( $I_a - I_b$ ) between the faulted phase currents, so that the impedance is

$$V_{ab}/(I_a - I_b) = V_a/I_a = Z_1$$

**Three-phase fault** Relays connected as for the phase-phase fault see the same impedance  $Z_1$ , because

$$V_{ab}/\sqrt{3}I_a = V_a/I_a = Z_1$$

and consequently operate correctly with the same setting.

**Earth current compensation** If, as is common, the system is earthed at more than one point, a proportion of the earth fault current will return by a path other than that at which the relays are located. The impedance seen is thus in error: it will be too low. This can be corrected in two ways.

**Sound-phase compensation** A fraction  $p = Z_e/(Z_1 + Z_e)$  of the sound-phase currents is added to the faulted-phase current, as shown in Figure 35.23(a). Typical values for a 132 kV line are  $Z_1 = 0.44 \Omega/\text{km}$  and  $Z_e = 0.21 \Omega/\text{km}$ , so that  $p = 0.34$ .

**Residual compensation** A fraction  $q$  of the residual current  $I_r$  is added to the relay operating current, as in Figure 35.23(b). If  $q = Z_e/Z_1$ , the measured impedance is  $Z_1$ , and the relays must be set for  $Z_1$  instead of for  $Z_e$  to give correct operation. With the typical values above,  $q = 0.52$ .

**Arc resistance** If the fault has an arc resistance, the relay will 'see' the fault as located too far away, and errors in discrimination may result. Typical values of fault resistance lie between 0.5 and 3  $\Omega$ , the higher values for lower currents.

**Power swing** If a power swing occurs, i.e. phase swinging of the terminal voltages of the section of the system concerned, the impedance seen by a relay may fall to a low value even if there is no fault in or near its protected zone.

Figure 35.23 Sound-phase and residual compensation

Figure 35.24 Impedance during power swing

In Figure 35.24 the impedance seen by the relay at X and looking towards B is given by

$$Z_p = Z[A/(A-1) - k] \ll$$

where  $A = (E_A/E_B) \angle \delta$ , with  $\delta$  representing the phase angle between  $E_A$  and  $E_B$ , and  $Z$  the total impedance of the line. The expression gives approximately the linear impedance locus shown, part of which around  $\delta = 90^\circ$  may well fall within the operating zone of the relay and cause false tripping unless special precautions are taken.

### 35.1.8.6 Relay characteristics

Characteristics for various relay constructions are given in Figure 35.25, the relays operating if the impedances seen by them fall within the shaded area. The impedance for which a relay is required to operate is given by  $OZ_1$ ,  $OZ_2$  or  $OZ_3$  in Figure 35.25, so that this value should lie within the shaded area and any other impedance seen by the relay (due to load, arc resistance, power swings, etc.) should lie outside it. The quadrilateral characteristic (f) is desirable, but it can be obtained only by electronic means.

Typical arrangements for the three steps of a stepped-time scheme are also shown in Figure 35.25. At (g) the directional feature is given by the 'mho' relays used for the first two stages, while at (h) the mho relay for the third stage is used as a starting element and also prevents the reactance relays operating under load conditions.

Inaccurate operation can result if the relay voltages are low, owing to a high source/line impedance ratio, e.g. 30/1 or more. A polarising winding on the relay fed (1) through a memory circuit so that it retains pre-fault voltage or (2) from the sound phases through a phase shifting circuit, may be used. Method (2) is not effective for three-phase faults.

Figure 35.25 Distance relay characteristics

### 35.1.8.7 Accelerated distance protection

It can be seen from Figure 35.22(b) that faults near the remote end of the protected section AB will only be cleared after an appreciable time lag. Such a fault will, however, be cleared 'instantaneously' by the right-to-left equipment at B; and if this equipment is also made to transmit a signal to A over a pilot circuit (usually carrier over the line), it can initiate the immediate tripping of the circuit breaker at A, thus giving almost instantaneous protection over the whole line.

## 35.1.9 Miscellaneous equipment

### 35.1.9.1 Negative sequence

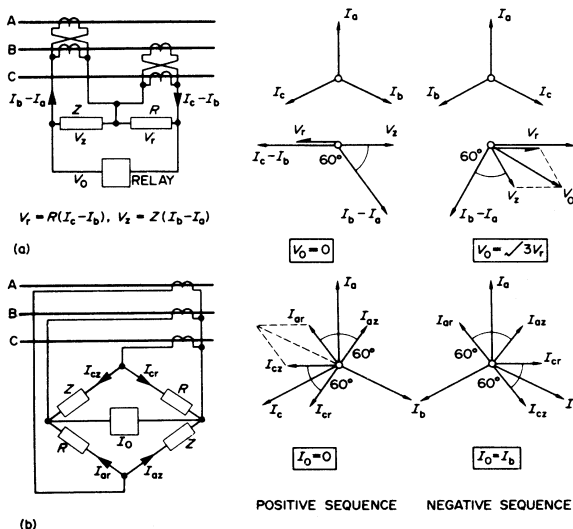

Any fault other than a symmetrical three-phase fault develops negative sequence currents, so that a network responsive to n.p.s. but not to p.p.s. components will indicate the presence of a fault and can be made to operate a relay. Two such circuits are shown in Figure 35.26. The cross-connection of the current transformers in (a) eliminates the z.p.s. components: the latter are earth leakage currents and are detected in other ways. The n.p.s. schemes illustrated employ impedance elements of resistance  $R$  and inductive impedance  $Z = R \angle 60^\circ$ ; but capacitive impedances  $Z = R \angle -60^\circ$  give the same results if the positions of  $R$  and  $Z$  are interchanged.

### 35.1.9.2 Neutral displacement

Displacement of the neutral point potential from its normal earth potential is indicative of a fault condition, and may be used to initiate tripping.

### 35.1.9.3 Buchholz relay

The Buchholz relay is used for the protection of large oil immersed transformers or shunt reactors with oil conservators, and is fitted in the pipe from the tank to the conservator. Any arcing fault causes the oil to decompose, generating gas which passes up the pipe to the conservator

**Figure 35.26** Negative-phase-sequence protection: (a) high-impedance relay; (b) low-impedance relay

and is trapped in the relay. In the case of a large fault a bulk displacement of the oil takes place. In a two-float relay the upper float responds to the slow accumulation of gas due to the mild or incipient faults, while the lower float is deflected by the oil surge caused by a major fault. The floats control contacts—in the first case, to give an alarm; in the second case to isolate the unit.

Such relays also incorporate a petcock at the top for the removal of the gas; its subsequent analysis can show the origin and severity of the internal fault.

### 35.1.9.4 Tripping of circuit-breakers

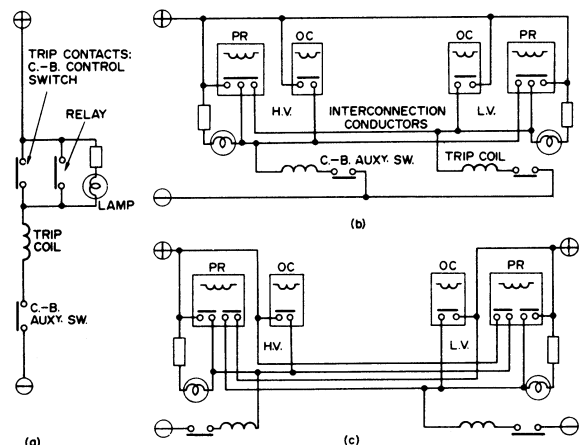

**Direct-operated trip coils** The circuit-breaker trip coil may be energised directly from the current in the main circuit for lower voltage circuit-breakers, or from a current transformer with the trip coil shunted by a fuse which blows on overcurrent to cause tripping. With c.t.s it is possible to use the residual current to operate the tripping at a much lower earth fault current than for overcurrents. The advent of solid-state relays enables much better fault discrimination to be achieved, and also obviates the need for external auxiliary supplies (usually d.c.) for tripping.

### 35.1.9.5 D.c. tripping and operating circuits

The d.c. circuits brought into operation by protective relays are of importance, as they are responsible for circuit-breaker actuation.

**Single tripping** The tripping of one local circuit-breaker ('unit tripping') by the operation of relays is applicable to overcurrent or balanced protection of feeders having relays at each end. The essentials are shown in Figure 35.27(a); it includes a 'healthy trip circuit' indicating lamp with external resistance of such value that, if the lamp is short-circuited, the current is less than that required for tripping. The lamp also serves as a 'circuit-breaker closed' indicator, and proves the continuity of the trip circuit when the breaker is closed.

**Intertripping** By this is meant the necessary tripping of circuit-breakers identified with the unit protected; for example, the tripping between HV and LV breakers on a

**Figure 35.27** Tripping circuits: (a) single circuit breaker; (b) common d.c. supply; and (c) separate d.c. supplies for intertripping of transformer HV and LV circuit-breakers

transformer with (1) overall circulating current protection or (2) balanced earth leakage and overcurrent protection on each side, it being necessary to trip *both* breakers for a fault on either side. Intertripping may be local and relatively straightforward, or it may require to be performed on circuit-breakers at separated points in the network.

**Local intertripping** When two circuit-breakers are involved, use can be made of a standard 'three-point' scheme, either with a three-point relay, or by the addition of an interposing relay which gives a positive tripping supply to two independent circuits. Figure 35.27(b) shows an arrangement with three-point relays and a common d.c. supply, and Figure 35.27(c) the modification for separate supplies. In both cases the overcurrent relays, whether for 'back-up' or phase fault protection, trip their respective breakers only. Buchholz protectors or high-temperature relays, where used, should be connected so as to intertrip. When transformers are feeding distribution networks, three overcurrent relays on the HV side only with intertrip to the LV breaker are sometimes used, i.e. with no overcurrent relays on the LV side. The disadvantage of this arrangement is apparent, for the tripping of the LV breaker depends solely on the intertripping wire or cable. Also, the overcurrent relays are inoperative with the transformer charged from the l.v. side only, and with balanced earth leakage on each winding there would be no phase fault protection, obviously a dangerous condition. It is considered better practice to install overcurrent relays on each breaker so that, in the event of damage or bad connection on the interconnecting pilots, the 'back-up' value of overcurrent relays will trip each breaker independently, as well as giving complete protection with either side energised.

**Distance intertripping** is applicable to feeder transformer protection with breakers situated in different stations, or to special schemes in some forms of bus-bar zone protection. Basically, feeder transformer protection is treated as a combination of (1) feeder protection, generally a balanced protection employing either circulating current or balanced voltage principles; (2) transformer protection in the form of restricted earth leakage or circulating current, both sections being independent on the a.c. side, but the arrangements necessitate the additional tripping of the breaker at the remote end of the feeder in the event of a fault on either side of the transformer.

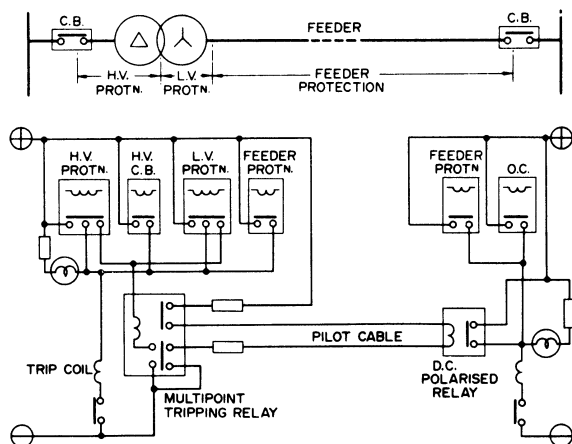

Figure 35.28 Intertripping of feeder transformer

Figure 35.28 shows an arrangement embodying a d.c. polarised relay which is energised over two pilot cables by the operation of the transformer protection relays. It is a 'dead pilot' system, as the pilots are connected to the d.c. supply through limiting resistors only when the protection operates—an obvious advantage. The scheme counters the induction of e.m.f.s in the pilots by earth fault currents in neighbouring main cables. Special relays, sensitive to d.c. but strongly biased against a.c., are also available for use in this arrangement.

Another method, applicable to certain types of balanced voltage protection, operates by interrupting one pilot cable and applying d.c. or a.c. injection across the break.

**Alarm systems** Modern protective relays are fitted with relay signals, but it is also necessary in attended stations to have audible and visual indication that a breaker has tripped. The methods are:

- (1) Electrically operated alarm systems in which an alarm bell and lamp circuit are energised by a relay, manually reset or with self-holding contacts; in some makes a shunt or series coil closing suitable contacts is embodied in the protective relay. Separate contacts on a multi-point tripping relay, which are bridged when the relay trips, may be utilised.
- (2) Mechanically operated free-handle type, in which an auxiliary switch is operated during the closing of the breaker, the alarm lamp and audible circuit being completed by an auxiliary switch on the circuit-breaker when it opens; this scheme gives the alarm not only when the breaker is tripped from protective relays, but also if the breaker slips or opens through mechanical vibration.

In all cases (with the exception of hand-reset alarm relays) cancellation of the alarm system is effected by turning the circuit-breaker controller to the open position.

**D.c. supply** In large stations it is the practice to employ a trickle-charged 'floating' battery with charging from the local a.c. supply through a rectifier. Where no charging supplies are available, a replacement routine must be employed.

To reduce fire hazard, modern switchgear is sectionalised. The d.c. control circuits should be similarly sectionalised and fed from the main d.c. panel by separate cables.

### 35.1.10 Efficacy of protection scheme

The true measure of the efficacy of a protective unit may be expressed in terms of the number  $N$  of operations, of which  $n$  are incorrect, as  $(N-n)/N$ . The number  $N$  includes both through-faults and internal faults;  $n$  includes failure to trip on faults in the protected zone and false operation under through-fault conditions. Many factors influence this efficacy, such as imperfect design, application or commissioning, or failure of the equipment from damage and other causes. Protective equipment must therefore be carefully selected and meticulously maintained.

### 35.1.11 Digital protection

A digital relay is distinguished from other static relays, largely by virtue of the fact that transduced voltages and/or current signals are sampled at regular intervals and converted, prior to further processing, to digital words (or

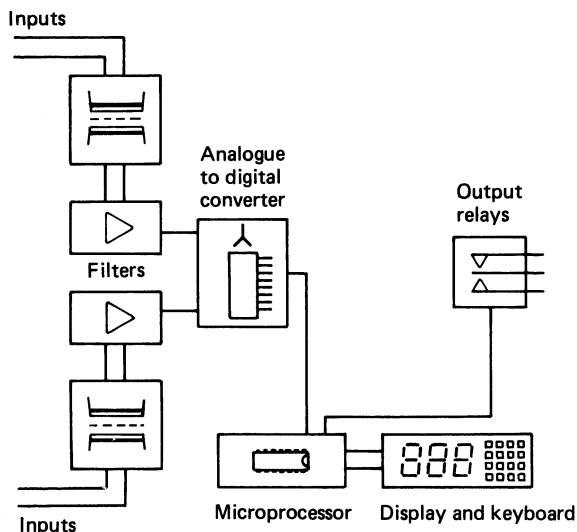

numbers) representing the instantaneous level of the signals sampled. Once converted, the sampled values are used as input values to the protection algorithm, which effectively comprises a set of equations that are continuously evaluated for each set of new data. The protection algorithms are stored in the memory associated with a digital microcomputer or microprocessor, which in turn performs the necessary calculations on each set of incoming data so as to determine the state of the item of plant or line protected.

The basic arrangement of a digital relay is shown in *Figure 35.29*. Each input signal is passed through an analogue low-pass filter which limits the frequency content of each signal to at least half the frequency at which data are produced.

In digital systems, any frequencies in the sampled signal above one-half of the sampling frequency appear in the digital area as lower frequency components or 'aliases' and prefiltering of the analogue data so as to band limit its frequency content is necessary to avoid such data corruption. An analogue-to-digital converter then performs the necessary conversion to produce a train of digital data to the microprocessor which performs the necessary protection algorithm calculations. In practice, sampling and associated calculations are performed at frequencies which range from typically 200 samples/s to 4000 samples/s; the sampling rate is to some extent dictated by the performance requirements of the protection and, in particular, the required operating times. Digital relays commonly quantise the incoming data into at least 12 bits which in turn enables the incoming signals to be represented by signals ranging from 0 to  $2^{11}$  (or  $\pm 2048$ ) levels. The algorithmic calculations performed by the microprocessor will commonly involve 16-bit digital words ( $\pm 32768$ ), which in turn generally enables the necessary degree of accuracy to be obtained. Where the algorithms are such that a high computational burden is imposed, due for example to its complexity and/or the need for a high sampling rate, it is common to use a high performance digital signal processor in preference to a conventional microprocessor.

The microprocessor is equipped with random-access memory (RAM) and read-only memory (ROM) for data and program storage. Communication with the outside

**Figure 35.29** Block diagram of digital relay

world is needed to program the relay settings into the device and display status information. This is achieved by a display and keypad. Alarm and tripping signals are produced via the outgoing relays and, in addition, digital outputs supporting fault location equipment, communications modems linking other digital equipment and relays at other locations, etc., are often integrated.

Digital relays offer a number of benefits over more conventional devices and, in recent years, a number of relays have been marketed. The primary impetus for the emergence of digital protection is a general increase in demands from utilities for faster fault clearance times, better discrimination and satisfactory detection of difficult or contingency fault conditions which are not easily met by more conventional relays. Complex operating characteristics are readily programmed into digital relays which have been designed to automatically monitor themselves by executing automatic check programs which identify potential problems by comparing the response of specific circuit elements with that expected for given reference test conditions. Digital relays are generally much more flexible than more conventional types since they often include multiple characteristics and options to select any one of these. They can readily accept inputs from the digital devices and are directly compatible with digital communication systems for performing data transmission, alarm handling and supervisory controls. It is highly likely that, in the future, increasing integration of digital protection with 'electronic transducers', e.g. fibre optic voltage and current sensing devices, will occur.

Digital relaying can be applied in unit or non-unit form to protect specific items of plant and/or power feeders. At the present time, the major applications have been in the area of e.h.v. transmission line protection of the *distance*, *differential* and *directional comparison* types.

#### 35.1.11.1 Distance protection

A digital distance relay has an algorithm which is designed to calculate the impedance between the point of measurement and the point of fault. This is done for each set of samples of voltage and current measured. There are a number of specific methods of calculating the impedances, the most common of which involve implementing an algorithm that is designed to evaluate the resistance and reactance of the fault loop. By reference to *Figure 35.30*, which is a simplified single-line diagram of a transmission line fault loop, the relationship between the voltage and current measured at the relaying point and the fault loop resistance  $R$  and inductance  $L$  is given by

$$v = Ri + L \frac{di}{dt} \quad (35.1) \Leftarrow$$

**Figure 35.30** Typical distance relay fault loop

This equation applies to all samples processed. For example, consider two samples taken at times  $t_1$  and  $t_2$  (for which the voltage and current samples are denoted by  $v_1, i_1$  and  $v_2, i_2$ , respectively). In this case the fault loop parameters can be obtained from an algorithm based on the equations

$$R \simeq (v_1 i_2' - v_2 i_1')/D \quad (35.2)$$

$$L \simeq (v_2 i_1 - v_1 i_2)/D \quad (35.3) \Leftarrow$$

where  $i'$  denotes a current signal rate of change ( $di/dt$ ) and  $D = i_1 i_2' - i_1' i_2$

Estimates of the current differential terms together with the instantaneous values in the above two equations are obtained typically by utilising a succession of two or three sampled values and in this way, successive estimates of impedances measured are obtained. Such estimates are compared with the distance relay characteristic boundary, which is defined in accordance with the requirements of particular applications (see Figure 35.25 and Section 35.1.8.6). Tripping is initiated when a defined number of successive samples of the fault loop impedance consistently lie within the defined characteristic boundary and tripping times typically as low as 8 ms are readily attainable for most applications.

### 35.1.11.2 Differential protection

The circulating current differential principle is at present that which is most commonly applied in digital form (see Section 35.1.8.1). Figure 35.31 shows a functional single-line diagram of such a scheme applied to a plain feeder. In this arrangement, the currents at the two ends are sampled and transmitted to a digital differential relay located at only one end, though separate devices located at each end can be used. Each sample is converted to digital form and transmitted to a digital communications link which, in the case of Figure 35.31, comprises a light fibre optic link. Other digital communications channels, e.g. microwave links can equally be used. The current differential quantity, which is of the form given in Equation (35.4) is evaluated at each sample instant and compared typically with a bias quantity

(Equation (35.5)). Internal faults are distinguished from healthy conditions by comparing the magnitude of successive estimates of the differential and bias quantities as determined by sampled digital values. In its simplest form, the algorithm checks that, for example, the differential quantity consistently exceeds the bias quantity for a number of successive samples before initiating circuit-breaker tripping. Where, as in Figure 35.31, the scheme is arranged on the 'master and slave' ends principle, a return fibre or digital communications channel can be used to transmit the signal from the measuring to the remote (slave) end.

$$i_P + i_Q \quad (35.4) \Leftarrow$$

$$i_P - i_Q \quad (35.5) \Leftarrow$$

### 35.1.11.3 Directional comparison protection

The basis of a directional comparison protection scheme is shown in Figure 35.32. In the particular arrangement shown, digital directional detectors measure from the voltage and current at each line end. Each directional measuring device is designed to determine the direction to the fault so that, for the faulted case shown, each measures the fault as being in the forward direction. The fault direction indicated is signalled to the equipment at the other end to produce a tripping signal. Conversely, any fault external to the line causes only one directional detector to indicate a fault in the forward direction and tripping is thereby inhibited. There are a number of alternative ways of utilising the directional indications issued, but the basic principle is the same as that outlined above. It is worth noting that only a single binary signal is required in transmitting the directional signal determined by the detectors, thus avoiding the necessity for multi-valued data communication channels.

It is common for digital directional comparison devices to measure from the fault superimposed voltages and currents. The superimposed measurands are in effect the difference between the actual value measured and the projection of the normal steady-state voltage (or current) existing at the point of measurement immediately before a fault.

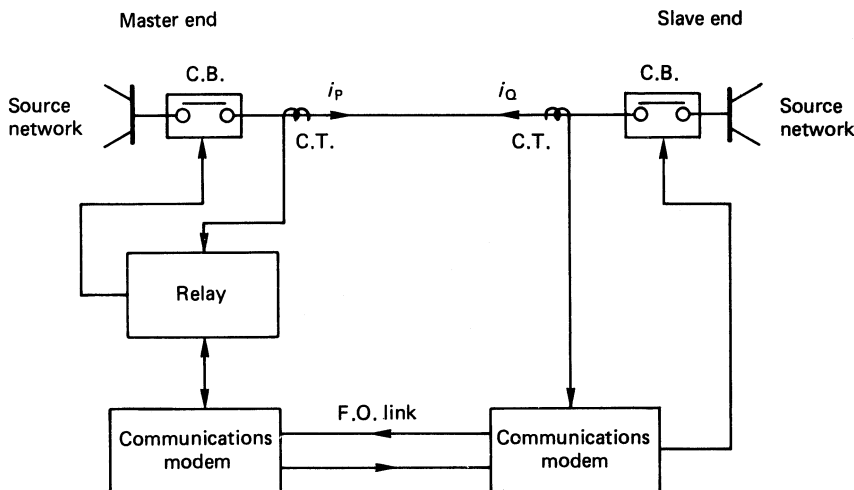

Figure 35.31 Digital difference

Figure 35.32 Basic directional comparison scheme

The superimposed voltages and currents can thus be considered as existing in their own right in an otherwise de-energised system, i.e. they propagate within a model of the system in which each voltage is hypothetically set at zero. For example, Figure 35.33 shows the form of the resulting superimposed circuit for a transmission line subjected to a fault somewhere behind (or in the reverse direction with respect to) the directional measuring point at end S. Figure 35.33 is a simplified superimposed model of a multiphase line in which the three-phase voltages and currents are combined into single voltage and current measurements. The means of achieving this network reduction is similar to that used to derive single measurements in distance protection (see Section 35.1.8.5) and further detailed information is given in the Bibliography at the end of this chapter.

The directional detectors derive superimposed measurements which are usually obtained by taking the difference between any sample on the incoming waveform and that derived from an integer number of power frequency

samples previously; this differencing is equivalent to projecting the prefault steady-state variations forward in time and makes the resulting measurements consistent with a system superimposed model of the type previously discussed.

With reference to Figure 35.33, the superimposed voltage and current measured at say end S ( $v_T$ ,  $i_T$ ) are related for all time up to twice the wave transit time ( $2\tau$ ) from S to R by  $v_T = z_0 i_T$ , where  $z_0$  is the line surge or characteristic impedance. Successive sampled values of  $v_T$  and  $i_T$  are used to form the directional signals

$$s_1 = v_T - z_0 i_T \quad (35.6)$$

$$s_2 = v_T + z_0 i_T \quad (35.7)$$

The directional signals given in the above equations are compared to determine the direction to the fault. For the reverse fault shown in Figure 35.33, the signal tends to zero whereas the signal  $s_1$  attains a relatively large value which leads to twice the superimposed voltage measured at end  $s_2$ . Conversely, for a forward fault, the superimposed voltage and current are of opposite sign and in this case a reverse fault direction is indicated by signal  $s_1$  exceeding signal  $s_2$ . Directional integrity is obtained by checking the relative size of signals over a number of post-fault samples, and the direction to a fault can be obtained in typically 2–4 ms when using a sampling rate of 3000 samples/s. The use of superimposed quantities brings a high degree of immunity to power swing and heavy circuit loading effects on account of their value being close to zero under normal steady-state conditions.

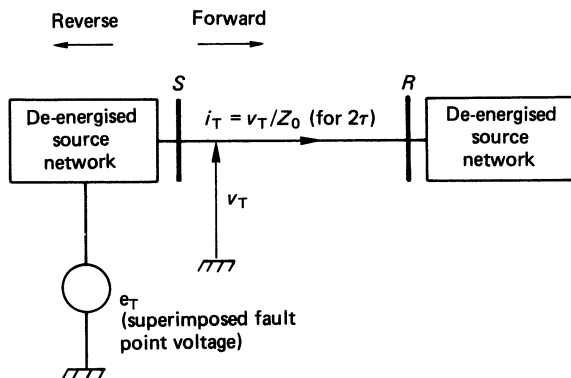

Figure 35.33 Superimposed circuit for fault behind relaying point

### 35.1.12 Artificial intelligence for protection

Conventional relays, including digital devices, rely heavily upon deterministic signal models and heuristic approaches

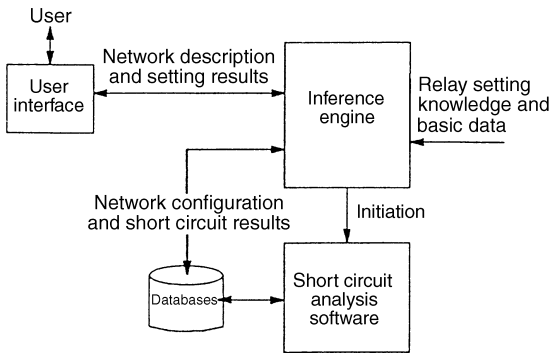

Figure 35.35 Basic elements of a relay setting expert system

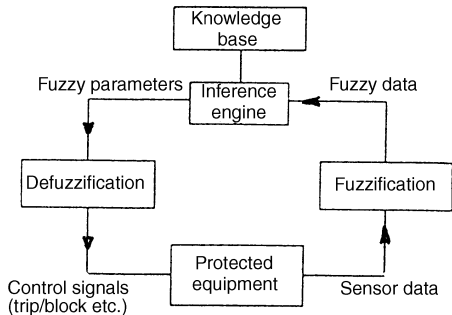

Figure 35.36 Basic arrangement of a 'fuzzy relay'

Figure 35.37 Typical membership functions

Figure 35.38 Rudimentary artificial neural network (ANN) topology

behave so as to produce an output level which suddenly switches from a low signal level to a high level when the summated input reaches a critical level.

Figure 35.39 shows the basic structure of a relay employing an ANN. As mentioned previously, the ANN needs to be trained. This is done using a training algorithm of which the 'backpropagation' algorithm is often used. In essence, the ANN is subjected to an input array derived via system simulation studies or actual recorded system data, for which the desired output is known. For example, the input may be derived from a faulted transmission line for which a tripping signal is required or conversely an input array associated with a healthy situation where the output should be zero. Training is performed iteratively by adjusting the weight of the input to each artificial neuron so as to obtain the desired output(s). In practice training has to be achieved using a training set which is large enough to ensure final convergence of the network weighing coefficients. Very significant progress has been made in the application of ANNs to protection and associated control functions such as single-pole autoreclosure. A number of commercial developments are underway and there is little doubt that ANN based protection and control will ultimately be applied. In this respect, it is likely that the first applications will be aimed at providing improved performance of protection in difficult applications and where it is necessary to cover contingency fault and systems conditions where more conventional protection, including digital measuring devices, often provide less than optimal response.

#### 35.1.12.4 Hybrid artificial intelligence networks

Recent research indicates that AI based protection techniques may be significantly enhanced by the integration of expert systems, fuzzy logic and artificial neural network techniques. Fuzzy neural networks are actively being researched as a means of further enhancing next generation protection performance. Further integration of expert system techniques is also likely to provide a very important way forward in future generations of 'intelligent protection', though much more on-going work is required in this area.

## 35.2 Application of protective systems

There are usually several ways of protecting any given equipment, and the more usual zones of protection are

**Figure 35.39** Basic structure of an (ANN) protection relay

**Figure 35.40** Zones of protection: A, bus-bars; B, generator; C, generator-transformer; D, power transformer; E, auto-transformer; F, unit transformer; G, earthing transformer; H, transmission line of feeder; I, transformer; J, reactor; K, induction motor; L, synchronous motor; M, rectifier

shown in *Figure 35.40*. One relay can often be used for several functions; for example, a triple-pole overcurrent relay can be used for both overcurrent and earth fault protection, and the following combinations are commonly found in practice: (1) inverse time overcurrent and earth fault; (2) inverse time with instantaneous high-setting overcurrent, with or without inverse time earth fault; and (3) thermal overcurrent, with instantaneous overcurrent and earth fault.

The power system neutral is considered to be earthed when the neutral point is connected to earth directly or through a resistor. Earth fault protection is applicable in all such cases. The neutral point is considered to be insulated when the neutral point is not connected to earth, or is earthed through a continuously rated arc suppression coil or through a voltage transformer.

Arc suppression coils are a form of protection applicable where the majority of the earth faults are expected to be of a transient nature only. They can be continuously or short-time rated (normally 30 s), with one phase of the system faulted to earth. The continuously rated coils can be provided with an alarm to indicate the presence of a persistent fault, and in some cases directional earth fault relays are used to indicate the location of an earth fault. The short-rated coil is short-circuited, either directly or through a resistor after a short time, so that persistent earth

faults can be cleared by normal discriminative earth fault protection.

### 35.2.1 Plant

#### 35.2.1.1 Generators

The core of an electrical power system is the generator, requiring a prime mover to develop mechanical power from steam, gas, water or diesel engines. The range of size extends from a few hundred kilovolt-amperes up to turbine driven sets exceeding 600 MV-A in rating. Small sets may be directly connected to the distribution system, while the larger units are associated with an individual step-up transformer through which the set is coupled to the transmission system.

A modern generating unit is a complex system consisting of the generator stator, the rotor with its field winding and excitors, the turbine and associated condenser, the boiler with auxiliary fans and pumps, and possibly an associated or unit transformer. Faults of many kinds can occur in such a system, for which diverse protective means are needed. The amount of protection applied will be governed by economic considerations. In general, the following faults need to be considered:

- (1) stator insulation earth faults;
- (2) overload;
- (3) overvoltage;
- (4) unbalanced loading;
- (5) rotor fault;
- (6) loss of excitation;
- (7) loss of synchronism;
- (8) failure of prime mover;
- (9) low vacuum in condenser;
- (10) lubrication oil failure;
- (11) overspeeding;
- (12) rotor distortion;
- (13) differential expansion; and
- (14) excessive vibration

The neutral point of a generator is normally earthed, with some impedance inserted in the earthing lead to limit the magnitude of earth fault current to values from a few amperes to about rated full load current. Phase-phase faults clear of earth are unusual, as are interturn faults; and they usually involve earth in a short time. Circulating current biased differential protection is the most satisfactory way of protecting a generator stator or a generator-transformer unit.

Generators on a large system under continuous supervision are not usually subject to prolonged accidental overloading and are often protected only by built-in temperature measuring devices on both stator and rotor. For the smaller machines inverse definite minimum time (i.d.m.t.) overcurrent

relays are used (often forming a back-up feature) and may be voltage restrained to give better discrimination.

Power frequency overvoltages are usually dealt with by instantaneous relays with fairly high settings, and transient overvoltages by surge diverters and capacitors connected to the generator terminals if the incoming surges are not sufficiently reduced by transformer interconnections.

Any unbalanced load produces negative sequence components, the resulting reaction field producing double-frequency currents in the field system and rotor body, which can result in serious overheating. For turbo sets the negative sequence continuous rating is only 10–15% of the continuous mean rating value for positive sequence. The unbalance is detected by relays in a negative sequence network, providing first an alarm and finally tripping the generator load.

Rotor faults due to earthing of the winding, or partial short-circuited turns, can be detected by methods involving a potentiometer across the winding, or a.c. or d.c. injection. Failure of the field system results in a generator losing synchronism, running above synchronous speed and operating as an induction generator with the main flux produced by reactive stator current drawn from the system. In general, a 60 MW machine with conventional cooling will not be overheated by asynchronous operation at full load for 5 min; but a hydrogen cooled 500 MW set should not be run like this for more than 20 s. A generator may also lose synchronism because of a severe system fault, or operation at a high load with leading power factor and, hence, a relatively weak field. This subjects the generator and prime mover to violent oscillations of torque, but synchronism can be regained if the load is reduced in a few seconds; otherwise it is necessary to isolate the machine. Alternatively, the excitation may be removed so that the generator runs asynchronously, thereby removing the violent power oscillations. Re-closing the excitation at a low value will then cause the machine to resynchronise smoothly. The range of possible positions of saving curves makes detection by simple relays relatively difficult, but by the use of two impedance relays, pole slipping can be detected and corrected by varying the excitation.

Various faults may occur on the mechanical side of the set, such as failure of the prime mover, overspeed, boiler failure, loss of vacuum, lubricating oil failure, rotor distortion, etc. These can all be protected, the inclusion being a matter of economics.

Where generator-transformers are used, the differential protection will always need to be biased, using either harmonic bias or special attention to settings. Earth fault protection will cover the generator and the transformer primary winding; in addition, the transformer h.v. winding will usually be provided with restricted earth fault protection and Buchholz protection (see Figure 35.41).

The field of a faulty generator should be suppressed as quickly as possible. For machines above about 5 MV-A this is usually done by connecting a field discharge resistor of about five times the rotor field-winding resistance in parallel with the generator field when the field circuit-breaker opens. This reduces the field time constant, but it may still be more than 1 s.

### 35.2.1.2 Transformers

The power transformer is one of the most important links in a transmission system, and as it has the greatest range of characteristics, complete protection is difficult. These conditions must be reviewed before detailed application of protection is settled. The ratings of units used in transmission and distribution schemes range from a few kilovolt-amperes to several hundred megavolt-amperes. The simplest protection, such as fuses, can be justified only for the small transformers; those of the highest ratings have the best protection that can be afforded.

A fault in a transformer winding is controlled in magnitude not only by the source and neutral earthing impedance, but also by the leakage reactance of the transformer, and the fact that the fault voltage may differ from the system voltage according to the position of the fault in the winding. Star-connected windings may be earthed either solidly or through an impedance, presenting few protection problems; but delta-connected windings require close consideration, as

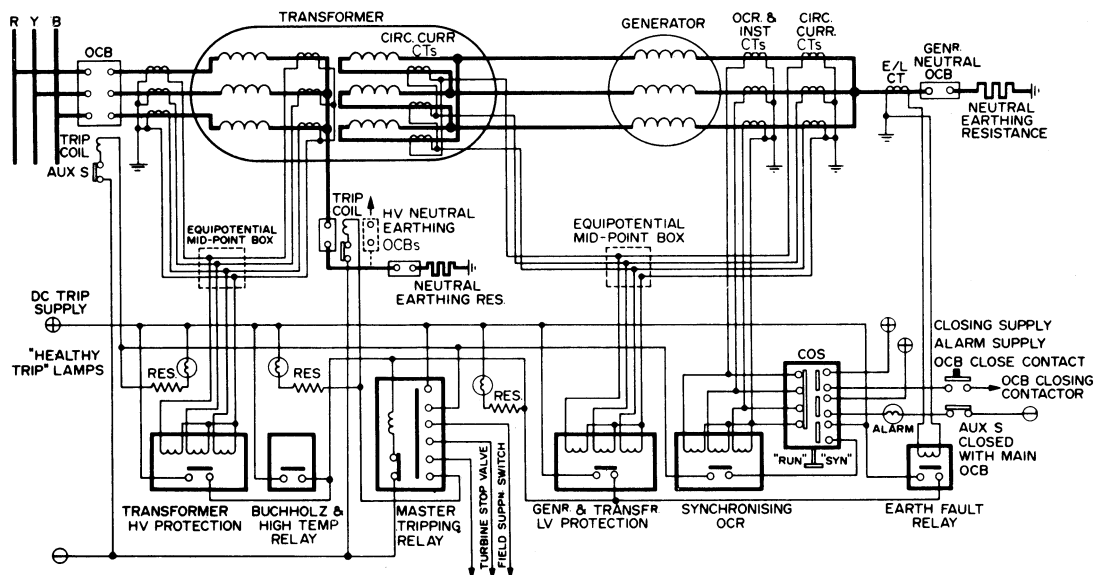

Figure 35.41 Generator-transformer protection

the individual phase currents may be relatively low. Faults between phases within a transformer are comparatively rare, and interturn faults in low-voltage transformers are unlikely unless caused by mechanical force on the windings due to external short circuits. Where a high-voltage transformer is connected to an overhead transmission line, a steep-fronted voltage surge due to lightning may be concentrated on the end turns of the winding, resulting in 70–80% of such transformer failures unless some form of voltage grading is employed. The bolts that clamp the core together are insulated to prevent eddy currents. Should this insulation fail, then severe local heating may damage the winding. As the oil is usually broken down, the gas produced can be used to operate a Buchholz relay. Tank faults are rare, but oil sludging can block cooling ducts and pipes, leading to overheating.

One of the major problems in the protection of large transformers is the phenomenon of magnetising current inrush when switching on. This is not a fault condition and the protection relays must not trip, although the inrush current appears superficially as an internal fault and may have a long time constant. To avoid long time delays and, hence, damage to important transformers, it is essential to clear all faults rapidly. Use is made of the fact that magnetising inrush currents contain a unidirectional component plus second, third and higher harmonics. The second harmonic is the most useful as a stabilising bias against inrush effects, and by combining this (extracted through a filter) with the differential current through a static device, a setting of 15% can be obtained, with an operating time of 45 ms for all fault currents of two or more times rated current. The relay will restrain when the second harmonic component exceeds 20% of the current.

Most of the usual transformer arrangements such as star/delta, auto-, earthing, etc., can be protected by differential relays, sometimes with restricted earth fault relays.

Sometimes transformers are connected directly to transmission lines without circuit-breakers. In such cases the transformer and feeder are both protected by differential protection plus intertripping of the remote circuit-breaker. An alternative to intertripping is to detect earth faults on a feeder connected to a non-earthed transformer winding by measuring the residual voltage on the feeder, using either voltage transformers or capacitors to detect the neutral displacement.

### 35.2.1.3 Reactors

The most common are the series and tie-bar reactors, for limiting overcurrents. On earthed systems with air insulated reactors the protection usually consists of differential relays or time-delayed overcurrent with time-delayed earth fault relays. For insulated-neutral systems the earth fault relays are unnecessary. Shunt reactors for compensating line capacitance are usually oil immersed and protected by time-delayed overcurrent relays, with instantaneous restricted earth fault relays where the system neutrals are earthed. Buchholz relays are often used on oil immersed reactors.

### 35.2.2 Feeders

Many schemes are available: therefore, only general guidance can be given. Scope still exists for adapting schemes to individual requirements. Fuses and/or overcurrent protection with graded time lags are commonly used for 11 kV

and 33 kV distribution systems with balanced opposed-voltage schemes for the more important 33 kV lines.

The protection can be by either electromagnetic or static relays, both of which may be switched by fault detectors, and for earthed systems can incorporate earth fault relays.

The length of feeder frequently results in additional circuits being necessary between the relays at each end. Pilot wires are often used for this purpose, but for distances above about 20 km the pilot wires may behave as a transmission circuit, and may need shunt reactors to compensate for the circuit capacitance. Pilot wires are also liable to electrical interference, manual disturbance and limits as to over-voltage and current, so that many schemes are provided with continuous supervision to warn that the overall protection is unsound and relay adjustment may be necessary. By using the line itself as a link and injecting high-frequency signals (70–700 kHz), the necessary end-to-end protective coupling can be achieved. Information is impressed on the signal by a modulation process. Attenuation of the signal carrier makes pilots unsuitable for transmitting the amplitude of a measured quantity; however, the phase can be transmitted satisfactorily. Frequency modulation can convey all the characteristics of the modulating quantity but involves frequency–amplitude conversion. The best use of carrier involves simple on/off switching: this method of modulation has been extensively used in conjunction with polyphase directional relays by transmitting a locking signal over the line for through-faults.

With extensive power systems and interconnection to ensure continuity of supply and good voltage regulation, the problems of combining fast fault clearance with protective gear co-ordination have become increasingly important. To meet these requirements high-speed protective systems suitable for use with automatic reclosure of the circuit-breakers are under continuous development and are already very widely used. The distance scheme of protection is comparatively simple to apply and offers high speed, primary and back-up facilities, and needs no pilot wires; but by combining it with a signal channel (such as carrier) it is particularly suitable for use with high-speed auto-reclosing for the protection of important transmission lines.

Since the impedance of a transmission line is proportional to its length, it is appropriate to use a relay capable of measuring the impedance of a line up to a given point. The basic principle of measurement (Section 35.1.8) involves the comparison of the fault current seen by the relay with the voltage of the relaying point, whence it is possible to measure the impedance of the line up to the fault. The plain impedance relay takes no account of the phase angle between the current and voltage applied to it, and is therefore non-directional. It has three important disadvantages:

- (1) it is inherently non-directional and therefore needs a directional element to give it discrimination;
- (2) it is affected by arc resistance; and
- (3) it is highly sensitive to power swings, because of the large area covered by the impedance circle.

The *admittance relay*, by addition of a polarising signal, combines the characteristics of the impedance and directional relays. It is satisfactory on long lines carried on steel towers with overhead earth wires, where the effect of arc resistance can be neglected, but for lines on wooden poles without earth wires the earth fault resistance reduces the effective zone to such an extent that most faults take longer to detect. This problem can usually be overcome by using either reactance or fully cross-polarised admittance relays for the detection of earth faults. In theory, any increase in the resistive component of the fault impedance has no effect

upon a reactance relay; however, in practice, when the fault resistance approaches that of the load, then the relay characteristics are modified by the load and its power factor and it may cover either more or less of the line. This can be overcome by the use of a fully cross-polarised circuit which needs two input signals for a  $\pm 90^\circ$  comparison angle.

A distance protection scheme comprises starting, distance measuring, auxiliary, zone timer and tripping relays. To cater for the economic and technical requirements of a particular power system, schemes are available using either a plain distance measurement with several steps of protection, or a combination of distance measurement and a high-speed signalling channel or power-line carrier to form a unit system of protection over the whole of the protected line and to provide its own back-up protection to the adjacent lines. Full-distance, or switched-distance, schemes are applied according to the system voltage and the importance of the lines to be protected. The main difference between the two arrangements is that the full-distance scheme uses six measuring units (three for phase and three for earth faults), whereas the switched-distance scheme uses only one measuring unit for all types of fault, this being switched to the correct fault loop impedance by means of a suitable set of starting units of the overcurrent or underimpedance type.

One of the main disadvantages of conventional time stepped distance protection is that the instantaneous zone of protection at each end of the protected line cannot be set to cover the whole of the feeder length. It usually covers about 80%, leaving two end zones in which faults are cleared instantaneously at one end of a feeder but in much longer time at the other end. In some applications this cannot be tolerated; either the delay in fault clearance may cause the system to become unstable, or, where high-speed auto-reclosing is used, the non-simultaneous opening of the circuit-breakers interferes with the auto-reclosing cycle. These objections can be overcome by interconnecting the distance protections at each end by a signalling channel to transmit information about the system conditions at one end to the other end of the protected line. It can also initiate, or prevent, tripping of the remote circuit-breaker. The former arrangement is a 'transformer trip scheme', while the other is a 'blocking scheme'.

If two circuits are supported on the same tower or are otherwise in close proximity over the whole of their length, there is mutual coupling between them. The positive and negative sequence coupling is small and usually neglected. The zero sequence coupling cannot be ignored. Types of protection that use current only (e.g. power-line carrier phase comparison and pilot-wire differential systems) are not affected, whereas types using current and voltage, especially distance protection, are influenced by the phenomenon and its effect requires special consideration.

The protective schemes described previously for the protection of two-ended feeders can also be used for multi-ended feeders with load or generation at any terminal. However, the application of these schemes to multi-ended feeders is much more complex and requires special attention.

As transient faults, such as an insulator flashover, make up 80–90% of all faults on HV and e.h.v. systems, and are cleared by the immediate tripping of one or more circuit-breakers, they do not recur when the line is re-energised. Such lines are frequently provided with auto-reclosing schemes, and result in a substantial improvement in continuity of supply and system stability. The choices of dead time, of reclose time, and of whether to use a single- or a multi-shot scheme, are of fundamental importance. With a three-phase scheme the tripping of all three phases on the occurrence of a fault means that no interchange of synchronising

power can take place during the dead time. If only the faulty phase is tripping during earth fault conditions (which account for the majority of faults on overhead lines), synchronising power can still be interchanged through the healthy phases, but this entails the provision of circuit-breakers provided with tripping and closing mechanisms on each phase, and the reclosing circuitry is more complicated. In the event of a multi-phase fault, all three phases are tripped and locked out. It is important to ensure simultaneous tripping of the circuit-breakers at all ends of the faulty section, and distance protection imposes some difficulties in this respect, so that a signalling channel is often used between ends. On highly interconnected transmission systems where the loss of a single line is unlikely to cause two sections of the systems to drift apart and lose synchronism, three-phase auto-reclosing can be delayed for 5–60 s with an increase in successful reclosures.

### 35.2.2.1 Bus-bars

Bus-bars have often been left without specific protection for one or more of the following reasons.

- (1) The bus-bars and switchgear have a high degree of reliability and are often regarded as intrinsically safe.
- (2) It was feared that accidental operation of bus-bar protection might cause widespread dislocation which, if not quickly cleared, would cause more loss of supply than the very infrequent bus-bar faults.
- (3) It was expected that system protection, or back-up protection, would provide sufficient bus-bar protection if needed.

The reasons are applicable only to small indoor metal enclosed stations: with outdoor switchgear the case is less clear, for although the likelihood of a fault is higher, the risk of damage is much less. In general, bus-bar protection is required when the system protection does not cover the bus-bars, or when, to maintain system stability, high-speed fault clearance is necessary.

To maintain the high order of stability needed for bus-bar protection, it is now an almost invariable practice to make tripping dependent on two independent measurements of fault quantities. Methods include: (a) two similar differential systems; (b) a single differential system (*Figure 35.42*), checked by a frame earth system (*Figure 35.43*); (c) earth fault relays energised by c.t.s in the neutral earth connection; (d) overcurrent relays; and (e) a frame earth system checked by earth fault relays. Separate current transformers are normally used with separate tripping relays series-connected in pairs to provide a single tripping output, so that independence is maintained throughout. The essential principle is that no single occurrence of a secondary nature shall be capable of causing an unnecessary trip of a bus-bar circuit-breaker.

## 35.2.3 Motors and rectifiers

### 35.2.3.1 Motors

Protection is required against (a) imposed external conditions, and (b) internal faults.

Category (a) includes unbalanced supply voltages, under-voltage, single-phasing, and reverse-phase-sequence starting; (b) includes bearing failures, internal earth faults and overloads.

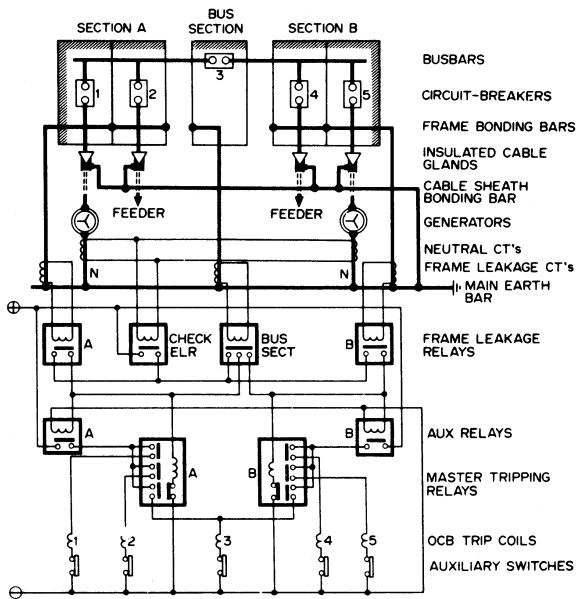

Figure 35.42 A single differential system for bus-bar protection

Figure 35.43 A frame earth system

Motors up to about 400 kW usually have ball or roller bearings which may fail very quickly: the only remedy is to disconnect the motor as rapidly as possible to avoid the overcurrent damaging the windings. Larger machines usually have sleeve bearings, incipient failure of which may be detected by a temperature device embedded in the bearing. As the current increase may be only 10–20%, it cannot be detected by the overload relays.

The majority of winding failures are caused by overload, leading to deterioration of the insulation followed by electrical fault in the winding.

The wide diversity of motor designs makes it impossible to cover all types and ratings with a simple characteristic curve. Motors with fluctuating loads where shutdown would affect the whole process might be left running by giving the overload relay a higher current setting. Motors on a steady load can be tripped more quickly, as overload will probably be due to a mechanical fault.

A temperature compensated static relay can follow changes of the working temperature of the motor more accurately, so that it will not be shut down on overload unless it is overheated. By including a number of alternative operating time–current characteristics it is possible to cover a wide range of motor designs and applications. Protection of motors operating on unbalanced voltages is provided by

separating the positive and negative sequence components of the line currents by means of a sequence filter, arranged to allow for the greater relative heating effect of negative sequence current components.

### 35.2.3.2 Rectifiers

The majority of rectifier duties are now performed by semiconductor devices: these have special demands for protection. Faults can be classified as: (a) cell overload and failure; (b) operational faults such as backfires; (c) d.c. faults on the bus-bars and cables; and (d) a.c. faults on the supply transformer and cables.

Because of their low thermal mass and consequent low fault-current withstand, the series- or parallel-connected cells need to be individually protected, usually by fuses shunted by a small indicating fuse which, on blowing, operates a microswitch to trip the supply or give an alarm.

Semiconductor cells are susceptible to overvoltage failures caused by switching or lightning surges, arc voltages on fuse clearance, chopping of load current, etc. Protection usually takes the form of surge diverters or resistor/capacitor networks connected to earth (or between phases) and across the d.c. output. Rectifier transformers are often provided with earthed screens between the windings to limit the surge transfer.

## 35.3 Testing and commissioning

The testing of protective schemes has always been a problem, because protective gear is concerned only with fault conditions and cannot readily be tested under normal system operating conditions. The problem has been aggravated in recent years by the complexity of protective schemes and relays.

Protective gear testing may be divided into three stages: (1) factory tests, (2) commissioning tests, and (3) periodic maintenance tests.

The first two stages prove the performance of the protective equipment during its development and manufacture, and in its operational environment. The last stage, properly planned, ensures that this performance is maintained throughout its life.

The relay manufacturer must provide adequate testing of protective gear before it is accepted and commissioned. The tests performed are (a) tests in which the operating parameters of the relays, etc., are simulated; (b) conditions such as temperature range, vibration, mechanical shock, electrical impulse withstand, etc., which might affect the operation in service. In some cases tests of both groups are conducted simultaneously to check performance.

With the advent of static relays the use of semiconductors and other electronic components has posed new problems to the manufacturer, because the production of such devices is not within his control. Quality control testing procedures have been established with the object of identifying the device that may fail early in its life, the usual method being to determine which critical parameters will show a substantial change when subjected to accelerated life testing and to examine these.

### 35.3.1 Commissioning tests

The object of the commissioning tests is to ensure that the connections are correct, that the performance of current transformers and relays agrees with the expected results,

and that no components have been damaged by transport or installation. This performance test includes correct current transformer ratio, correct calibration of relays and tests proving that the tripping, intertripping and indication of the scheme are in order.

Although the details of every protective scheme vary, the main points to be checked on every scheme are: (a) stability of the system under all conditions of 'through' current; (b) that the sensitivity of all relays with reference to the primary current is correct.

Prior to making these final checks on site a very careful preliminary check on the protective gear scheme should be made. Such tests would include:

- (1) examination of all small wiring connections, and insulation resistance tests on all circuits;
- (2) identification of all pilot cables—insulation resistance tests and loop resistance tests on balanced pilot-wire schemes;
- (3) polarity and ratio check (if possible) on all current transformers;
- (4) tests on d.c. tripping, intertripping and operation of all breakers connected with the unit, including alarm circuits and relay signals;
- (5) checking of calibration of all relays by secondary injection; and
- (6) miscellaneous tests depending on special details of a particular scheme.

#### 35.3.1.1 Saturation curve

Considerable use on site may be made of a c.t. saturation curve using a LV local supply; it compares closely with results obtained by primary current. An LV a.c. supply is fed to the secondary winding through a control rheostat, and a curve of voltage–current for the secondary is plotted. The equivalent primary current is inferred from the turns ratio. The test is useful for comparing the performance of c.t.s required to have matched characteristics.

Such preliminary tests ensure that components are correct. The commissioning process thereafter must depend upon site facilities. The following notes give a general outline.

### 35.3.2 Primary current tests

A generator is isolated with the unit under test and by means of primary short circuits and earth faults stability figures, on balanced systems, under full load conditions and operation tests with internal faults may be carried out. It is important that the makers of the generator be consulted before it is used for steady unbalanced conditions, e.g. testing with one phase earthed, as the distortion of flux combined with armature reaction, if prolonged, may result in excessive heating. Earthing resistors and transformers should be short circuited or bypassed during current testing, as they are normally short time rated. An *inverted transformer* is a means of stepping-up testing current where a transformer is available between the unit under test and the source of test supply. For example, if the transformer has a normal step-up ratio of 6.6 kV to 66 kV, then by connecting the testing supply (isolated generator or low-voltage source) to the 66 kV windings and supplying the test current from the output of the 6.6 kV windings a 10/1 step-up of current is obtained. This 'inversion' can readily be carried out by flexible cabling when the connections to the transformer are made through open-type bushings, and is applicable to any power transformer.

A heavy current *testing transformer* may be designed with an input suitable for a general range of low-voltage supply. The types available include three-phase and single-phase units with resistance or induction regulator control. For the purpose of producing primary current the output terminals are connected across the primary of the circuit under test, to test windings or test bar primaries embodied in the current transformers. On metal clad switchgear, connection to the primary can be made through the circuit spouts with testing plugs; potential transformer spouts may also be used, but the current-carrying capacity should be investigated.

When using externally mounted current transformers around cables, e.g. in core balance types of protection, flexible cables may be used for threading through the transformers with current supplied from a heavy current testing transformer. The cable should be as central as possible, as small errors are introduced if the cable is asymmetrically located. For balancing purposes it is noted that if the relative position of each cable in each transformer is the same, the same error will be introduced and the effect neutralised.

### 35.3.3 Secondary injection tests

The preceding methods utilise primary current, but use can be made of secondary injection. The effect of primary current in a c.t. is to develop a secondary voltage; in secondary injection, voltage is applied to the secondary terminals, usually from an injection transformer, so applying the 'output' voltage. The method has application for checking relays, calibration, commissioning and maintenance. It is not in itself sufficient for balanced schemes, and must in such cases be supplemented by tests on load; however, it is possible in most cases to simulate through-faults to earth, and phase–phase conditions, by rearrangement of the secondary c.t. connections. One limitation is that the 'load' current is dependent on the load on the unit, usually determined by network conditions, and on balanced systems the stability check may be at a low primary current.

The various types of injection transformers generally have a tapped primary winding, with a secondary resistance controlled output covering a range of voltage. The method gives fine control for calibrating and enables a low power input to be used.

When using injection transformer for timing tests on induction-type relays with inverse time characteristics, the waveform characteristics should be carefully ascertained. Such relays are very sensitive to wave form (having an inherent, saturable iron circuit), and a more satisfactory and reliable method for checking timing is to supply the test current from a low voltage with resistance control. In this way the saturating feature of the relay is absorbed by the controlling resistance, the source of supply being treated as a transformer of relatively high capacity. It must be noted that the saturation of the injection transformer itself is important.

### 35.3.4 Fault location

Rapid location of a fault, together with some idea of its nature, is clearly an essential preliminary to its quick repair. With overhead lines visual inspection either from the ground or from a helicopter may be possible, but if this is not practicable, and almost always in the case of underground cables, inspection of the flag indicators on protective relays and simple Megger or continuity tests will usually provide useful evidence and enable a suitable method of more detailed investigation to be selected.

### 35.3.4.1 Loop tests

If the fault is of low resistance, a low-voltage (car) battery may suffice for the test supply. For higher-resistance faults about 500 V from, say, a Megger may be required, while for very high resistance, where it is necessary to break down the fault, an HV rectifier set may be used.

### 35.3.4.2 Other tests

Fall-of-potential, capacitance and pulse reflection tests are more sophisticated methods. Such tests, with loop tests, may be accurate to a location within 20 m or so of the fault point. In the case of underground cables a more precise location is desirable before excavation. Typical are induction and discharge methods.

## 35.4 Overvoltage protection

Lightning, switching and other less common phenomena produce overvoltages on transmission and distribution systems. Precautions against consequential damage and system outage must be taken, by (a) preventing overvoltages from being impressed on the system, and (b) protecting vulnerable equipment from voltage surges.

Insulation levels are based on combinations of short-duration power-frequency overvoltages, and impulse voltages arising from lightning or switching. Protective devices are (1) non-linear resistor surge arresters, (2) expulsion surge arresters (up to voltages not exceeding 36 kV), and (3) spark-gaps. These do not provide the same degree of protection, and the choice between them depends on such factors as the relative importance of the plant to be protected, the consequence of an outage, the system layout, the probable lightning activity and the system voltage.

The breakdown of plant insulation varies with the time for which an overvoltage is maintained. Figure 35.44 indicates typical voltage–time relationships for plant insulation and overvoltage protection devices. A surge arrester has a characteristic similar to that of the plant, and is usually arranged to spark-over at a voltage slightly lower. A spark-gap has a more nearly hyperbolic characteristic, so that the plant insulation may break down first on overvoltages of short duration; but if, to avoid this, the spark-gap breakdown voltage is reduced, many unnecessary outages may result.

Figure 35.44 Typical voltage/time relationships for plant insulation and overvoltage protection devices

### 35.4.1 Insulation co-ordination

International and national standards for phase-to-earth insulation are referred to three system voltage ranges, viz. 1–36, 52–245 and 300–765 kV r.m.s. (Standards for other than phase-to-earth insulation are under consideration.) Tables 35.1 to 35.3 give the standard voltage levels in terms of:

- $V_0$  highest system voltage (in kilovolts r.m.s.) at which the plant and the protective equipment have to operate normally;
- $v_{lp}$  rated lightning-impulse withstand voltage (in kilovolts peak);
- $v_{sp}$  rated switching-impulse withstand voltage (in kilovolts peak); and
- $V_1$  rated power-frequency short-duration withstand voltage (in kilovolts r.m.s.).

*Lower range* Table 35.1 gives voltage values in two series based on current practice (I) in Europe and (II) in the USA and Canada, and applicable to other countries within the sphere of influence of (I) or (II). There are two lists in (I), the choice between them being made on consideration of the degree of exposure to lightning and switching impulse voltages, the type of system neutral earthing and (where applicable) the type of overvoltage protective devices. In (II) the data are based on the apparent power rating of the plant protected.

*Middle range* In Table 35.2 more than one level of  $v_{lp}$  is given, the highest being for plant in systems where the earth fault factor exceeds 1.4.

*Higher range* Table 35.3 specifies no power-frequency values, the switching overvoltage having priority. The rated values of  $v_{lp}$  associated with a standard  $v_{sp}$  have been chosen in accordance with: (a) for plant protected by

Table 35.1 Insulation co-ordination, 1–36 kV

525	1050	1175, 1300, 1425
525	1175	1300, 1425, 1550
765	1300	1425, 1550, 1800
765	1425	1550, 1800, 2100
765	1550	1800, 1950, 2400

surge arresters the two lowest values apply, and (b) for plant not—or not effectively—protected by arresters only the highest value applies.

Several insulation levels may exist in the one power network, appropriate to different situations or to the characteristics of different protective equipments.

### 35.4.2 Protective equipment

#### 35.4.2.1 Lightning

Underground cables are virtually immune from direct lightning strokes, so that preventive measures apply in general only to overhead lines.

**Earth wire** Shielding the line conductors by an earth wire is reasonably effective in preventing a direct stroke to the conductors, provided that the conductors lie within a segment subtending an angle of about  $45^\circ$  (or preferably  $25^\circ$  for towers above 50 m high) from the earth wire to the ground. Owing to the complex (and not fully understood) nature of the leader stroke as it approaches the earth, such protection sometimes fails; in cases of particular importance, e.g. near a major substation or where lightning is particularly prevalent, two earth wires may be installed.

**Tower footing resistance** A lightning stroke to the earth wire can produce a back-flashover to the line conductors resulting in a line surge voltage unless the tower footing resistance is very low, e.g. not greater than  $1\ \Omega$  per 100 kV of impulse level. In difficult situations a buried *counterpoise* earthing system, comprising wires radiating from the foot of the tower to a distance of 30–60 m, or continuous wires from tower to tower, help to lower the footing resistance.

#### 35.4.2.2 Switching surges

While switching surges cannot be entirely avoided, it is desirable on lines of 300 kV upward to limit them by shunting across circuit-breaker contacts, during closure, resistors of value approximating to the surge impedance of the line (300–400  $\Omega$ ).

#### 35.4.2.3 Damage to plant

Overhead-line damage by overvoltage can occasionally occur, but is generally repairable fairly quickly, but damage to substation plant (particularly to transformers) is costly

and results in a long outage. Overvoltage protection is thus aimed primarily at the defence of transformers.

**Surge attenuation** A travelling wave of voltage attenuates (mainly by corona loss) as it is propagated along a line, and its magnitude and wavefront steepness are mitigated. Inductive coupling with the earth and with earth or counterpoise wires assists in this process. A reduction by one-half may thus occur in a line length of 5–8 km.

A length of underground cable between the terminal of an overhead line and the substation plant also reduces the magnitude of an incoming voltage surge, owing to the lower surge impedance of the cable. Additional reflections from the junctions may, however, partially offset this advantage and the cable is itself vulnerable. Although such a section of cable is often desirable for amenity or other reasons, it is rarely installed solely for protective purposes.

**Surge arrester** The aim is to direct a surge to earth before it reaches a vulnerable plant. The arrester must be located as near as is practicable to the terminals of the plant. An ideal arrester (a) takes no current at normal system voltage, (b) establishes an instantaneous path to earth for any voltage that is abnormally high, (c) is capable of carrying the full discharge current and (d) inhibits subsequent power-frequency current. The modern device comprises an assembly of small gaps and non-linear resistors in series, the whole being contained in a cylindrical porcelain housing. The use of multiple rather than single gaps gives the most rapid breakdown. The resistor elements offer a low resistance to surge currents (limiting the voltage across the arrester) and a much higher resistance to the power-frequency follow current. Careful gap design ensures that the follow current does not restrike.

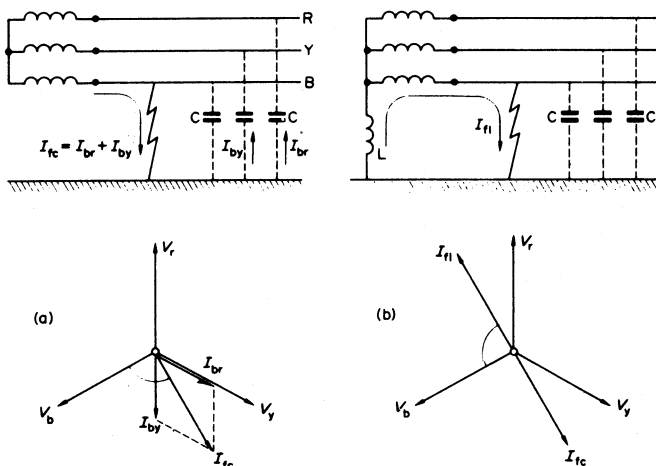

**Rod gap** A plain air-gap is cheap, and it satisfies requirements (a), (b) and (c) above. However, it does not fulfil condition (d), and although gap breakdown protects the plant from overvoltage, there may be a power-frequency follow current which must be cleared by a circuit-breaker operation, involving an outage. A plain rod gap, connected between line and earth, has the following typical gap lengths giving breakdown at about 80% of the plant impulse level:

System voltage (kV)	36.2	72.5	145	300	420
Gap length (m):	0.23	0.35	0.66	1.25	1.70

#### 35.4.2.4 Prevention of outages

About 80% of the earth faults on overhead lines are of a transient nature resulting from lightning, birds or other causes, and no damage to the equipment is caused; however, the ionised path caused by the transient flashover permits a power-frequency follow current to flow which must be cleared by a circuit-breaker operation. Such outages can, however, be avoided in certain cases by the use of arc suppression coils (Petersen coils) or auto-reclose circuit-breakers.

**Arc suppression coil** For reasons of insulation economy and/or safety it is customary to earth the neutral point of a system either directly or through a resistor. Any earth fault results in fault current and necessitates a circuit outage to clear it. Were the neutral point isolated, it might be expected that an earth fault would result in no fault current and that

**Figure 35.45** Action of arc-suppression coil: (a) isolated neutral; (b) neutral earthed through arc-suppression coil

the system could continue to operate, provided that the raising of the two sound phases to line voltage above earth potential were acceptable. However, owing to the system capacitance a leading current will flow through the fault as shown in *Figure 35.45(a)*. If the fault involves an arc, any such current, if it exceeds a few amperes, is likely to cause damaging voltage surges and to be very persistent. Operation with a completely isolated neutral point is therefore impracticable except on very small isolated systems.

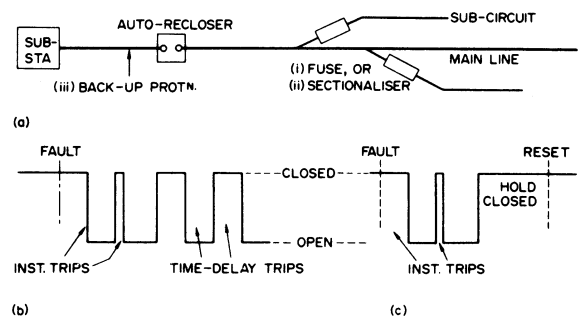

If, however, the neutral is earthed through a high inductive reactance  $X$  (several hundred ohms), the resulting lagging current can, neglecting losses, precisely neutralise the capacitance current, as shown in *Figure 35.45(b)*. There will thus be no fault current and the system can be operated with the fault until such time as it can conveniently be repaired. To secure precise balance the value of the arc suppression coil reactance must be  $X = 4/3\omega C$ .

Arc suppression coils are effective on 12 kV, 36 kV and occasionally up to 245 kV systems, but at the higher voltages and with long lines the resistive and other losses prevent precise phase opposition of  $I_{f1}$  and  $I_{fc}$  so that there is a resultant current in the fault which, if it involves an arc, is inextinguishable and damaging.

**Auto-reclose circuit-breaker** A transient flashover rarely causes damage if the fault is cleared by the normal protective equipment. After an interval of 0.4–0.8 s, sufficient for the natural de-ionisation of the arc path, the circuit-breaker can be reclosed with safety.

Circuit-breakers with automatic reclosure were widely used on 12 kV and 36 kV radial distribution networks. They are required to provide time delay switching in the event of a permanent fault; permit of normal fuse discrimination to limit the area of interruption; operate rapidly on the initial passage of a fault current. *Figure 35.46(a)* shows three applications. In (i) all transient faults are cleared by the recloser, and in the case of permanent faults the recloser sequence provides a time delay trip to blow the fuse only on the faulty sub-circuit. In (ii) sectionalisers provide the disconnecting means for faulty sub-circuits. Method (iii) operates as (i), except that on permanent fault the recloser holds closed and back-up protection operates.

A typical current operated recloser comprises a normally closed oil circuit-breaker for pole mounting. The breaker is held closed by springs. When the current exceeds, for

**Figure 35.46** Auto-reclosing: (a) system; (b) lock-open sequence; (c) hold-closed sequence

example, twice full-load value, movement of the plunger of a series solenoid causes the recloser to open. The plunger is then spring-reset and the reclosing is automatic. Relay features control the reclosing and opening times, and a mechanism is provided to enable the recloser to lock open or hold closed at the end of its operating sequence.

*Figure 35.46(b)* shows a lock-open sequence, the open-circuit times being adjustable between 0.25 and 1 s. If the fault clears and operation is stopped during the cycle, the mechanism returns to the starting position. The 'instantaneous' trips are rapid (2–7 cycles) to avoid fuse deterioration: they give two chances for fault clearance. The time delay switching occurs twice to blow the fuses on a permanently faulted section. If the sequence continues, the operation terminates with the recloser locked open. In *Figure 35.46(c)* is shown a sequence ending in a hold-closed condition. A permanent fault is cleared by other means, after which the mechanism automatically resets. Transient faults are cleared as with type (b).

Where adequate fuse co-ordination is not obtainable, the alternative is the use of sectionalisers, as at (ii) in *Figure 35.46(a)*, associated with automatic reclosers. A sectionaliser comprises a normally closed oil switch latched in against spring loading. When a fault occurs, the current passes through a series coil which actuates the mechanism and counts the fault current impulses during the recloser sequence, opening the sectionaliser automatically during a

pre-set open-circuit period. The mechanism resets if the fault clears prior to the end of the sequence, but if the sectionaliser reaches the open condition, it must be reset by hand.

Auto-reclosing is also sometimes used on transmission systems to assist in maintaining stability by reclosing before synchronous machines have had time to lose synchronism. In some cases, particularly on single-circuit lines, the added complication of selecting, tripping and reclosing only the faulty phase is justified.

When the loss of supply may have serious consequences, duplicate supplies or a ring main may be installed.

## 36.1 Introduction

Although a power system operates in the steady state for a large part of its time, it must be capable of withstanding the overvoltage and overcurrent stresses generated during transient conditions. The size of transmission line towers, the clearance for conductors, the insulation of windings, the rating of circuit-breakers, the loading capabilities of lines, cable, etc., and the operating performance of protection relays are all dictated by consideration of the amplitude and frequency of the power system transients. Consequently, to design and operate a power system to deliver a reliable and high quality power supply, it is crucial to have a thorough understanding of its transient behaviour.

In terms of modelling and analyses of power system transients, since they usually consist of multiple frequencies, phasor representations of voltages, currents and impedances are no longer valid. Furthermore, representation of a power system by a single-line diagram derived from say, symmetrical components, is no longer appropriate since the latter are derived from steady state phasor analysis.

The foregoing analysis problem is compounded by the fact that a single physical component in power system network may have a different model representation (depending on a specific transient phenomenon being investigated) in order to achieve the requisite accuracy. For example, a transmission line (or an underground cable) may be modelled by a short bus section, an inductance, a resistance, a series RL circuit, an RLC II or T section (or multiples of such sections cascaded together), or a fully distributed line/cable model. Likewise, a transformer or a shunt reactor may be modelled by simply an inductance, or a network of capacitances or by a combination of the two.

Transient phenomena in power systems is caused by such disturbances as switching operations, faults including those induced by lightning strikes, partial discharges due to defects in power equipment, etc. They involve a frequency range from d.c. to several MHz. In this respect a rudimentary distinction is usually made between electromechanical transients, traditionally covered by transient stability studies, and electromagnetic transients. The latter types of transients can occur on a time scale ranging from microseconds to several cycles. They are a combination of travelling waves on overhead lines, underground cables and buses, and oscillations in lumped element circuits of generators, transformers and other devices. Some slower electromechanical transients, such as subsynchronous resonance (associated for example with series capacitor compensated lines), for which detailed machine models are needed, are usually included in this class of transients.

Transients may result in overvoltages, overcurrents, distorted waveforms or electromechanical oscillations. In general, a single event will cause all of these effects, but depending upon the requirements, a particular one might be of greatest concern. Briefly, the aforementioned four categories within the transient phenomena can be described as:

**Overvoltages** The design and insulation requirements of power equipment is determined by the overvoltages it must withstand. The overvoltage could be quasi-steady state (principally 50/60 Hz) or due to the short duration high frequency phenomena. Examples of the former are voltage excursions due to load rejection or loss of shunt reactive compensation. Examples of the latter are the voltage surge due to a lightning strike or the overvoltages caused by the opening and closing of a circuit-breaker. In this respect, a voltage surge generated by lightning may have a wavefront

as steep as a fraction of a microsecond and may last for a few microseconds. Alternatively, switching surges may have wavefronts of several microseconds and may persist for a few power frequency cycles. It is thus apparent that if the effect of lightning is being studied, the system model must be capable of accurately simulating the power system transients at frequencies up to hundreds of kHz (or even MHz); for studying switching operations, frequencies up to tens of kHz (or even 100 kHz) will be of interest.

**Overcurrents** Overcurrents result from system faults and their knowledge helps to determine the performance of protection relays the required interrupting duty of circuit-breakers, and mechanical and thermal stresses on power equipment. Since a power system is mainly inductive in nature, the transients with short circuit currents are largely restricted to the lower frequency. However, it must be mentioned that although higher frequency transients are also present, they are relatively of much smaller magnitudes in comparison to the lower frequency current transients and/or high frequency voltage transients.

**Distorted waveforms** An accurate knowledge of the shape of the voltage and current signals during either transient or abnormal steady state operating conditions is of considerable importance. For example, when testing a high speed protection relay, the distortion in the voltage and current waveforms immediately after a fault will affect the operating time or stability of the relay. In addition, some protection relays will be affected by the harmonics generated by d.c. converters or non-linear circuit elements.

**Electromechanical oscillations** One particular type of such oscillations, viz, subsynchronous resonance type, are caused by a combination of the series capacitors and natural line inductance; this resonance can exacerbate the torsional oscillations on the generator shaft to cause mechanical failure. Such oscillations thus require detailed simulation models.

This chapter deals with several aspects associated with the electromagnetic transients. It describes in some detail some of the fundamental concepts for transient analysis and an outline of the tools available for simulating such transients through setting up models of the various components within a power system network. An understanding of the transient phenomena is enhanced by an illustration of typical voltage and current transient waveforms.

## 36.2 Basic concepts of transient analysis

As mentioned before, the main causes of power system transients are:

- lightning surges;
- switching surges;
- faults; and
- resonance.

### 36.2.1 Lightning surges

Lightning is the greatest single cause of line outages; for example, it accounts for about 70% of outages on the high voltage transmission system (275 kV, 400 kV, 500 kV, etc.). The physical phenomenon of lightning shows that clouds acquire charge, or at least become polarised. Electric fields become excessive to the extent that the dielectric of the

intervening space can no longer support the electrical stress and breakdown or lightning flashover occurs; this is usually a high-current discharge.

The lightning strikes that create problems for the power engineers are those that terminate on or near to power lines. These can be looked upon as equivalent to closing a switch between the cloud and the power line or adjacent earth, thus constituting a circuit change condition. This is either a direct connection to the line or it completes a circuit with close mutual coupling to the line. Direct consequences of this phenomenon are:

- very often the line will be raised to such a potential that further flashes will occur to grounded structures;
- the grounded structures may be raised to such a potential that they flash over to the line.

The disturbance created on a power line due to the lightning phenomenon involves *travelling waves*. These are essentially voltage surges which, although of short duration, can nonetheless cause overvoltage well in excess of the insulating capabilities of power lines, thus posing a serious threat of damage to expensive equipment and causing disruption.

The basic wave shape of a lightning strike is the 1.2/50  $\mu$ s wave and typifies the lighting surge. This is shown in Figure 36.1.

Figure 36.1 represents a current waveform which rises in 1.2  $\mu$ s and falls to half the peak value in 50  $\mu$ s. Normally only heavy current flowing over the first 50  $\mu$ s is of importance and the magnitude of the peak current ranges from 20 kA to 200 kA. The current/time relationship for the aforementioned wave shape is given by:

$$i = I_{\text{peak}} \left( e^{-\alpha t} - e^{-\beta t} \right) \quad (36.1)$$

where  $t$  is in  $\mu$ s. The values of the constants  $\alpha$  and  $\beta$  depend on the nature of the surge and are typically  $\alpha = 0.002$  and  $\beta = 30$ .

When a lightning strike arrives on an overhead conductor, equal current surges of the waveform shown in Figure 36.1 are propagated in both directions, away from the point of impact. The magnitude of each voltage surge set up is therefore given by:

$$V = \frac{Z_0 I_{\text{peak}} [e^{-\alpha t} - e^{-\beta t}]}{2} \quad (36.2)$$

where  $Z_0$  is the conductor surge impedance.

Figure 36.1 Typical waveform due to lightning

The voltage surge set up depends upon the effective surge impedance of the conductors into which the current discharges (and, of course, on the peak current) but this value is rarely less than about 3 MV peak. Such a voltage is well above the insulating capability of transmission line insulators. It would, however, be economically nonviable to design them to withstand such high voltages (it can be shown that  $\text{cost} \propto V^2$ ). In this respect, overhead shield (or earth) wires are used, which largely prevent direct strikes to the phase conductors.

When an earth wire exists over the overhead line, a strike arriving on tower or on the wire itself sets up the surges in both directions along the wire. On reaching neighbouring towers, they are partially reflected and transmitted further and this process continues over the length of the line as and when towers are encountered. Under this condition, the voltage surges set up on the main phase conductors are significantly smaller than would be the case if the earth wire were absent. This is because, in the presence of an earth wire, the voltage surges set up on the phase conductors are due to the mutual coupling effect between the earth wire and the phase conductors. The coupling factor is typically in the range of  $0.15 < k < 0.3$ .

The initial voltage surge generated on the earth wire depends upon both the tower impedance ( $Z_T$ ) and the earth wire surge impedance ( $Z_{EW}$ ). In this respect, different tower designs present different surge impedances. For example, if the tower tops are connected by a single earth wire of surge impedance  $Z_{EW}$  then the effective surge impedance is given by:

$$Z_{TE} = \frac{Z_T \times 4/2Z_{EW}}{Z_T + 4/2Z_{EW}} \quad (36.3)$$

The half is included with the  $Z_{EW}$  since a wave propagates in both directions from the stricken point.

Current and voltage waves radiate from the point of contact in both directions along the earth wire and down the tower if the tower is involved. These waves rapidly encounter discontinuities such as adjacent towers in the case of earth wires or footing resistance in the case of the tower.

A direct consequence of this phenomenon is that reflected waves are initiated, which cause yet other waves when they return to the stricken point. The effect of these waves will depend on the change of surge impedance at the point of discontinuity. For example, if the initial wave going down the tower encounters a low footing resistance  $R$ , then the reflected wave will be of opposite sign and will act to reduce the tower potential. The reverse will occur if the footing resistance is high.

Transmission line theory<sup>1</sup> shows that reflection coefficient  $\rho_G$  at ground is given by:

$$\rho_G = \frac{R - Z_T}{R + Z_T} \quad (36.4)$$

Also of interest are the refracted ( $\beta_E$ ) and reflected ( $\rho_E$ ) coefficients experienced by the reflected waves returning to the tower top from the ground. Again, using transmission line theory, these can be shown to be:

$$\beta_E = \frac{Z_{EW}}{1/2Z_{EW} + Z_T} \quad (36.5)$$

$$\rho_E = \frac{1/2Z_{EW} - Z_T}{1/2Z_{EW} + Z_T} \quad (36.6)$$

### 36.2.1.1 Back flashover

The potential difference across the suspension insulators is of particular concern since a flashover can occur and a fault is placed on the phase if this voltage becomes excessive. Waves travelling along the earth wire induce waves on the phase conductors, the conductor closest to the earth wire experiencing the highest induced voltage. The effect of this coupling between the earth wire and the phase conductors (typically between 0.15 and 0.3) is to lessen the stress on the line insulators. The induced voltages add to, or subtract from, the power frequency voltages. At any instant, at least one phase will have the same polarity as the lightning surge; such a phase is more likely to flashover. This phenomenon is more commonly known as *back flashover*.

It is desirable, therefore, to have a lower footing resistance. There are two considerations:

- the local resistivity of the earth itself; and
- the connection that is made between the tower and ground.

A typical value for the tower footing resistance  $R$  is  $25\ \Omega$ . After a lightning strike, the time taken for the voltage surge to travel from the tower top to the tower footing and back at the speed of light is typically  $0.25\ \mu\text{s}$ . The resulting magnitude of the voltage surge is thus reduced to typically about 500 kV which is far less daunting than the above 3 MV surge generated at the instant of a lightning strike.

### 36.2.1.2 Summary

- Lightning-induced flashovers are the greatest cause of line outages.
- Overhead earthwires reduce the magnitude of phase conductor voltage surges.
- Low tower footing resistance will reduce tower surge potential and the likelihood of back flashover.

## 36.2.2 Switching surges

### 36.2.2.1 Interruptions of short-circuits and switching operations

When a fault occurs on a transmission line, due for example to a lightning strike, then in order to clear the fault (i.e. if the fault is transient in nature) and at the same time minimise damage, it is normal practice to isolate the faulted conductor(s). This is done by tripping the nearest circuit-breakers, once the fault has been detected by protective relays. However, no circuit which contains an appreciable inductance can have the current in it broken instantly. As power circuits are always inductive, a high induced voltage will occur across any break in the circuit at the instant of current interruption. This voltage is sufficient to ionise the gas molecules in the gap between circuit-breaker contact and conductor, resulting in an arc which strikes between circuit-breaker contact and conductor at the instant of a separation.

It is important to note that the extinction of arc current on opening of a particular circuit-breaker will only remain permanent if the restriking voltage is less than the recovery voltage (see Figure 36.2).

*Note:*

- Restriking voltage is the voltage across the contacts of a circuit-breaker at current extinctions.
- Recovery voltage is the voltage that can be withstood across the contacts of a circuit-breaker after current

**Figure 36.2** Breaker restriking voltage characteristics: 1—breaker recovery voltage, 2—restriking voltage transient with initial rapid rate of rise, 3—restriking voltage transient that does not cause a restriking

extinction. It increases with time. Re-ignition voltage is another term for recovery voltage.

The restriking voltage transient is very largely independent of the breaker characteristics and very much depends upon the transient response of the system with respect to a particular breaker location.

### 36.2.2.2 Current chopping

Current chopping is the extinction of arc current before natural current zero. It is very important that circuit-breakers are designed so that they do not prematurely *chop* the fault current. Unfortunately, current chopping does arise with certain types of circuit breakers, namely the air-blast circuit breakers which operate on the same air pressure and velocity for all values of interruption current.

On low-current interruption, the breaker tends to open the circuit before the current natural-zero and the electromagnetic energy present is rapidly converted to the electrostatic energy.

## 36.2.3 Overvoltage induced by faults

Overvoltage may be produced by certain types of asymmetrical fault such as a ground fault on one of the phase conductors of a three-phase transmission line. The situation is somewhat analogous to the switching transients except that here instead of injecting a current, a voltage equal and opposite to the prefault voltage at the fault point is applied (see Figures 36.3(a)–(d)).

- Figure 36.3(a) shows the faulted system in which a ground fault has occurred on the 'a'-phase at point F.
- Figure 36.3(b) shows the prefault steady-state voltage  $V_{\text{fSa}}$  at the fault point.
- If it is assumed that a fault occurs at the peak of the prefault voltage and  $t = 0$  at this instant, then the voltage injected at the fault point is as shown in Figure 36.3(c).
- Figure 36.3(d) shows the de-energised network to which is applied the voltage  $V_{\text{ffa}}$ . This is also known as the *super-imposed voltage*.

We can study the problem of overvoltage by asking how the de-energised network behaves in response to the application of this voltage. Complex analysis based on travelling-wave theory (such as Bewley lattice diagrams<sup>2</sup>) can be used to depict the level of overvoltage likely to be induced, particularly

**Figure 36.3** A faulted three-phase system: (a) faulted network; (b),(c) faulted network voltage; (d) superimposed network

Figure 36.4 Overvoltage phenomena on a faulted three-phase system

on the unfaulted phases due to the injection of the suddenly applied voltage at the fault point. A line-ground fault of the type considered here can produce an overvoltage on an unfaulted phase as high as approximately twice the normal line-to-neutral voltage.

Figure 36.4 typifies an example of such an overvoltage, in particular when the fault occurs at the midpoint of the line; then maximum voltage is at the midpoint of the unfaulted conductor.

A more comprehensive set of transient voltage and current waveforms associated with different forms of electromagnetic disturbances will be illustrated later on in this chapter.

In practice, since insulator chains are designed to withstand approximately 1.4 times the normal steady-state voltage, there is a likelihood of a fault being induced on a healthy phase (this is also commonly known as an evolving fault) and this can have a detrimental effect on systems employing single-pole tripping.

### 36.2.4 Resonance

It is well-known that, in resonant circuits, severe overvoltage occurs, dependent on the resistance present. For example, voltage at resonance across the capacitance can be high. Although it is unlikely that resonance in a supply network can be obtained at normal supply frequencies, it is possible to have this condition at harmonic frequencies. Resonance is normally associated with the capacitance to earth of items of plant and often occurs on an opened phase due to a broken conductor or a fuse operating.

In circuits containing windings with iron cores, e.g. transformers, a condition due to the shape of the magnetisation curve known as *ferroresonance* is possible. This can produce resonance with overvoltage and also sudden changes from one condition to another with the possibility of an overvoltage surge.

The problems associated with subsynchronous resonance have already been briefly discussed before.

## 36.3 Protection of system and equipment against transient overvoltage

Surges in power systems can be very destructive. It is important to protect power equipment against them wherever possible, consistent with sound economics.

- Firstly, we must strive to prevent lightning surges gaining entry to the systems.
- Secondly, we must minimise the effects of those that do enter.

We must accept switching surges—they are the inevitable consequence of normal system operation. However, we can mitigate their effect by careful design.

The protection of terminal equipment in substations is of particular concern because damage there can be very costly in replacement and in outage time. A family of surge protection devices has been developed over the years which assist greatly in this task.

Surges can intrude into control circuits causing destruction and/or maloperation of relays, measuring equipment, monitors, etc.

### 36.3.1 Protection of transmission lines against lightning

As mentioned before, it is common practice to protect overhead lines against lightning by the employment of one (or more) earth wires that are strung from tower to tower above the phase conductors. These wires are bonded to the towers so that they are essentially at ground potential under normal conditions.

The intent in the disposition of these wires is to have them intercept lightning strikes that would have otherwise terminated on the phase conductors themselves, the effects of induced surges from indirect strikes is significantly lessened.

An aspect of vital importance, quite apart from the prevention of damage, is the maintenance of supply. Most flashovers do not cause permanent damage and therefore a complete and lasting removal of the circuit from operation is not necessary. Nowadays this is achieved by the use of *autoreclosing* circuit-breakers.

### 36.3.2 Surge protection

Inevitably, even the best shielding schemes will either not be fully effective or fail from time to time. Some switching operations and faults may generate overvoltage which can be potentially hazardous to the insulation of the plant. To protect the equipment against these contingencies, various devices have been developed. These devices are placed in parallel with the plant to be protected. Their purpose is to ensure that under no circumstances will the voltage across them exceed what the protected object can support.

#### 36.3.2.1 Rod gaps and resistance suppressors

In the case of a transmission line insulator, a surge diverter in the form of *rod gaps* is commonly used as a crude protection device by placing it in parallel with the conductor insulator. However, it does have the disadvantage that often, after the surge responsible for breaking the gap between the rods has discharged, a power arc is maintained, i.e. a fault is thrown on the circuit. It is true that this can be removed by opening circuit-breakers at the two ends of the line and the power then restored by reclosing the breakers after the rod gap has de-ionised (the commonly employed circuit-breaker autoreclosing technique). Certainly, this is preferable to damaging a costly piece of equipment and perhaps sustaining a lengthy outage; but a device that can effect the voltage limiting without creating a fault is obviously more attractive. The *non-linear* resistor is such a device. These resistors have the property that their resistance diminishes sharply as the voltage across them increases.

36.3.2.2 Lightning arrester

Circumstances will arise in which it is impossible to obtain the desired protection by using non-linear resistors. For example, if the ceiling voltage to which surges must be limited are  $\leq 3$ -times the normal system voltage, the values of the resistance at system voltage may be so low that they make the steady-state losses prohibitive.

An improved but more expensive surge diverter is the lightning arrester. In such devices, the non-linear resistance elements are as before but they have a gap(s) in series with them. In this way, the resistor is isolated from the circuit in normal conditions and is introduced when a surge appears by the sparkover of the gap(s).

36.3.2.3 Surge capacitors and surge reactors

If a capacitor is placed in parallel with a piece of equipment it will provide some measure of protection against voltage surges—the surge can only impress a high voltage on the equipment as quickly as it can charge the capacitor. The effectiveness of the capacitor in holding down the voltage depends on the energy conveyed by the surge and the capacitance of the capacitor. Such capacitors are particularly effective against voltage *spikes*, i.e. short duration voltage surges. In this respect, the combination of a capacitor and some other protective device such as an arrester, can be very useful because they complement each other.

Surge reactors are sometimes used to protect voltage surges, particularly within pieces of a.c./d.c. conversion equipment, in a manner that complements the use of surge capacitors. The capacitor parallels the equipment to be protected; the reactor is placed in series with the equipment. When a surge reaches such a series combination, the initial tendency is for the surge voltage to appear primarily across the reactor because this offers the highest impedance to the rapidly changing surge current.

Like capacitors, the ability of reactors to store energy is limited, but again like capacitors, they can take care of low energy surges, or act temporarily to protect a device until such time as a gap can flashover or an arrester operates.

36.3.3 Transient voltages and grounding practices

Good grounding practices can contribute quite significantly to more reliable and safer utility and industrial power systems. We are concerned with minimising the damage to equipment and false operations of equipment, under transient conditions and also with the avoidance of shock hazard to personnel.

Under steady-state, quiescent operating conditions in a power system:

- the integrity of equipment is preserved by adequate insulation; and

- the safety of personnel is secured by keeping sufficient separation between people and high-voltage conductors.

Preferably, a *grounded barrier* in the form of a metal enclosure, wire fence etc. is placed between the circuit and any personnel. In this respect, grounded barrier refers to a physical equipotential surface, at the same potential as local ground and any other grounded objects around. However, under abnormal conditions such as when a fault occurs, this situation may no longer prevail and *ground* becomes a relative thing.

In industrial plant, ground fault currents are usually confined to the specially laid ground mat of the building and to cable sheaths. In utility systems, *true* ground is often involved and it is vitally important to connect the buried mat to ground via metal rods (typically 2–3 m long) into the ground. The effectiveness of these rods is critically dependent on the resistivity of the soil; it varies widely with location and weather conditions, from a few thousand to hundreds of thousands of ohms cm.

36.3.4 Insulation co-ordination

The equipment used in a power system comprises items having different breakdown withstand voltages and different volt/time characteristics. In order to protect adequately all items of the system it is necessary to consider the situation as a whole and not items of plant in isolation, i.e. the insulation protection must be co-ordinated. To assist this process, standard insulation levels are recommended and are summarised in *Table 36.1* below.

36.3.4.1 Definitions

- Impulse refers to a transient voltage developed in a laboratory test and is an approximate representation of a surge that develops in nature.
- The term impulse is defined as the impulse peak voltage/crest value of the power frequency voltage to cause flashover.

36.4 Power system simulators

Simulation is one of the most powerful tools available to the power systems engineer when confronted with the need to study complex power systems phenomena. In this respect several tools have been used over the years to model and analyse electromagnetic transients. At early stages, miniature power system models, known as transient network analysers (TNA), were used. At present, the digital computer is the most popular tool, although TNAs are still used. In addition, the new generation of real-time digital systems are probably the most adequate tool in certain applications

Table 36.1 British substation practice

Nominal voltage (kV)	Impulse (peak kV)	Power frequency withstand (peak kV)	Minimum clearance to ground (m)	Minimum clearance between phases (m)	Co-ord gap setting (m)
11	100	29	0.2	0.25	$2 \times 0.03$
132	550	300	1.1	1.25	0.66
400	1425	675	3.05	3.55	1.5–1.8

for which either a very high-speed or a truly real-time simulation is required.

### 36.4.1 The transient network analyser (TNA)

In a TNA, the power system components such as transmission lines, transformers, shunt reactors, circuit-breakers, etc. are scaled down to low current, low voltage, lumped inductance, capacitance and resistance circuits. A power network modelled using these circuits is then energised using generators modelled by ideal voltage sources behind *Thevenin* equivalent reactances.

The main advantages of a TNA are that the simulator operates in real time (providing analogue signals), there are no computationally unstable solutions and many users believe that a physical miniature model is closer to the actual system than a mathematical model.

The main disadvantages of a TNA are inflexibility, large capital cost (including regular maintenance cost), the time required to set up the system, limitations on the number/type of equipment models, problems associated with designing miniature inductors with the same 'R' to 'L' ratio as the actual power components, a drift in the component values due to ageing/environment and the finite length of lines that can be modelled using serially connected  $\Pi$  (or T) circuits.

### 36.4.2 Digital computer simulation

The studies to solve travelling wave problems by means of a digital computer were started in the early 1960s using two different techniques, the Bewley lattice diagram and the Bergeron method.<sup>2,3</sup> These techniques were applied to solve small networks with linear and non-linear lumped-parameter, and distributed-parameter elements. The extension to multi-node networks was made by Dommel<sup>4</sup>; this scheme essentially combined the Bergeron method and the trapezoidal rule into an algorithm capable of solving transients in single and multi-phase networks with lumped and distributed parameters. This solution was the birth of the now very widely employed and universally accepted Electromagnetic Transients Program (EMTP).

Essentially, the trapezoidal rule is used to convert the differential equations of the network components into algebraic equations involving voltages, currents and past values. The algebraic equations are assembled using a nodal approach given as:

$$[G] \cdot [v(t)] = [i(t)] - [I] \quad (36.7) \Leftarrow$$

where  $[G]$  = nodal conductance matrix  
 $[v(t)]$  = vector of node voltages  
 $[i(t)]$  = vector of current sources  
 $[I]$  = vector of 'history' terms

Very often, the network contains voltage sources to ground; the equation is then split up into part E with unknown voltages and part F with known voltages given as:

$$[V_E(t)] = [i_E(t)] - [I_E] \Leftarrow [G_{EF}] \cdot [v_F(t)] \Leftarrow \quad (36.8) \Leftarrow$$

The resulting conductance matrix is symmetrical and remains unchanged as the integration is performed with a time-step size. The solution of the transient process is then obtained using triangular factorisation. One of the main advantages of this approach is that it can be applied to networks of arbitrary size in a very simple manner.

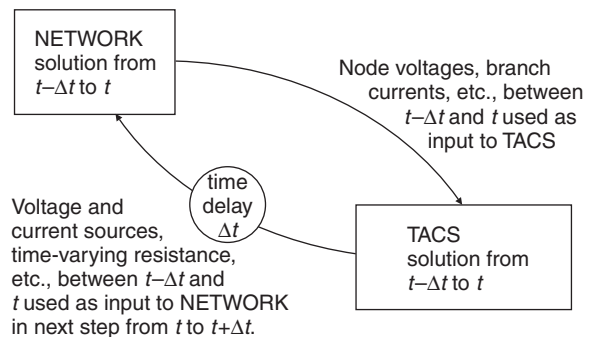

Bergeron's method can be efficiently used with lossless and distortionless lines. However, in practice, parameters of actual transmission systems are frequency dependent. Much effort has been expended since then into developing alternative frequency-dependent line models<sup>5,4</sup> and these have been subsequently incorporated within the EMTP software. In this respect, it should also be mentioned that some researchers have overcome this problem by developing simulation techniques for transmission systems which are totally frequency-domain based such as the one developed by Johns and Aggarwal.<sup>7</sup> Although the latter approach gives a very accurate solution to the problem, the principal disadvantage is that for any time-domain circuit change (most circuit changes are time-domain based), the variable in question has to be transformed into its frequency spectrum first before a solution can be effected.

The drawback of the original Dommel's scheme was that it could be used to solve only linear networks. However, many power components such as transformers, reactors, surge arresters, circuit-breakers, etc., exhibit a non-linear behaviour. Several modifications to the basic method were thus proposed to cater for non-linear and non-stationary elements.<sup>8</sup>

The development of the very widely used EMTP software has been evolutionary in nature. Apart from the foregoing changes, a very important development was that of a section for representation of control systems, initially motivated by studies of HVDC links. The Transient Analysis of Control Systems (TACS) option was implemented in the EMTP in 1976.<sup>9</sup> Although the main goal was the simulation of HVDC converters, it soon became apparent that TACS had many other applications, a major attribute was in the fact that many externally developed non-linear models representing, for example, fault arcs (primary and secondary), dynamic arcs in circuit-breakers, protection relay, etc. can be interfaced to the main EMTP-based system model via TACS. Control systems are represented in TACS by block diagrams with interconnection between system elements. Control elements can be transfer functions, FORTRAN algebraic functions, logical expressions and emulation of special devices. Essentially, when employing TACS, the network solution is first advanced, network variables are next passed to the control section and then the control equations are solved. Finally, the network receives control commands. The whole procedure introduces a time-step delay as illustrated in *Figure 36.5*.

### 36.4.3 Digital real-time electromagnetic transient simulator

One of the limitations with digital computer based simulator programmes, such as the EMTP, is that a single run can

**Figure 36.5** Interface between a network and a control system

take many minutes (or even hours) to complete the modelled system's response over a period of, say one second. Such non real-time operation precludes interfacing the simulator to physical control or protection devices. Generally, testing of such devices is done using an analogue simulator (such as a TNA) or a special device which plays back, in real time, the stored results of an off-line computer simulation to the device under test.

As mentioned before, one of the drawbacks of the analogue simulator is its high capital and operating costs. Furthermore, general accessibility is low since a single study may occupy the analogue simulator for many weeks. With the playback device, major drawbacks include the long time required to obtain the simulated results coupled with the fact that only open loop testing is possible i.e. it is not possible to study the effect of circuit changes (such as those due to circuit breaker operations) within a network on the devices under test.

The principal advantages of a fully digital simulator capable of real-time operation are that it incorporates the best features of both the computer-based digital simulation tool and the analogue simulator.

## 36.5 Waveforms associated with the electromagnetic transient phenomena

### 36.5.1 Introduction

As mentioned before, the electromagnetic transient phenomena in power system networks can have a wide range of frequencies varying from d.c. to several MHz. Modelling of power components taking into account the frequency-dependence of parameters can be practically made by developing mathematical models which are accurate enough for a specific range of frequencies. Each range of frequencies usually corresponds to some particular transient phenomena. A widely accepted classification of frequency ranges is in the following four groups (with some overlapping):

- low-frequency oscillations, 0.1 Hz–3 kHz;
- slow-fronted surges, 50/60 Hz–20 kHz;
- fast-fronted surges, 10 kHz–3 MHz; and
- very fast-fronted surges, 100 kHz–50 MHz.

This section illustrates some typical transient waveforms associated with the aforementioned categories of frequencies.

### 36.5.2 Transient waveforms

As mentioned before, a common cause of low-frequency electromagnetic transients is resonance:

- (i) Sub-synchronous resonance (typically about 20 Hz) due to the interaction of an externally inserted series capacitor into a transmission line and the natural inductance of the line; such phenomenon can have a detrimental effect on the rotating shaft of a generator, bringing about its premature failure;
- (ii) Ferro-resonance (typically about 16 Hz) due to the interaction of the saturable magnetising inductance of a transformer and a capacitive distributive cable or transmission line connected to the transformer. An abnormally large exciting current is drawn resulting in a significantly distorted transformer voltage output.

Slow fronted surges commonly emanate from switching of circuit breakers and shunt faults. The results involving such studies are useful for:

- (i) evaluating the performance (or new design) of protection/control devices;
- (ii) insulation co-ordination to determine overvoltage stresses on equipment;
- (iii) determining the surge arrester characteristics;
- (iv) determining the rupturing capacity of circuit breakers and/or the transient recovery voltage across circuit breakers; and
- (v) assessing the effectiveness of transient mitigating devices such as pre-insertion resistors, inductors, etc.

*Figure 36.6(b)* typifies the three voltage waveforms, simulated at the open end of a high voltage transmission system shown in *Figure 36.6(a)*, when the line is energised by closing the circuit breaker. It is assumed that prior to circuit breaker reclosure, the line carries a trapped charge of  $-0.9$ ,  $-0.8$  and  $0.8$  per unit on the a, b and c phases, respectively. It is apparent that the transient overvoltages produced are significantly higher than the nominal source voltage.

The electromagnetic transient phenomena associated with faults on overhead transmission lines is largely dictated by a number of factors, the principal of which are: type of fault, fault location, fault inception angle, bus-bar terminations in terms of source capacities.<sup>7</sup> *Figure 36.8* typifies the voltage and current waveforms when an 'a'-phase-ground fault occurs near voltage maximum of the 'a'-phase, and at the mid-point of a 400 kV transmission system shown in *Figure 36.7* (the waveforms are simulated at end S). Comparing *Figure 36.8(a)* and *Figure 36.8(b)*, it is apparent that the magnitude of the high-frequency distortion is very significantly mitigated by the relatively large source capacity termination at end S.

*Figure 36.9* interestingly shows that when an 'a'-phase-ground fault occurs near minimum of the 'a'-phase, there is little high frequency distortion in the voltage waveforms; importantly, there is a large d.c. offset in the current waveforms.

The electromagnetic transient phenomenon of much interest is that associated with the sequence of events that take place on high voltage transmission systems employing three-phase tripping. The voltage and current waveforms simulated at end S of the transmission system as shown in *Figure 36.10* very vividly depicts the electromagnetic transients generated on waveforms (voltage waveforms in particular) following a fault (time  $T_1$ ) and their characteristic features on circuit breaker opening ( $T_2$ )/fault break off ( $T_3$ ). Of particular importance is the large d.c. levels on the previously healthy phases 'b' and 'c', and these are as a direct consequence of the line trapped charge; in practice, care needs to be exercised when reclosing the breakers as such d.c. levels can significantly accentuate the overvoltage phenomenon, posing serious problems for such devices as the capacitor voltage transformers (CVTs) employed for protection devices.

A study of the electromagnetic transient phenomenon associated with arcing faults on long distance high-voltage transmission lines, in particular those employing shunt compensation for suppressing secondary arcs in single pole auto-reclosure, is of particular interest to design engineers worldwide. *Figure 36.11* depicts the voltage and current waveforms attained for an 'a'-phase-earth fault on a shunt compensated 500 kV high voltage transmission line, 540 km in length. In the Figures, ' $t_1$ ', signifies breaker opening time

**Figure 36.6** Switching transients on a high voltage transmission line: (a) the transmission system studied; (b) the voltage waveforms simulated at the line open end

Figure 36.7 A typical transmission system simulated

Figure 36.8 Effect of source capacities on voltages and currents: 'a'—earth solid fault at mid-point of line; scl = short circuit level; (a) end S scl = 35 000 MVA, end R scl = 35 000 MVA; (b) end S scl = 5 000 MVA, end R scl = 35 000 MVA

**Figure 36.9** Waveforms for fault applied at voltage zero; 'a'—earth solid fault at receiving end; end S scl = 5000 MVA, end R scl = 35 000 MVA

**Figure 36.10** Three-phase tripping transient fault simulation; 'a'—earth mid-point fault;  $T_1$  = fault inception (5 ms);  $T_2$  = breaker contacts at ends S and R separate (65 ms);  $T_3$  = fault breaker off ( $\sim 80$  ms)  $\odot$  a-phase;  $\oplus$  b-phase;  $\otimes$  c-phase; (a) voltages on line side of breaker at end S; (b) line currents at end S

on the faulted 'a'-phase conductor and ' $t_2$ ' the secondary arc extinction time. Apart from the high frequency distortion, interestingly, the voltage waveforms also show the 'slow' beating frequency (typically 5 Hz) due to the interaction of the external shunt reactors with the natural line parameters.

The waveforms presented here are only a small sample of those encountered in practice. A more comprehensive knowledge of the electromagnetic transient phenomena on high voltage transmission lines can be attained from references.<sup>7,10-12</sup>

As mentioned before, the fast-fronted transients in power systems cover a frequency range from 10 kHz up to about 1 MHz. One of the principal causes of such transients is the lightning strikes to the transmission lines and associated backflashovers. It is important to note that although the foregoing waveforms (Figures 36.8–36.11) are also associated with faults on transmission lines caused by lightning strikes, the transients considered are at the lower-end of the frequency spectrum ( $< 5$  kHz). The transient waveforms presented henceforth typify those encountered inside a substation and are at the higher end of the frequency spectrum. One of the important objectives of performing power system studies involving lightning surge phenomena is to design substations, principally to:

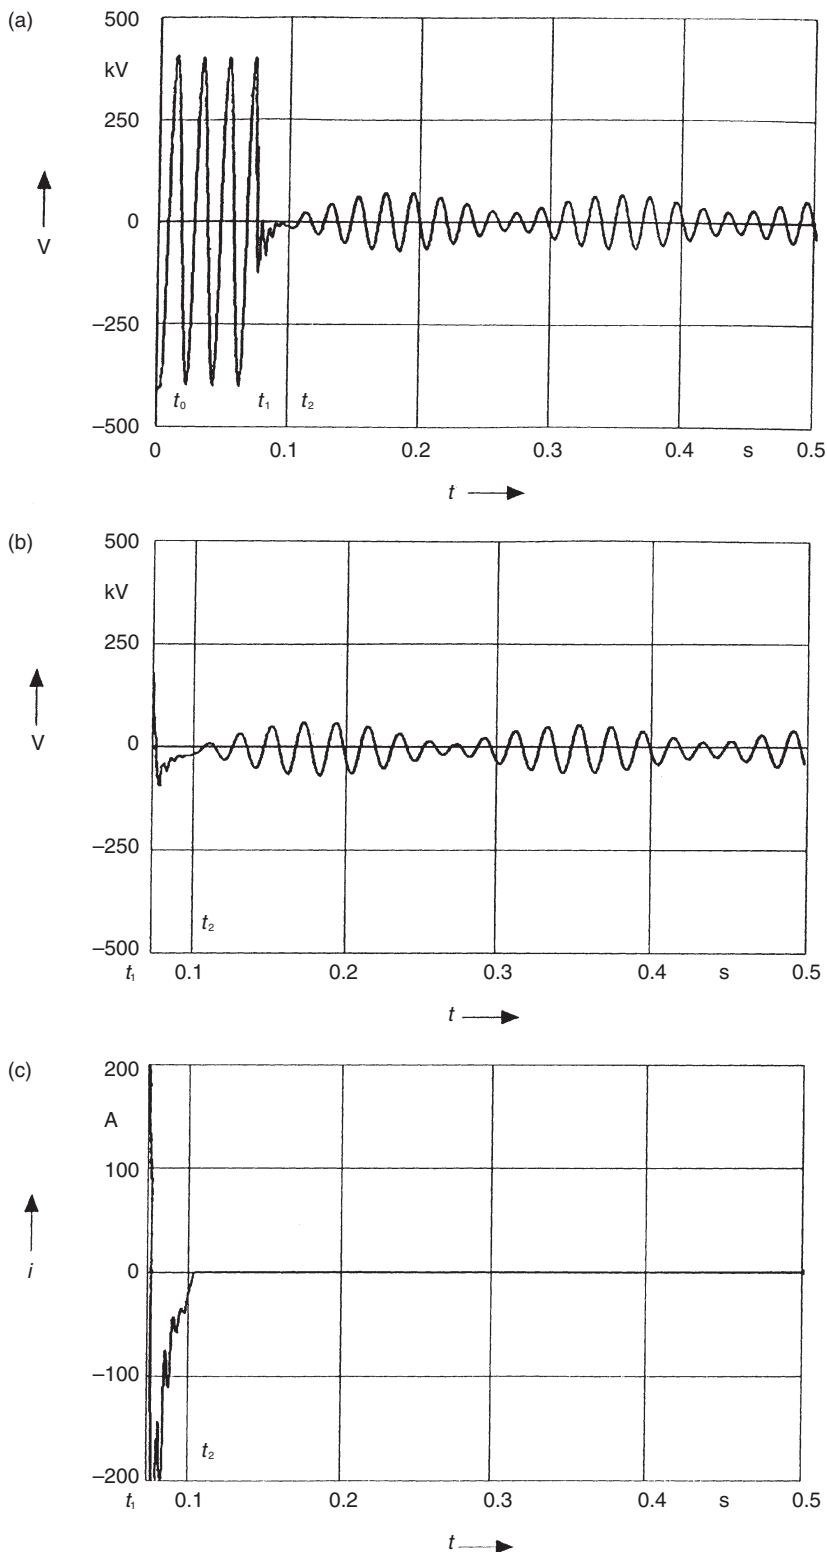

- establish/verify surge arrester ratings;
- find optimum location for surge arresters for lightning surge protection;
- determine minimum phase-to-ground and phase-to-phase clearances;
- calculate mean time between failure for the substation; and
- determine optimum location of capacitances to reduce steepness of surges.

Figure 36.12 typifies the steep-fronted voltage waveforms at various equipment locations inside a 230 kV substation with 500 kV insulation breakdown level (BIL) when there is a  $3/75 \mu\text{s}$  lightning strike of 110 kA striking a tower approximately 150 m from the substation. It is apparent from the transient waveforms that in spite of the very large overvoltages encountered, the surges are well below the equipment BIL of the substation and this can be directly attributed to the presence of surge arresters placed at strategic points within the substation. It should be mentioned that the transients presented herein are for one case study only. However, there are situations whereby the BIL rating of the substation could be exceeded and hence it is crucial to perform a comprehensive set of studies in order to ascertain the type/rating of arresters and their optimal locations.

Very fast transient (VFT) overvoltages are commonly encountered in a gas insulated substation (GIS), and they are primarily generated during disconnector operations, but other events such as the operation of a circuit-breaker, the closing of a grounding switch or the occurrence of a fault can also cause VFTs. During a disconnector operation, a number of prestrikes or restrikes occur due to the relatively slow speed of the moving contact.

The generation and propagation of VFT from their original location throughout a GIS can produce internal and external overvoltages. The main concerns are internal overvoltages between the centre conductor and the enclosure. However, external VFT can be dangerous for secondary and adjacent equipment. These external transients include transient voltages between the enclosure and ground at GIS-air interfaces, voltages across insulating spacers in the vicinity of GIS current transformers, particularly when they do not have a metallic screen on the outside surface, voltages on the secondary terminals of GIS instrument transformers, radiated electromagnetic fields which can be dangerous to adjacent control or relay equipment.

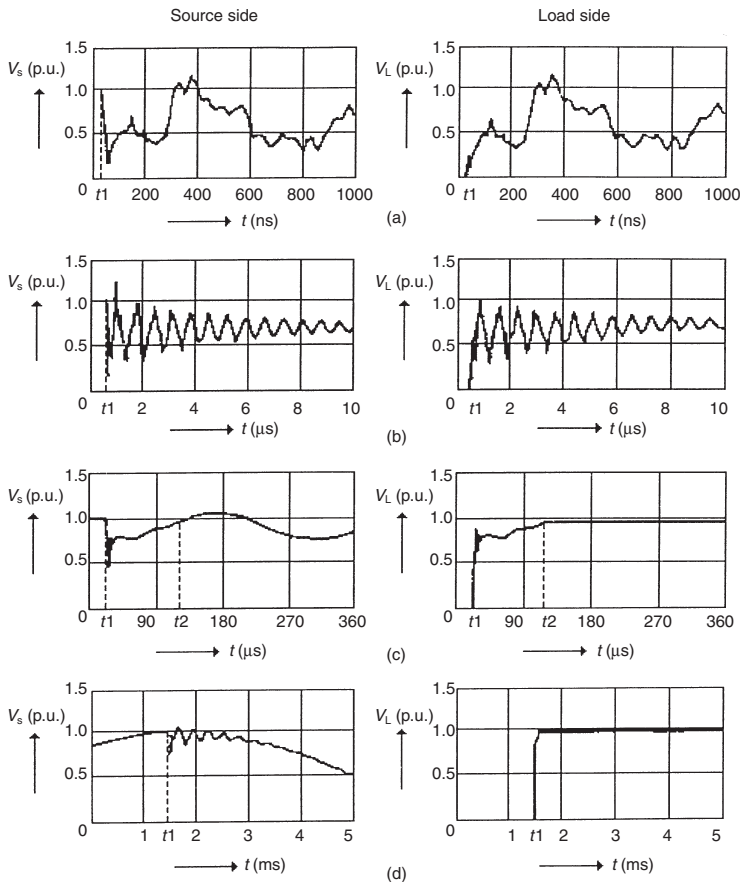

An example of the foregoing transient phenomenon in an actual GIS is given in Figure 36.13, where one pre-strike of

**Figure 36.11** Voltage and current characteristics for a long distance practical system, phase-to-ground fault 400 km from the local end: (a) sending end voltage ( $t_0 = 0$ ,  $t_1 = 0.078$  s,  $t_2 = 0.101$  s); (b) secondary arc voltage; (c) secondary arc current

**Figure 36.12** Phase-ground voltage waveforms inside the substation: (a) dead-end tower; (b) station entrance; (c) circuit-breaker; (d) remote switch; (e) operating bus; (f) inspection bus. All voltages in kV

**Figure 36.13** Transients on the source and load sides of a GIS due to disconnecter switching: (a) steep voltage transients; (b) basic frequency components of the VFT in the MHz range; (c) overall transients in the KHz range; (d) low frequency transient and steady state condition

a disconnecter switching is depicted showing the steep fronted voltage transients at the supply and load sides. The basic frequency component is in the MHz range; the overall transient and the steady state waveforms are also shown.

## 37.1 Introduction

In the 1980s when optical fibres were in their infancy, they were primarily used by the telecommunications industry to replace the copper lines normally used in telephone networks and the long-haul coaxial trunk links between telephone exchanges. Nowadays, this cost-effective medium with its high transmission bandwidth, low attenuation and relative immunity to ElectroMagnetic Interference (EMI) has become increasingly advantageous in the fields of data communications, Local Area Networks (LANs), Urban Broadband Service Networks (UBSNs), Community Antenna Television (CATV), and control applications. Fibre (especially in digital communications) overcomes the problems of different earth potentials between locations, is unaffected by the electric fields found in high-voltage environments, lightning strikes and other electromagnetic interference (e.g. the high magnetic fields caused by transformers and motors etc.). As the data transfer rates of local area networks increase, fibre becomes increasingly attractive and more economically viable. In terms of pence per metre per unit bandwidth, in an increasing number of applications, fibre as a transmission medium is the obvious choice.

In the electrical power industry, these advantages have meant that fibre optics and the technology of fibre optics has replaced normal cable systems and is now widely used for a variety of purposes. The adoption of fibre optics by the telecommunications technology is already well advanced and the realisation of reliable optical data transmission for protection and control has been convincingly demonstrated. Furthermore, research into optical fibre based parameter sensing has reached the stage that properly engineered systems are now available and their integration into optical fibre networks has produced a purely optical monitoring and transmission system.

This chapter of the *Electrical Engineers' Reference Book* contains a brief introduction to optical propagation in fibres followed by a description of the technology of cabling and interconnecting fibres. The present status of communication and telemetry along high voltage transmission lines is discussed and progress towards the optical fibre monitoring of power equipment in substations and elsewhere on a power system is described.

## 37.2 Optical fibre fundamentals

### 37.2.1 Optical propagation in fibres: ray theory

Strictly speaking, one should not use the term 'light' when referring to most optical fibre transmission systems. Normally, near infra-red radiation (with a wavelength in the range 780–1550 nm), derived from a light-emitting diode (LED) or semiconductor laser, is employed and as such, the radiation is not usually visible to the naked eye. However, 'light' is the term commonly employed, and is used here.

Light propagation through an optical fibre depends upon total internal reflection at the interface between two transparent materials with high and low refractive indices. Figure 37.1 shows that as a ray approaches a boundary within a transparent medium, it can be totally internally reflected at the high–low refractive index interface, and will be guided along the high refractive index medium. As the angle at which the approaching ray increases, a critical value ( $\theta_2$ ) may be reached beyond which light 'leaks' out of both media.

The most basic type of optical fibre can be developed from the above principle by using a cylindrical geometry. Rays beyond the critical angle are trapped within the fibre core and travel down the fibre.

Figure 37.1 Ray diagram for multimode step index fibre

### 37.2.2 Acceptance angle and numerical aperture

The acceptance angle is a function of the refractive indices of the core and the cladding materials. The sine of the acceptance angle is called the numerical aperture.

Consider the fibre illustrated in *Figure 37.1*, having a circular core of diameter  $d$ , and a uniform refractive index  $n_1$ , surrounded by a cladding layer of uniform refractive index  $n_2$ . Light launched into the core at angles  $\theta_1$  will be propagated within the core at angles  $\theta_3$  up to a maximum value  $\theta_2$  to the axis. Light at angles greater than  $\theta_2$  will not be internally reflected and will be refracted into the cladding. The maximum launch or acceptance angle  $\theta_1$  can be expressed as a function of the Numerical Aperture (NA), where:

$$NA = (n_1^2 - n_2^2)^{1/2} = \sin \theta_1 = n_1 \sin \theta_2 \quad (37.1)$$

Note that reciprocity dictates that what is true for light entering the core of a fibre is also true for light exiting. The fibre core diameter ( $d$ ), the NA, and the operating wavelength ( $\lambda$ ) are often used together in a single parameter, known as the normalised frequency, waveguide parameter, or fibre parameter ( $V$ ), which is of importance in characterising all fibres:

$$V = \frac{\pi d}{\lambda} \cdot NA \quad (37.2)$$

### 37.2.3 Basic fibre types, modes, mode conversion and bandwidth

Two types of fibre are used for optical transmission (step-index and graded-index) and two modes (single-mode and multimode).

**Figure 37.2** Single-mode optical fibre, together with its refractive index profile and cross-section

#### 37.2.3.1 Single-mode fibre

Single-mode fibre (also referred to as fundamental or mono-mode fibre) will permit only one mode to propagate and, as such, cannot suffer mode delay differences. Single-mode fibres are capable of wide bandwidths (e.g. >40 GHz) and are, therefore, ideally suited for long-haul and high capacity circuits. Single-mode fibre are used almost universally in telecommunications over 1 km or so and are generally used at the 1300 nm and 1550 nm wavelengths where attenuation is low and sources and detectors are available.

#### 37.2.3.2 Multimode fibre

In comparison to single-mode fibre, multimode fibre has a relatively large core (typically 50–60  $\mu\text{m}$ ) and a high numerical aperture. As the name implies, multimode fibres are capable of propagating more than one mode at a time and they are ideally suited for high bandwidth (i.e. a few GHz) and medium haul applications. Multimode fibre has become increasingly popular in the last decade and is now widely used in high-speed (e.g. 100 Mbit/s) local area networks, and 62.5/125 (core/cladding diameters in  $\mu\text{m}$ ) fibre was specified as the first choice for the ANSI X3T9.5 committee Fibre Distributed Data Interface (FDDI) standard.

#### 37.2.3.3 Step index fibre

A small glass fibre in air has a large critical angle of approximately  $42^\circ$ . This enables propagation along paths that are much longer than the axial route but attenuation and dispersion losses are substantially increased. By making the fibre core extremely narrow (e.g. 150  $\mu\text{m}$ ) and enclosing it in a cladding material whose refractive index is only slightly lower than the fibre, will not only reduce the critical angle but also reduce the losses.

Waveguide theory shows that the total number of modes which can be sustained in a step index fibre is given by

**Figure 37.3** Step-index multimode fibre, together with its refractive index profile and cross-section

Figure 37.4 Refractive index profiles (typical dimensions shown)

$N = 4\pi^2/\lambda^2$ . Modes can be visualised as rays propagating at differing angles to the fibre core. Discrete and definable modes only can propagate because of the geometrical constraints of the fibre, and are analogous to modes in hollow metallic waveguides used at microwave frequencies (ca. 1–100 GHz). Typical multimode fibres, with core diameters of 50–200  $\mu\text{m}$  propagate 100–1000 modes. It is not necessary for the general user of fibres, however, to understand the mathematics of propagation.

In a multimode step index fibre (Figure 37.4(a)), no matter how careful one is to launch a single mode, conversion between modes or ray angles is inevitable because of bending and fibre imperfections. This is a great drawback for such fibres, because different modes travel at different speeds down the fibre, causing different arrival times at the receive end. The difference in transit time between the extreme ray paths for a multimode step index fibre of length  $L$  is given by:

$$\Delta T_{\text{intermodal}} = \frac{L}{c}(n_1 - n_2) \quad (37.3)$$

where  $c$  is the velocity of light. The difference in transit times causes a sharp pulse of launched light to become spread at the distant end, limiting the bandwidth of a system. Typically, for an all-silica based fibre of  $\text{NA} \approx 0.2$ , pulse spreading is of the order of 50 ns/km, and is inversely proportional to the length of the system; the longer the system, the lower the bandwidth.

As  $V$  is reduced, less guided rays or modes can be supported, and when  $V < 2.405$ , only a single waveguide mode can propagate. Such single mode fibres have a core diameter which is comparable with the wavelength of light ( $d$  is commonly 8–10  $\mu\text{m}$  for telecommunications fibres see Figure 37.4(b)), making fibre-fibre and fibre-device interconnection more difficult and generally less efficient than for multimode fibres. Intermodal dispersion does not occur, and bandwidths can be very high.

It should be noted, however, that a fibre which is single mode at, say, 1300 nm will not necessarily be single mode at 850 nm or below.  $V$  increases as the wavelength decreases, and will generally be greater than 2.405 at 850 nm. A wavelength known as the cut-off wavelength is an important manufacturing parameter defining the onset of multimode behaviour.

Simple ray optics cannot describe the propagation of energy through a single mode fibre very well as it is difficult to depict a single ray being guided. Mathematical modelling of single and multimode fibre may be achieved by solving Maxwell's equations with boundary conditions defined by fibre geometry and wavelength. This involves Bessel functions and is beyond the scope of this introduction. One of the important results of mathematical modelling, however, is that optical power is not confined to the core alone, but extends appreciably into the cladding region—the power distribution is approximately Gaussian. The extent of cladding penetration is dependent primarily on refractive index difference and wavelength.

#### 37.2.3.4 Graded index fibre

In an effort to overcome bandwidth and connection difficulties, a fibre type (known as graded index fibre) was developed as an intermediate step between index multimode and step index single mode. Although previously only used for long-haul (i.e. trunk) networks, graded index fibres are nowadays frequently being employed in local networks at the 850 and 1300 nm wavelengths.

The principle behind graded index fibre is shown in Figure 37.4(c). Here, the refractive index profile is graded, and ray paths are curved as the rays are continually refracted (Figure 37.5). Rays which travel closer to the core-cladding boundary are in a region of lower refractive index, and will, therefore, travel faster than those in the denser central core area. The overall effect, given the appropriate refractive index profile, is that rays travelling

Figure 37.5 Typical ray paths for graded index fibre

different paths arrive at the far end at approximately the same time. The exact index profile to minimise dispersion effects is dependent on the composition of the fibre and the operating wavelength, but is approximately parabolic.

### 37.2.3.5 Material dispersion

As the refractive index of a glass prism varies with wavelength, different wavelengths (from an LED and even a narrower linewidth laser source) travelling at different velocities down the fibre will arrive at different times. This causes an energy loss which is called material dispersion, and which predominates in single-mode fibres. The speed of light propagating in the fibre is inversely proportional to the refractive index of the propagating medium, and the refractive index of silica drops from 1.46 to 1.44 between 600 and 200 nm, approximately. The variation of the material dispersion parameter  $M(\lambda)$  with respect to wavelength is given by

$$M(\lambda) = -\frac{\lambda d^2 n_1}{c d\lambda^2} \quad (\text{ps/nm/km}) \quad (37.4) \Leftarrow$$

and is shown for silica in Figure 37.6. Pulse broadening in a particular case can be calculated by multiplying the value of  $M(\lambda)$  by both the length of fibre in question and the linewidth of the source in nanometres. An LED source, for example, operating at 850 nm, and with a linewidth of 40 nm will give pulse spreading of some 4 ns/km, and this spreading may be significantly reduced by using a laser source with much reduced linewidth of typically 4 nm or less. The bandwidth length product is generally specified for multimode telecommunications and data communications grade fibres, and is generally of the order of a few hundred megahertz-kilometre product.

Note that  $M(\lambda)$  goes through zero at approximately 1300 nm. First generation telecommunication systems operated with multimode fibre in the region of 850 nm, called the first window (where many sources and detectors were available, and fibre losses were acceptable at approximately 3 dB/km or greater), but second generation (or second window) systems operate at 1300 nm and can exploit the dispersion zero to give high bandwidths. At 1300 nm, losses can also be substantially below 1 dB/km, giving far greater transmission distances before regeneration is required. A third window at 1550 nm, at which attenuation can be less than 0.2 dB/km, is now widely used throughout the telecommunications industry. Figure 37.7 shows nominal attenuation

Figure 37.6 Material dispersion versus wavelength for silica

**Table 37.1** Fibre types

Type	Core/cladding diameter (µm)	Typical attenuation (dB/km)	Typical bandwidth (MHz/km)	Applications
<i>All silica</i>				
Step index multimode	50/125–200/300	3–10 at 850 nm	20	Data links
Graded index multimode	50/125–100/140	3 at 850 nm <1 at 1300 nm	200–1000	Telecommunications, data links
Single mode	5/125–10/125	<0.5 at 1300 nm <0.25 at 1550 nm	>1000	Telecommunications, high speed data links
<i>Other</i>				
PCS	50/125–200/300	5–50 at 850 nm	20	Data links
All plastic	50/100–50/1000	>100	<20	Light pipes, electrical isolation, short data links

**Figure 37.7** Nominal attenuation versus wavelength for silica fibre (showing operating windows)

versus wavelength for all-silica fibre, and indicates operating windows.

By modifying the chemical composition of single-mode fibre, and the geometry of the core and cladding, the zero of  $M(\lambda)$  can be moved to 1550 nm (the third window), which gives further advantages in terms of attenuation, as is explained in the next section.  $M(\lambda)$  can also be flattened to give near zero dispersion at both 1300 and 1550 nm, but this is achieved only at the expense of an attenuation penalty and is not common practice. (High-bandwidth systems are generally achieved by using very narrow spectral linewidth lasers.)

The above treatise generally refers to all-silica fibres which are widely used in the telecommunications industry. The two other common types are Plastic-Clad-Silica (PCS) and all-plastic fibres.

PCS fibres have an all-silica core and a polymer based cladding (commonly a silicone resin) which also serves as a protective layer. They are generally less expensive to manufacture, but are characterised by higher attenuation and lower bandwidth (as they have a step index) than all-silica fibres, but are used for relatively short data links.

All-plastic fibres, generally manufactured from Poly-Methyl-MethAcrylate (PMMA) are the least expensive type.

They currently have the highest attenuation of commonly available fibres, and are generally step index. They have application as ‘light pipes’ over short distances (i.e. a few metres).

### 37.2.4 Fibre protection

#### 37.2.4.1 Microbending losses

If a fibre is subjected to mechanical stress, local discontinuities can be introduced. Curvatures of the fibre involving axial displacements of a few millimetres may cause a light ray on the outside radius of a bend to approach or exceed the optical angle and light may be lost through the cladding and also result in additional attenuation losses. These are referred to as microbending losses, or in the case of macroscopic axial deviation of the fibre from a straight line, macrobending losses. To overcome these problems, high-density laser diodes are frequently used.

A guide to the susceptibility to microbending of a particular multimode fibre type can be made by using the following ‘figure of merit’ (this is based on step-index analysis but can be used as a general guide):

$$\gamma_s = \frac{d_{\text{core}}^4}{NA^6 d_{\text{cladding}}^6} \quad (37.5)$$

An optical fibre must therefore be protected against radial forces. This is accomplished by mechanically decoupling the fibre from its immediate surroundings, and is commonly achieved by surrounding the fibre with a very low-elastic modulus material such as a silicone rubber followed by an extruded polymer layer (termed a ‘tight’ packaged fibre), or by encapsulating the fibre loosely within a polymer tube (‘loose’ packaging). The type of protection depends upon the particular application.

Note that the pristine surface of an all-silica fibre is always protected during manufacture by a thin UltraViolet (UV) radiation or heat cured polymer layer.

### 37.2.5 Fibre strength

#### 37.2.5.1 Proof testing

Silica is, to all intents and purposes, purely elastic and has no plastic deformation prior to tensile failure. The strain at which a fibre breaks is dictated by its surface condition.

Minute flaws, 1  $\mu\text{m}$  or less in size, and generally at the surface, act as stress raising points and the effective stress at the flaws may be much higher than that directly imposed. The flaws are generally created during fibre fabrication, and are caused by (inevitable) contamination. Although all manufacturers take immense care to produce fibre in scrupulously clean conditions, some particles (from the hot furnace element, for example) inevitably reach the fibre. A flaw 1  $\mu\text{m}$  deep will cause failure at about 1% strain.

The stress intensity at a crack flaw tip can be explained by classic Griffith crack theory. Local stress intensification can be described by an intensification factor  $K_I$ , which reaches a critical value  $K_{IC}$  when fracture occurs:

$$\sigma \leq \frac{K_{IC}}{Y a^{1/2}} \quad (37.6) \Leftarrow$$

where  $\sigma$ , is the applied stress,  $a$  the crack depth, and  $Y$  is a geometric factor.  $\sigma$  is always less than the theoretical breaking stress for the material in question.

Flaws can be introduced easily, and that is one reason why fibres are coated, within seconds of being drawn from the melt, with a UV curing polyurethane acrylate or a thermally curing silicone material to a diameter of 250  $\mu\text{m}$ .

Strength is guaranteed by subjecting all delivered fibre to a proof or screen test, commonly 0.5–1% strain. The strain is applied after production by passing the fibre continuously through two capstans, and loading the section in between.

Fibre manufacturers will generally specify the minimum radius to which a fibre should be bent (about 50 mm for telecommunications fibres). There are two reasons; a bend causes tensile strain on the outer edge, and severe bending will cause light leakage.

### 37.2.5.2 Static fatigue

Static fatigue is caused by the combined action of tensile stress and moisture on a fibre surface, and causes weakening over time. Because glass is a supercooled liquid, it has an amorphous or non-crystalline structure. The lattice is quite open and water (in the form of  $\text{OH}^-$  ions), if it reaches the fibre surface, destroys silica-silica surface bonds. The energy for this to happen is supplied by external (tensile) stress, and the rate increases with the applied stress.

Although there has been much research on the phenomenon, it is still not fully understood. The generally accepted model is for a growth law of the form:

$$V = AK_1^n \quad (37.7) \Leftarrow$$

where  $V$  is the velocity of crack growth,  $K$ , is the stress intensification factor mentioned above, and  $A$  and  $n$  are constants. If the above is combined with the Griffith equation and integrated, the following result is achieved:

$$t = BS_1^{n-2} \sigma_1^n \quad (37.8) \Leftarrow$$

where  $t$  is the time to failure,  $S_1$  is the inert strength of the material (the stress required to produce instant failure or failure in the absence of crack growth),  $B$  is a constant related to both  $a$  and  $n$ , and  $\sigma$ , is the applied stress.

The time to failure is thus finite and inversely proportional to the  $n$ th power of the applied stress or strain. Values of  $n$  usually lie in the range 14–30, the higher the better. The lowest value corresponds to 100% relative humidity and higher values to dry laboratory conditions.

The time to failure is thus extremely sensitive to changes in both  $\sigma$  and  $n$ , and accurate values are needed to enable cable lifetime to be reliably extrapolated. During cable design, manufacturers take account of static fatigue; to ensure that design lifetimes are achieved, maximum installation and service loads must be adhered to.

## 37.3 Optical fibre cables

### 37.3.1 General

Unlike copper cables, where the performance of conductors is largely immune to bending and tensile forces, optical cables are designed to protect the contained fibres. This does not suggest that properly designed fibre cables are fragile, but merely that care has been taken during both design and manufacture. Optical cables have and are being installed in environments that are as harsh as those experienced by copper cables—for example, sub-sea, between high-voltage electricity pylons, and in the military environment.

Suppliers of optical cables use many different manufacturing techniques and, although it is beyond the scope of this introduction to include them all, the most common types encountered in data communications and telephony are covered.

### 37.3.2 Low fibre count cables

The requirement for low fibre count cables is generally for a cost-effective, compact construction which provides a package with ample mechanical protection. Typical uses are for inbuilding telephony, data and control links, rack-to-rack links, and electrical isolation.

Both ‘tight’ and ‘loose’ designs of cable are used. ‘Tight’ designs utilise fibre which has been packaged in a closely fitting polymer jacket, commonly nylon, PolyVinyl Chloride (PVC), polypropylene, or polyester elastomer, the outer diameter of which is between 0.5 and 1.0 mm. One or more individually jacketed fibres are generally positioned at or near the neutral bend axis of the cable, with a peripheral tensile strength member. The simplest design is for a single jacketed central fibre provided with stranded polyaramid yarns (e.g. Kevlar and Twaron) for axial reinforcement, and an overall sheath. Similar designs are available for ‘loose’ packaged fibre with a tube outer diameter of 1.5–3.0 mm, but these may have an increased overall diameter.

‘Tight’ fibre designs have the advantage that, once broken out of the cable, the fibre still maintains some measure of protection, and may be routed over short distances without a splice. Utilisation of this approach can be cost-effective and will generally keep overall losses to a minimum. *Figure 37.8* shows a typical single-fibre cable design.

### 37.3.3 High fibre count cables

As the fibre count increases, suppliers generally encounter a cost and overall diameter trade-off between centrally and peripherally positioned fibres. The break point varies between manufacturers and manufacturing methods, but is typically between 8 and 20 fibres.

The approach adopted in most cases is to bundle the fibres together in some form of unit packaging or element. This may take the form of tubes containing one or more loose fibres, placing the fibres in a grooved or slotted former, using fibre ribbons akin to copper ribbon cabling

Figure 37.8 Single-fibre cable

(but with much reduced dimensions), or a combination of the above.

An extruded thermoplastic sheath is then applied to elements stranded helically or in an oscillating fashion (commonly called 'S-Z' stranding) around a central axial strength member. In external cables, interstitial filling compounds and/or an aluminium-polymer laminate barrier are used to prevent moisture reaching the fibres and exacerbating static fatigue effects. Figures 37.9 and 37.10 show typical high fibre count cable designs.

Figure 37.9 Loose tube type cable

Figure 37.10 Slotted core type cable

### 37.3.4 Cable protection

#### 37.3.4.1 Ruggedisation

Ruggedisation of the cable can be achieved by utilising some form of strength member (e.g. Kevlar) which is either laid helically or braided around the fibre coating. This is then surrounded by a tough outer sheath to provide the required environmental and mechanical protection. Figures 37.11 and 37.12 show two examples of ruggedised optical fibre cables.

#### 37.3.4.2 Armouring

Sometimes even ruggedising an optical cable is insufficient for some environments, especially where the cable is liable to mechanical radial forces (caused by digging implements) and rodents. In these cases the optical cable will need to be armoured. The most usual forms of armour are stranded steel wires, polymer laminated tapes, Kevlar and corrugated steel tape, the latter being particularly effective against rodent bites. The steel must, of course, be protected against corrosion by moisture.

#### 37.3.4.3 Fire safety (internal cables)

As the fire safety properties of a cable are dependent on both the materials and the construction, cables which are to be sited within buildings require constructions which make them safe to use in the event of fire. Polyethylene, used commonly as a sheathing compound for external cables, has poor fire safety properties, and flame retardant PVC sheaths have been and are used for internal (electric) power and data cables. For more demanding applications, for example at sites where the public has common access, it is prudent to use cables which in a fire will:

- resist the spread of flame (flame retardance);
- produce minimal smoke; and
- produce minimal toxic emissions.

#### 37.3.4.4 Environmental considerations

The service environment of a cable will, again, affect both the materials and the construction used. Principal considerations will be temperature, aggressive gaseous and liquid chemicals, radiation, electric fields, and extreme mechanical and other forces such as hydrostatic pressure.

Figure 37.11 Construction of a single-fibre ruggedised optical fibre cables

**Figure 37.12** Construction of a multi-fibre ruggedised optical fibre cable, suitable for harsh, military environments

### 37.3.5 Cable usage

Optical fibre cables, because of their mechanical strength and low weight, can be pulled into ducts, ploughed in, cleated to walls, installed in vertical runs of over 1000 m in length (particularly important in multistorey office blocks and mines etc.) placed on cable trays and planer shelves (or PVC conduit) installed aerially, attached to supporting wires (e.g. high-voltage cables), or even immersed in water (oceanographic systems).

The technique used, of course, not only depends upon the environment but on the length of cable to be installed. Today, one of the most practised methods of installing short lengths into highly populated duct systems is to use compressed air to inject an auxiliary rope. This will then be connected to a winch rope which in turn will be connected to the cable.

#### 37.3.5.1 In buildings

In buildings, cables tend to be of the 'tight' type, for two main reasons. Firstly, they allow for connectors to be directly mounted on to buffered fibre, minimising the number of splices and 'pig-tails' (i.e. factory assembled single-fibre cables with a connector at one end). This is generally a more cost-effective means of installation, and also keeps

route losses to a minimum. Secondly, the tight construction relieves axial fibre stress in vertical runs due to its own weight (i.e. the fibre is continually supported by the cable strength member along its entire length).

#### 37.3.5.2 External

In external applications, it is important to keep moisture away from the fibre surface, and to minimise fibre stress. 'Loose' cable types prevail, generally using a combination of filling or flooding compounds designed to displace water, plus an aluminium-plastic-laminate moisture barrier. Axial strength is provided by a stranded steel or glass reinforced member, and/or polyaramid yarns.

Because optical fibre cables are very light they can be incorporated into overhead power line routes without any additional stress being exerted onto the existing mast. In addition, as the optical fibre cable is completely non-metallic, any problems associated with inductive interference are eliminated.

The process is very similar to installing normal copper aerial cables and the optical fibre is merely lashed to the phase conductors or ground wires of the overhead power line. This is further explained in Section 37.5.

### 37.3.6 Splices and connectors

When an optical fibre cable is damaged it can be repaired either by splicing a new piece of cable into the existing line or, if sufficient cable is available, by cutting out the damaged portion and splicing the two ends together. This process is referred to as concatenation.

Most techniques for joining fibres rely on accurate geometry. The core/cladding concentricity is also very important in all-silica fibres where alignment of the cores usually depends on alignment of the outside surfaces of the cladding. In any optical system, there is likely to be a mix of splices and connectors for active device to fibre interconnection and for fibre to fibre interconnection (e.g. external cable to in-building cable, or for patching).

Both splices and connectors require the achievement of fibre end faces which are flat and at 90° to the fibre axis. Two methods (or a combination of both) are commonly used; cleaving, and cut-and-polish. Tools for either method are commonly available.

**Figure 37.13** Ground wire, incorporating optical fibres, mounted on the top of a pylon power line structure

### 37.3.6.1 Splices

A number of techniques for permanently and temporarily splicing optical fibres are available, including fusion, V-groove (now largely obsolete), and sleeve splices. Sleeve splices have obvious mechanical advantages for single-fibre jointing in the field, but have the disadvantage of 'slop', due to the clearance required to insert the fibres in the sleeve. Fusion splices are attractive but they require precise external alignment of the fibres to be joined. The fusion type is permanent, but some sleeve splices can be demounted and re-used.

In a typical sleeve splice, an elastomeric tube is used to locate the fibre ends which are simply inserted into the sleeve, together with a small amount of index adhesive to fuse the two fibre ends together. Alternatively, the splice connector can be crimped to the optical fibre cable. Supports are available to house the sleeve and to clamp the fibre/cable. An insertion loss of 0.2 dB is typical for both single and multimode fibres, and the elastomeric tube can be re-used up to 50 times.

Fusion splicing for silica fibres has been developed by numerous companies world-wide. In this technique, the fibres to be joined are visually or automatically aligned using micromanipulator movements. The aligned fibres are then fused together using a suitable localised heat source. Electric arcs are most common, but for high-strength splices, an oxy-gas torch is sometimes used. Losses less than 0.1–0.2 dB are routinely and reliably achieved for both multi- and single-mode fibres. Alignment is commonly achieved by locally injecting light in one fibre and detecting in the other, using a severe bend to cause core/cladding mode coupling. Fusion is activated when the locally detected signal is maximised.

Fibres are usually protected from the environment after splicing by some type of reinforced heat shrink tube, or by coating reinstatement.

**Splice losses** Splice losses can be due to variations in the outer diameter of the fibre core, differences in index profile, differences in the ellipticity of the core, misalignment of the fibre ends, poor quality of the refractive index match at fibre ends, waveguide imperfections, etc.

In practice, splice losses of about 0.5 dB are typical for fusion-spliced multimode fibres while single-mode fibres (because of the narrowness of the core diameter) are not as much (e.g. 0.1–0.2 dB). Mechanical splicing, whilst still being more lossy than fusion-splicing, is nevertheless appreciably less than that of a connector.

**Figure 37.14** Principle of an elastomeric splicer, which aligns fibres in a hole in the flexible plate

**Figure 37.15** Principle of an elastomeric splicer, which aligns fibres in a hole in the flexible plate

### 37.3.6.2 Connectors

Demountable connectors for optical fibre (cables) need to perform several functions. The primary function is to couple light from one fibre to another efficiently and repeatably. If a connector is to operate satisfactorily it must also protect the fibre ends from damage which may occur due to handling, to protect against environmental factors such as moisture and dust, and to carry tensile loads on the cable, whilst allowing rapid connection and disconnection when required. For optimum performance in hostile environments the cable and connector must be considered as an integral unit.

An optical fibre connector can usefully be considered in three parts:

- (1) Fibre terminations which protect and locate the fibre end;
- (2) Alignment guides which position the pair of fibre terminations for optimum coupling; and
- (3) Connector shells which protect the optical contacts from the environment, hold the alignment guides and fibre terminations in place, and terminate the cable sheath and strain member.

There are two main categories of demountable optical connector. The first is the butt joint in which the prepared ends are close to each other and are aligned so that their fibre axes coincide. The second major category uses the expanded beam technique. In this approach the diameter of the transmitted beam is increased by one half of a connector and this expanded beam is reduced again to a size compatible with the core of the receiving fibre by the second half of the connector.

This expansion can be achieved by tapering the fibre, but generally lenses are used.

**Butt jointing** In a butt joint, a ferrule usually protects the fibre. The main types are jewelled, ceramic, and tri-ball. A typical jewelled metal ferrule is manufactured with an accurate outside diameter and a 1 mm counterbore at one end. A standard watch jewel, with a hole size closely matching the diameter of the fibre to be used, is press-fitted into the counterbore giving a fibre size hole which is accurately concentric with the outside diameter of the ferrule. The close diameter and concentricity tolerances of the fibre hole are achieved more easily and cheaply by drilling a 1 mm hole and using a watch jewel than by drilling a small hole directly into the end of the metal ferrule.

To terminate a fibre in a jewelled ferrule, the protective coating is removed over a short length from the end, and the fibre is fed into the ferrule filled with a suitable adhesive and through the close fitting jewel hole at the front. The fibre is then polished back flush with the ferrule end. Typical concentricity errors between the fibre core and the outside diameter of the ferrule are 2–6  $\mu\text{m}$ . The termination technique has been developed for silica and plastic-clad-silica fibres.

Another similar technique uses a precision ceramic rod with a central hole, and has fast become the standard for most fibre connectors as the rods can be manufactured very cost effectively.

Another technique uses three precision balls (as used in the bearing industry) to locate a fibre centrally within a conical hole.

Butt joint connectors are by far the most common; those regularly encountered are SMA, bi-conic (both types for multimode all-silica fibres), ST (for both multimode and single mode), and FC/PC (for single mode).

*Expanded beams* The expanded beam method uses a different mechanism to achieve alignment. When a prepared fibre end is fixed at the focus of a convex lens, a collimated beam, with a diameter greater than the fibre core diameter, emerges from the lens. When two of these terminations are aligned an optical connector is produced. The fibre must be positioned at the focus with the same accuracy as two fibres in a butt joint since the receiving fibre is in effect forming a butt joint with the image of the transmitting fibre. At first sight this may appear to forfeit the advantages of this technique; however, since the accurate positioning of the fibre in the lens termination unit is only required once, it would normally be done in a factory. Making and breaking of the connection occurs between the two lenses. The required connection tolerances are reduced since the increased beam diameter allows greater lateral misalignment than with a simple butt. Owing to the collimation of the beam, a small separation of the terminations, and/or angular misalignment can be tolerated without significantly increasing attenuation.

The increased beam diameter reduces the effect of dust on the connector loss. The separation of the terminations minimises the risk of permanent damage arising from grit scratching or chipping the optical surfaces when the connector is inadvertently coupled in a dirty condition. For these reasons, this type of connector is useful in harsh environments.

*Alignment and connector shells* For accurate alignment of two fibres within the connector shell, precision holes are used. Watch jewels are used for fibre guidance as well as precision bores, bioconical systems, and helical springs. In the FC/PC type (used for single mode), a factory set keying system is used to optimise connector angular orientation to optimise connector angular orientation to optimise connector loss. Springs overcome the need for a sliding fit tolerance by using the fact that as they are unwound, the inner diameter increases; at this stage the two ferrules are inserted, and then the spring relaxed.

Many connector bodies or shells are available, generally using bayonet or screw threads to mate. Hermaphroditic types are also available. The shell may be for a single connection, or for multiple fibres.

Connectors tend to be very specific to the type of cable which they will accept and the need to clamp onto the cable strength member rather than the fibre itself for strain relief is always advisable.

## 37.4 British and International Standards

Listed below are current British (BS), American (ANSI) and international (ISO) standards that concern optical fibres and Fibre Distributed Data Interface (FDDI).

**ANSI X3.139 (1997)**—INFORMATION SYSTEMS—FIBER DISTRIBUTED DATA INTERFACE (FDDI)—TOKEN RING MEDIA ACCESS CONTROL (MAC)

Describes Media Access Control, lower sublayer of Data Link Layer for FDDI, which provides high-bandwidth (100 Mbits/s), general-purpose interconnection among

computers and peripheral equipment using fibre optics in ring configuration.

**ANSI X3.148 (1999)**—INFORMATION SYSTEMS—FIBER DISTRIBUTED DATA INTERFACE (FDDI)—TOKEN RING PHYSICAL LAYER PROTOCOL (PHY)

Describes Physical Layer Protocol standard, upper sub-layer of Physical Layer, for FDDI which provides high-bandwidth (100 Mbit/s), general interconnection among computers and peripheral equipment using fibre optics. Coverage includes definitions, conventions, coding, symbol set, line states, coding overview, general organization, smoothing function, repeat filter and ring latency. Also gives detailed diagrams and tables.

**ANSI X3.166 (1995)**—FIBER DISTRIBUTED DATA INTERFACE (FDDI) PHYSICAL LAYER MEDIUM DEPENDENT (PMD)

Gives a specification for Physical Layer, Medium Dependent (PMD) requirements for the FDDI high-bandwidth (100 Mbit/s) general purpose interconnection among peripheral and computer equipment that use fibre optics as the transmission medium.

**ANSI X3.263 (1995)**—FIBRE DISTRIBUTED DATA INTERFACE (FDDI)—TOKEN RING TWISTED PAIR PHYSICAL LAYER MEDIUM DEPENDENT (TP-PMD)

Defines Twisted Pair Physical Layer Medium Dependent (TP-PMD) criteria for FDDI high-bandwidth, (100 Mbit/s) general purpose interconnection among computers and equipment using fibre optics and twisted pair as the transmission media. It can be shaped to support a sustained data transfer rate of 80 Mbit/s or more, and allows connection for nodes distributed over distances of several kilometres. Default values are calculated on the basis of 1000 physical links and total fibre path of 200 km in length. (Typically corresponding to 500 nodes and 100 km of dual fibre cable.)

**BS 6004 (1995)**—SPECIFICATION FOR PVC-INSULATED CABLES (NON-ARMOURED) FOR ELECTRIC POWER AND LIGHTING

Specifies requirements and dimensions for non-armoured PVC insulated cables for fixed installation and for operation at voltages up to and including 450 V to earth and 750 V a.c. between conductors. Coverage includes: voltage designation, conductors, insulation, core identification, sheath, marking, electrical requirements and fillers and extruded inner covering. Also gives definitions, tables, diagrams and annexes.

**BS EN 186000 PT1 (1994)**—HARMONIZED SYSTEM OF QUALITY ASSESSMENT FOR ELECTRONIC COMPONENTS. GENERIC SPECIFICATION: CONNECTOR SETS FOR OPTICAL FIBRES & CABLES—REQUIREMENTS, TEST METHODS AND QUALIFICATION APPROVAL PROCEDURES

Applies to fibre optic connector sets for optical fibres and cables. Coverage includes definitions, environmental category, gauges, corrosion resistance, component marking, package marking, spectral loss, cable torsion, cable pulling, static load, nuclear radiation, solar radiation, spectral loss, axial compression and industrial atmosphere.

**BS EN 187000 (1997)**—GENERIC SPECIFICATION FOR OPTICAL FIBRE CABLES

Applicable to optical fibre cables to be used with telecommunication equipment and devices having similar techniques and combining optical fibres and electrical conductors.

**IEC 60793-1 (1992)—OPTICAL FIBRES—GENERIC SPECIFICATION**

Applies to primary coated or primary buffered optical fibres for use in telecommunication equipment and in devices employing similar techniques. Establishes uniform requirements for the geometrical, optical, transmission, mechanical and environmental properties of optical fibres and includes measuring methods for dimensions, transmission and optical characteristics. A guide for fibres for short distance links is in Annex A.

**IEC 60793-1.1 (1999)—OPTICAL FIBRES—GENERIC SPECIFICATION—GENERAL**

Applies to primary coated or buffered optical fibres for use in telecommunication equipment and in devices employing similar techniques and defines categories of optical fibres as well as packaging.

**IEC 60793-1.2 (1996)—OPTICAL FIBRES—GENERIC SPECIFICATION—MEASURING METHODS FOR DIMENSIONS**

Gives the measuring methods applicable to environmental tests of optical fibres. The methods are to be used for inspection of optical fibres for commercial purposes. They establish uniform requirements for geometrical characteristics of optical fibres.

**IEC 60793-1.3 (2000)—OPTICAL FIBRES—PART 1-3: GENERIC SPECIFICATION—MEASURING METHODS FOR MECHANICAL CHARACTERISTICS**

Applicable to the tests of mechanical strength, ease of handling or the recognition of physical defects or primary coated or primary buffered optical glass fibres. The methods are to be used for inspecting fibres for commercial purposes. The aim of this part is to establish uniform requirements for mechanical characteristics of optical fibres.

**IEC 60793-1.4 (1998)—OPTICAL FIBRES—GENERIC SPECIFICATION—MEASURING METHODS FOR TRANSMISSION AND OPTICAL CHARACTERISTICS**

Applies to the practical measurements of transmission and optical parameters of fibre. The methods are to be used for inspection of fibres and cables for commercial purposes to establish uniform requirements.

**IEC 60793-1.5 (1995)—OPTICAL FIBRES—GENERIC SPECIFICATION—MEASURING METHODS FOR ENVIRONMENTAL CHARACTERISTICS**

Describes measuring methods which apply to environmental tests of optical fibres. The methods are to be used for inspection of optical fibres.

**IEC 61218 IEC (1993)—FIBRE OPTICS—SAFETY GUIDE**

An interpretation of IEC 825 with respect to fibre optic transmission systems. Some additions have been made in this guide wherever IEC 825 and its amendment do not cover a specific fibre optic subject. Applies to the wavelength range of 400 nm–10 (to the power 5) nm. IEC 825 addresses equipment based on lasers only.

**IEC 61292-1 (1998)—FIBRE OPTICS—PARAMETERS OF AMPLIFIER COMPONENTS**

Applicable to optical components of Optical Fibre Amplifiers (OFAs). Provides information on the most relevant parameters of OFA optical components, but does not define included definitions as these require more research.

**IEC 61930 (1998)—FIBRE OPTIC GRAPHICAL SYMBOLOGY**

Applicable to graphical symbols that are used in IEC publications dealing with fibre optics. The aim is to give uniform graphical symbols for the various fibre optic elements and devices.

**IEC TR 61282-1 (2000)—FIBRE OPTIC COMMUNICATION SYSTEM DESIGN GUIDES—PART 1: SINGLE-MODE DIGITAL AND ANALOGUE SYSTEMS**

Gives guidance for system design methodology for users and suppliers of fibre optic transmission systems for telecommunications and broadband video distribution applications. The function of the systems is to interconnect signals between defined digital and analogue interfaces via a fibre optic link. Generally, fibre optic systems are built-up from Basic Fibre Optic Systems (BFOS).

**ISO 9314-1 (1989)—INFORMATION PROCESSING SYSTEMS—FIBRE DISTRIBUTED DATA INTERFACE (FDDI)—TOKEN RING PHYSICAL LAYER PROTOCOL (PHY)**

Specifies the Physical layer protocol (PHY), for FDDI.

**ISO 9314-2 (1989)—INFORMATION PROCESSING SYSTEMS—FIBRE DISTRIBUTED DATA INTERFACE (FDDI) TOKEN RING MEDIA ACCESS CONTROL (MAC)**

Specifies the Media Access Control (MAC), the lower sub-layer of the Data Link Layer (DLL), for an FDDI high-bandwidth (100 Mbit/s), general-purpose interconnection among computers and peripheral equipment using a transmission medium of fibre optics in a ring configuration.

**ISO 9314-3 (1990)—INFORMATION PROCESSING SYSTEMS—FIBRE DISTRIBUTED DATA INTERFACE (FDDI)—PHYSICAL LAYER MEDIUM DEPENDENT (PMD)**

Describes Physical Layer, Medium Dependent requirements for FDDI high-bandwidth (100 Mbit/s) general-purpose interconnection among computers and peripheral equipment using fibre optics as the transmission medium. May be configured to support a sustained transfer rate of approximately 80 Mbit/s. May not meet the requirements of all unbuffered high-speed devices. It establishes the connection among many nodes distributed over distances of several kilometres. Default values were calculated on the basis of 1000 physical connections and a total fibre path length of 200 km.

**ISO 9314-13 (1998)—INFORMATION TECHNOLOGY—FIBRE DISTRIBUTED DATA INTERFACE (FDDI)—CONFORMANCE TEST PROTOCOL IMPLEMENTATION—CONFORMANCE STATEMENT (CT-PICS) PROFORMA**

Gives the PICS proforma for the FDDI specified in the base standards as denoted in clause 5.

**37.5 Optical fibre telemetry on overhead power lines****37.5.1 Introduction**

The advent of optical fibre links has provided significant improvements in the communication facilities needed for

the effective operation of power systems. Such links are well suited to the electrically noisy environments of power systems due to their immunity from electromagnetic interference. They are also free from the difficulties encountered with purely electronic systems due to local earth potential variations which may arise from the heavy earth currents that can occur during a power system fault. The wide information-carrying bandwidths of such systems leads to low costs per channel on trunk routes, can conveniently accommodate extra information transmission and provide the means for more rapid signal transmission which is important for protection and control under power system fault conditions. In addition, they are electromagnetically compatible in not generating stray or spurious interference as can be the case with microwave and power-line carrier systems.

The main uses on power systems for long-haul optical fibre links include telephony, telemetry, telecontrol, protection (the control of circuit-breakers), data transmission between computers, and possibly video signalling.

### 37.5.2 Fibre cable configurations

Optical fibre cables are generally available for use on overhead power lines. Such cables fall into three main generic types; (1) All-Dielectric Self-Supporting (ADSS); (2) spiral wrap-on or lashed; and (3) Optical Ground Wire (OPGW) where the optical fibres are included in the earth wire.

All-dielectric self-supporting cables require tensile members which offer a high strength-to-weight ratio such as glass reinforced plastic or aramid yarns. The presence of these cables imposes an additional load on the support structures which must be considered with regard to statutory support safety factors. An ADSS cable is inherently light and small relative to the phase conductor and earth wire which limits the effects of environmental factors such as wind and ice loads minimising any additional steel work or structural reinforcement needed. Clamping arrangements can also be chosen which allow slippage of the cable under conditions of differential loading (i.e. when one span adjacent to a support structure is loaded more or less than the other span adjacent to that support structure) further safeguarding the integrity of the supports. The optical fibre cables must also meet any ground clearance requirements imposed by the power utility. The principal benefits of ADSS cables are that they offer post-fit solutions for power utilities and can allow installation with one or both power circuits live avoiding costly supply interruptions.

Wrap-on or lashed cables can be fitted to either the earth wire or a phase conductor, although the earth wire is most common. The wrap-on cables are spirally applied to minimise the susceptibility of the resulting composite line to wind-induced vibration known as 'galloping'. Galloping is caused by light winds flowing over the cable giving rise to high and low pressure regions (similar to the action of an aircraft wing) producing up-lift or down-force depending on the orientation of the cables. By spirally applying the wrap-on cable the effective profile presented to the wind varies along the span such that consecutive spirals oppose each other cancelling any net effect.

Wrap-on or lashed cables also offer the advantage of being post-fit systems if the cable is installed on the earth wire. Live line installation of such systems on the phase conductor are being discussed.

Optical ground wire (OPGW) cables encase the optical fibres within the earth wire which is used to carry fault currents and to provide shielding from lightning. One structure of such a composite cable includes aluminium or steel strands helically wound around a hollow aluminium core

carrying a polyethylene sheath which holds typically between two and four pairs of optical fibres, along with the option of a polymer tension member.

The OPGW cables offer the advantage of not imposing additional loads on the support structure as they replace the existing earth conductor. However, these cables are not post-fit solutions to the needs of power utilities for telecommunications purposes as the replacement of the existing earth wire is costly and time consuming. Therefore, such cables are generally used on new lines or when the existing earth wire is scheduled for replacement.

Any optical fibre cable used for aerial applications must be capable of operating under a range of environmental conditions without eroding the optical and power transmission characteristics or the service life of the cables and support structures.

Optical fibre cables incorporate strain relief between the strength member and the fibres to protect the optical fibres during service. Strain relief can be provided by overfeeding fibre into small polymer tubes which are then stranded around a central member or by overfeeding ribbon arrays of fibres within a slot. The amount of strain relief required is determined by relating the maximum cable strain expected during service to the maximum allowable fibre strain calculated for the required service lifetime (a function of the initial fibre proof test level) and the optical performance of the fibres when they are strained. Multiple fibres constrained in loose tubes tend to interact with each other when strained, giving increased attenuation.

The variation in cable tension and strain produced by climatic changes such as temperature, wind strength, and ice loads can be solved mathematically. The optical cable, as with the phase conductors and earth wires, adopts the shape of a catenary when suspended between two points. An initial set of known conditions (usually corresponding to those during installation) are used to determine the basic catenary and then all changes in tension due to climatic variations are related to this. The principal effect of a wind acting on the cable, apart from that on the tension in the cable, is to cause the cable to 'blow out' from the vertical.

Cable or conductor ageing must also be considered. ADSS cables generally have good self-damping characteristics which vibration in the cable and that transmitted to the support structure. Wrap-on and lashed cables tend to vibrate in harmony with the conductor or earth wire on which they are installed and hence do not produce a significant effect on the vibration behaviour of the host. OPGW cables are used instead of standard earth wires and behave in a similar fashion to those wires. Therefore, OPGW cables tend to use the same precautions (typically dampers) as earth wires.

In addition to vibration, a further consideration is a phenomenon known as 'creep' where the presence of a permanent tensile load produces a reduction in the strength of the cable or conductor leading to failure below the initial breaking load. Optical cables use strength members manufactured from materials which have been shown to be resistant to 'creep' within the operational strain window experienced during service.

The electric field in which these optical fibre cables reside can combine with onerous climatic conditions and have an effect on the sheath materials used. ADSS and wrap-on cables can be degraded by the local electric field. Careful selection of sheath materials which are resistant to dry band arcing, the phenomenon which causes sheath degradation, ensures that such cables fulfil service lifetime requirements. OPGW cables have metallic outer layers and are used for earthing purposes and so are not prone to damage from dry band arcing but can be subject to galvanic action between the dissimilar metals used in the cable construction.

### 37.5.3 Factors governing system design

In the UK, telephony traffic over single-mode fibre is common with bit rates up to 565 Mbit/s, and systems are installed operating at over 2 Gbit/s. The major telephony carriers use single-mode fibre only. Operation is generally at an optical wavelength of 1300 nm, with longer haul systems (e.g. intercontinental submarine links) using 1.55  $\mu\text{m}$  where intrinsic fibre losses are lower (ca. 0.2 dB/km, and ca. 0.35 km at 1.3  $\mu\text{m}$ ). For a laser diode source with output power of typically—3 dB/m, and photodiode receiver sensitivity—50 dB/m, link lengths greater than 50 km and bit error rates of  $10^{-9}$  are readily achieved, with a power margin to allow for component ageing and possible fibre repair splices. Such lengths generally allow for signal repeaters/regenerators to be situated within buildings.

Multimode fibre is used for data transport, analogue video transmission, etc., over short distances to approximately 2 km. Both 62.5/125  $\mu\text{m}$  and 50/125  $\mu\text{m}$  (core/cladding diameters) are commonly used, the former being the preferred FDDI standard. Multimode fibre, despite its higher cost, is used to allow the use of more cost-effective connectors, and launch and receive devices.

## 37.6 Power equipment monitoring with optical fibre sensors

### 37.6.1 Introduction

Although early forms of optical fibre sensing systems have illustrated the potential of such methods for power system monitoring there have been practical deficiencies which have detracted from their widespread use. The original systems were cumbersome, unreliable, costly and involved

much unfamiliar optical processing and interfacing. It may be argued that insufficient attention was given to the real needs of power system monitoring. The problem has been exacerbated because the power industry has been unsure of the modes in which such novel technology might best be used whilst simultaneously a major thrust of optical fibre sensors research has been for methods which are oversophisticated and costly for power system applications.

However, the many fundamental advantages of optical fibre sensing systems remain attractive. For instance, a major advantage is for the condition monitoring of a circuit-breaker during fault current interruption when signatures of impending faults may be more distinguishable. A further implication is that such an approach minimises supply disruption since such monitoring would be undertaken live, a capability which emerges because of such a system's electromagnetic immunity and its inherent electrical insulation properties.

This contribution examines the advantages of optical fibre monitoring for power equipment applications, reasons for limited progress in implementing such technology and possible strategies which are evolving for the site testing and evaluation of these systems.

### 37.6.2 Technology implementation difficulties

One objective of the realisation of optical fibre sensing in the power industry is for the implementation of an optically controlled substation system. Such an objective involves producing optical fibre sensors for monitoring a range of parameters governing the condition and operation of power equipment such as circuit-breakers and transformers. It entails interlinking the various monitoring systems with an optical fibre system and connecting these to various data stations and control units (*Figure 37.16*).

**Figure 37.16** Optically monitored substation concept. (Source: Courtesy of Mitsubishi)

The attraction of optical fibre sensors for such monitoring is that their intrinsic properties offer many advantages in hostile and challenging environments. For high-voltage power apparatus applications these properties include:

- inherent isolation of electronic instruments;
- immunity from electromagnetic interference;
- geometric flexibility;
- inherent electrical insulation;
- no electrical shock hazard;
- corrosion resistance; and
- compact and lightweight.

Despite such attractive advantages, the uptake of the fibre sensing technology has been retarded because of general market penetration problems. These include:

- uncompetitive prices;
- end-user unfamiliarity;
- conservative attitude of large industries;
- range of different optical systems for monitoring various parameters;
- failure of early, immature systems; and
- absence of established markets.

Recent developments in optical fibre sensing have addressed these commercial problems. In order to appreciate the significance of the developments it is necessary to review briefly the methods available for modulating an optical signal.

The basic modulation methods involve modifying either the amplitude, phase or polarisation of the optical signal (Figure 37.17). Absolute amplitude monitoring is unreliable for sensing purposes because a number of external (e.g. fibre bending) and intrinsic factors (e.g. source variability) in addition to the sensor may modify the amplitude. Phase monitoring is based upon optical interferometry which involves complex instrumentation and because of its digital nature is not so attractive for situations in which the instrument power supply may be interrupted. Methods based upon monitoring changes in the plane of polarisation of an optical signal have hitherto relied upon even more complex optical systems.

Attempts to overcome the deficiencies of the amplitude modulation method by referencing a modulated signal at one wavelength ( $\lambda_1$ ) with respect to an unmodulated signal at a second wavelength ( $\lambda_2$ ) has met only with limited success because the referencing is not completely reliable and because of power-budget limitations.

The problem with these basic methods is that the intention with any measurement system is to seek an output ( $V$ ) which is proportional to the measurand ( $M$ ) via a constant which is the sensitivity  $S$ :

$$V = S \cdot M \quad (37.9)$$

With an optical fibre system the relationship (Equation (37.10)) between the output  $V$  and modulation (by measurand)  $M_1(\lambda)$  is complicated and depends upon parameters such as source power ( $P(\lambda)$ ), fibre transmission ( $T(\lambda)$ ), and fibre perturbation ( $M_2(\lambda)$ ) which can be induced by external influences or age.

$$V = \sum_{\lambda} \left( \int_{\lambda} [P(\lambda) T(\lambda) M_2(\lambda) d\lambda] R(\lambda) M_1(\lambda) d\lambda \right)^P \quad (37.10)$$

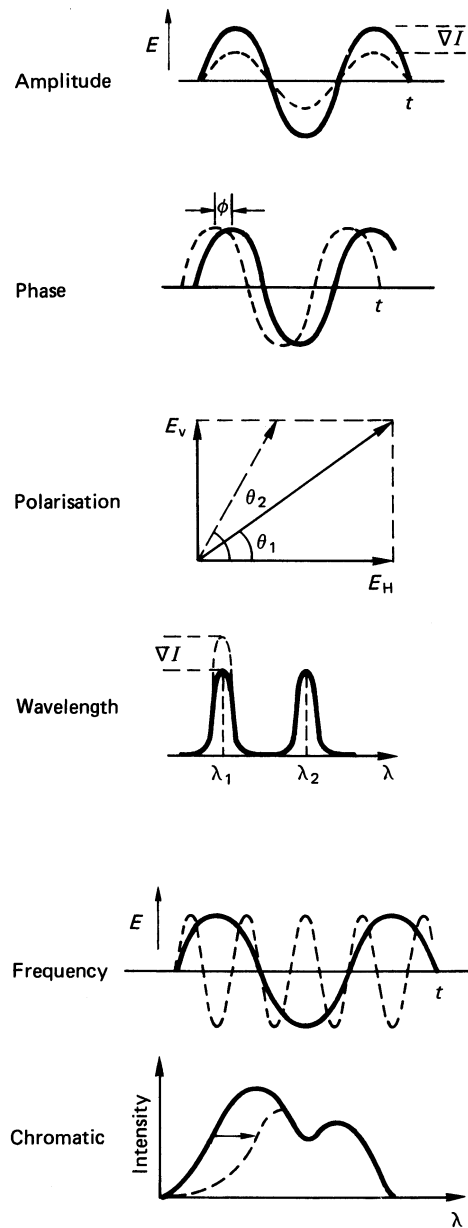

Figure 37.17 Basic optical modulation methods

It was, therefore, necessary to seek modulation methods which are less susceptible to these effects. Two main methods emerged. The first relied upon frequency modulation which was solution adopted by the telecommunication industry. The second method relied upon chromatic modulation whereby the spectral content of the optical signal is varied and the optical signal is monitored over its entire spectral range by several detectors each having a different but overlapping spectral response.

Both these methods are intensity independent and lead to practical, cost effective fibre sensing systems. The chromatic approach has the added bonus of using common instrumentation for monitoring a range of different parameters.

## 38.1 Layout

This chapter deals with the installation of a power supply to a consumer. One example might be a large industrial concern with a factory complex spreading over several hectares; another the single tower-block with one supply entry point in the basement but with additional substations at intermediate floors. At the other extreme is the small dwelling-house.

The general rules of safety of personnel and equipment, continuity of supply and ease of operation and maintenance apply to all consumers, but the layout naturally varies with the individual establishment.

### 38.1.1 System supply

When an electricity supply is to be provided to a factory or building complex, there are several features that must be taken into account. Safety is one that cannot be measured in terms of capital cost, but it should not be difficult to achieve an acceptable standard, provided that good-quality equipment is purchased, properly installed and well maintained, and operated by experienced staff.

Loss of supply may result in loss of output from factory or danger to life in a hospital. The system designer must take these matters into account. To eliminate all risk of outage is likely to be very costly: the alternative of accepting some measure of risk is often preferable, bearing in mind the present-day reliability of the public electricity supply and the equipment available for installation.

Losses occur in cables, overhead lines and transformers, and the system should be designed to minimise these, by locating substations as near as possible to the centres of the load. The system power factor is also relevant, for it can affect equipment sizing,  $I^2R$  losses and the cost of electrical energy.

In few installations is maintenance afforded the importance it deserves. The design and installation engineer cannot control this, but he can ensure that the equipment supplied allows for proper isolation and regular testing with the minimum interruption of supply.

Few installations remain unchanged throughout their life. Whether it be the provision of a spare way on a distribution board or space for an additional high-voltage ring-main circuit, thought should be given to the problem at the time of design and installation.

In determining the cost of installation it must be borne in mind that, in addition to the capital cost of the equipment, attention must be given to the running cost, and also to the cost of providing accommodation for the equipment. For example, it may be better to provide outdoor equipment rather than less costly indoor plant when provision of a building to house it, is taken into consideration.

## 38.2 Regulations and specifications

In the UK, the supply of electricity to premises is governed by the Electricity Supply Regulations, which require that all electrical equipment in the premises shall be maintained in an efficient state and that, as regards high-voltage equipment, authorised persons are available to cut-off supply in emergency. Users must also be mindful of the Electricity at Work Regulations 1989 (EAW). These have extended the powers of the Health and Safety Executive to all places of work. They impose legal requirements on a wide range of personnel, with the object of insuring safe working practices

in the use, operation and maintenance of electrical installations. The reader's attention is particularly drawn to an associated document 'Memorandum of Guidance', which as its title suggests, provides extremely useful help in interpreting the EAW Regulations. It should be pointed out that the Health and Safety Executive regards compliance with the Institution of Electrical Engineers (IEE) Wiring Regulations [BS7671:1992 with amendments] (referred to in detail in the following paragraphs) as being likely to achieve compliance with the relevant aspects of the EAW Regulations, but it is also necessary to have safe operational and maintenance procedures for personnel working on, or near, electrical installations to ensure full compliance with the EAW Regulations.

The actual erection and installation should comply with the IEE Wiring Regulations—Requirements for Electrical Installations: compliance with these Regulations will produce a high standard of work and allow a good factor of safety against possible breakdown.

In 1981 the new edition (15th) of these Regulations (referred to as WR15) marked a radical change in both style and approach. It is based on internationally agreed installation rules, the two bodies concerned being the International Electro-technical Commission (IEC) and the European Committee of Electro-technical Standardisation (CENELEC). This approach has now been carried a stage further with the introduction in May 1991 of the 16th edition of the Wiring Regulations (WR16). The concept has been carried further with the 1992 updated edition of the 16th edition of the Wiring Regulations (WR16) and the 2000 amendment no 3 available on the internet.

Every IEC Standard issued expresses, as nearly as possible, an international consensus on its subject, and the intention is that every member country should adopt the text of the standard, as far as the individual country's conditions will permit. Additionally, the members of the EEC are committed to removing trade barriers, and CENELEC aims to help in this by attempting to 'harmonise' the corresponding national standards. In 1968 IEC started work to formulate standard rules. It was soon realised that combining the existing rules of member countries was not feasible, and so IEC decided to go back to fundamentals. Whilst the work continues, some sections have been published, and the IEE made use of the IEC plan and the technical content already agreed by IEC in revising the Wiring Regulations. This resulted in the 15th and 16th editions of the Wiring Regulations being very different from any previously published. Basically, they were aimed directly at the designer of electrical installations rather than at the site installer. They demanded an analytical, mathematical approach to the design of the installation. Additional design time is needed, but the designer is given a greater degree of freedom to produce an economic design.

In the latest edition (WR16) there is no fundamental change in this approach, but harmonisation is taken a stage further, as can be seen from the list of CENELEC harmonisation documents in the Preface. The number of appendices has been greatly reduced, but in their place the IEE has published a series of guidance notes on specific subjects. Of particular relevance is the 'On Site Guide', which should prove invaluable for the installer who may not be totally familiar with every detail of the Wiring Regulations. By following the 'On Site Guide' in his work the installer can be assured that the installation will be acceptable, and safe in operation, although it may not be the most economical design possible.

Mention must also be made of two books sponsored by the Electrical Contractor's Association, the Handbook on

the 16th Edition of the IEE Regulations (which is also sponsored by the National Inspection Council for Electrical Installation Contracting) and Electrical Installation Calculations, the latter by B. D. Jenkins.

It must be pointed out that casual and occasional reference to the Wiring Regulations is not enough to inform readers of the requirements. This can only be achieved by study of the Regulations in detail.

Mention can be made of other regulations and specifications used in other parts of the world. In the former UK colonies earlier versions of the IEE Wiring Regulations have been adopted and modified to suit the engineering environment of the country, i.e. The Central African Standards (CAS Wiring Rules) are based on the earlier 13th and 14th IEE Wiring Regulations and are used in central Africa including Zimbabwe and Malawi.

In parts of the world where there is an American influence then the NFPA70 (National Electrical Code) is adopted.

The National Fire Protection Association has acted as sponsor of the National Electrical Code since 1911. The original Code document was developed in 1897 as a result of the united efforts of various insurance, electrical, architectural, and allied interests.

NFPA has an Electrical Section that provides particular opportunity for NFPA members interested in electrical safety to become better informed and to contribute to the development of the National Electrical Code and other NFPA electrical standards. Each of the Code-Making Panels and the Chairman of the Correlating Committee reported their recommendations to meetings of the Electrical Section at the 1995 NFPA Annual Meeting. The Electrical Section thus had opportunity to discuss and review the report of the National Electrical Code Committee prior to the adoption of this edition of the Code by the Association.

### 38.2.1 Purpose

*Practical Safeguarding* The purpose of this Code is the practical safeguarding of persons and property from hazards arising from the use of electricity.

*Adequacy* This Code contains provisions considered necessary for safety. Compliance therewith and proper maintenance will result in an installation essentially free from hazard but not necessarily efficient, convenient, or adequate for good service or future expansion of electrical use.

Hazards often occur because of overloading of wiring systems by methods or usage not in conformity with this Code. This occurs because initial wiring did not provide for increases in the use of electricity. An initial adequate installation and reasonable provisions for system changes will provide for future increases in the use of electricity.

*Intention* This Code is not intended as a design specification nor an instruction manual for untrained persons.

### 38.2.2 Scope

The Code covers:

1. Installations of electric conductors and equipment within or on public and private buildings or other structures, including mobile homes, recreational vehicles, and floating buildings; and other premises such as yards, carnival, parking, and other lots, and industrial substations.

For additional information concerning such installations in an industrial or multibuilding complex, see the *National Electrical Safety Code*, ANSI C2-1993.

2. Installations of conductors and equipment that connect to the supply of electricity.
3. Installations of other outside conductors and equipment on the premises.
4. Installations of optical fibre cable.
5. Installations in buildings used by the electric utility, such as office buildings, warehouses, garages, machine shops, and recreational buildings that are not an integral part of a generating plant, substation, or control centre.

## 38.3 High-voltage supplies

The general method of supplying bulk power to factories or other complexes is by means of an HV supply, usually at 11 kV, occasionally at 6.6 kV. The installation comprises a main substation at the point of entry, with HV cables to supply subsidiary substations located near load centres. Where desirable, it may be possible for the consumer to obtain two supplies from the power authority, and in special cases where loss of supply could give rise to a particular hazard (e.g. the danger to life in a hospital), the two supplies may be provided from separate sources. In buildings containing IT equipment requiring  $n + 1$  reliability in power supplies then dependability calculations would be undertaken to determine the Reliability, Availability, Maintainability and Safety (RAMS) of the bulk power supply systems.

The distribution system generally comprises either radial feeders or a ring main using underground cables to supply the subsidiary substations. The emphasis today is towards ring-main supplies, and this is considerably helped by the ready availability of competitively priced ring-main switchgear. The basic unit comprises two switches, earlier installations used to be oil but SF<sub>6</sub> has now taken over, capable of making on to a fault and of breaking load current, and

Figure 38.1 SF<sub>6</sub> insulated ring main unit. (Courtesy of ABB)

a fuse switch. Other units are available, assembled into various configurations. They can include circuit-breakers. The SF<sub>6</sub> insulated ring-main unit switching takes place in a SF<sub>6</sub> pressurised compartment. This equipment has obvious advantages for indoor installation because of the reduced fire risk.

A SF<sub>6</sub> ring-main unit is illustrated in *Figure 38.1*.

Four distribution arrangements are illustrated in *Figure 38.2(a–d)*, although variants are also available.

*Figure 38.2(a)* is a radial-feeder arrangement with each feeder controlled by its own automatic circuit breaker. A cable or transformer fault will result in loss of supply only to the one sub-station, but supply cannot be restored until the repair is effected.

*Figure 38.2(b)* is a simple ring-main arrangement which allows for any individual transformer substation to be isolated for inspection or test without interrupting the supply to the other substations. Any fault occurring on the system will result in a total shut down, but the fault can be isolated and the supply restored to all substations but one, unless the fault is in the cable between substations C and D, in which case all substations can be re-energised.

In *Figure 38.2(c)* the distribution substations have their outgoing cables controlled by switches and the transformer by a fuse switch. Hence, every transformer can be independently switched, and should a fault occur and one of the fuses blow, the fuse switch is arranged to open all three phases automatically, thus disconnecting the transformer from the system.

The system would normally be operated with the ring open, but any cable fault will result in part of the system being shut down until the fault is located, when power can be restored to all the substations.

By using automatic circuit-breakers throughout, as shown in *Figure 38.2(d)*, a greater degree of security of supply is obtained. The system can be operated as a closed ring, and even greater security is obtained by duplicating the transformers as shown in the figure.

Modern transformers and switchgear are very reliable, and, provided that cables are installed carefully, the number of faults that will occur will be extremely small. Since cost will always be of importance, it is common to use the simplest ring-main switchgear configuration that is acceptable for the particular application, and switches with a fuse-switch tee-off represent very good value for money and are widely used both by public electricity authorities and by industry. The situation is helped by the availability of fault monitoring and locating equipment, usually of the earth fault passage indication variety. This comprises a core balance current transformer on the out-going feeder cable with an associated hand or self-reset relay. Remote tripping of the switch fuse is also available. With the advent of low-cost micro-processor equipment the system of fault location and monitoring has been extended to provide more exact information to identify the location of a fault.

## 38.4 Fault currents

A relatively simple calculation determines the required interrupting capacity of switchgear. This is particularly useful to the installation engineer when it is necessary to provide extensions to an existing system. He must ensure that any changes in fault currents are safely interrupted via the breaking capacity of 13.1 kA at 11 kV switchgear. Where old gear is already in use, problems could arise.

The technique involves using the reactances of the equipment. In the case of underground cables, the resistance is

high compared with the reactance and so for calculation purposes the impedance of the cable is used. For generators the sub-transient reactance is used, as it is effective for the first few cycles following a fault.

The ratio between the phase voltage drop and the normal line-to-neutral voltage for a stated current (or kilovolt-amperes (kVA)) is the per-unit (or per cent) impedance at that current. For example, if a 1000 kVA transformer has a 0.05 p.u. (or 5%) reactance, then its voltage drop on rated load is 0.05 of the line-to-neutral voltage. It follows that if the transformer output terminals are short-circuited, the volt drop is 1.0 p.u. (100%) and the short circuit kVA loading is  $1000 \times (1/0.05) = 20\,000$  kVA, and this is the maximum that the transformer can pass. Again, consider a length of 11 kV cable of impedance 1 Ω/phase and carrying 1000 kVA. The current is  $I = 4000/(11\sqrt{3}) = 52.5$  A, the phase voltage is  $E_{ph} = 41/\sqrt{3} = 6.35$  kV, the volt drop is  $v = 52.5 \times 1 = 52.5$  V, and the impedance of the cable is  $(52.5/6350) = 0.0083$  p.u. (0.83%).

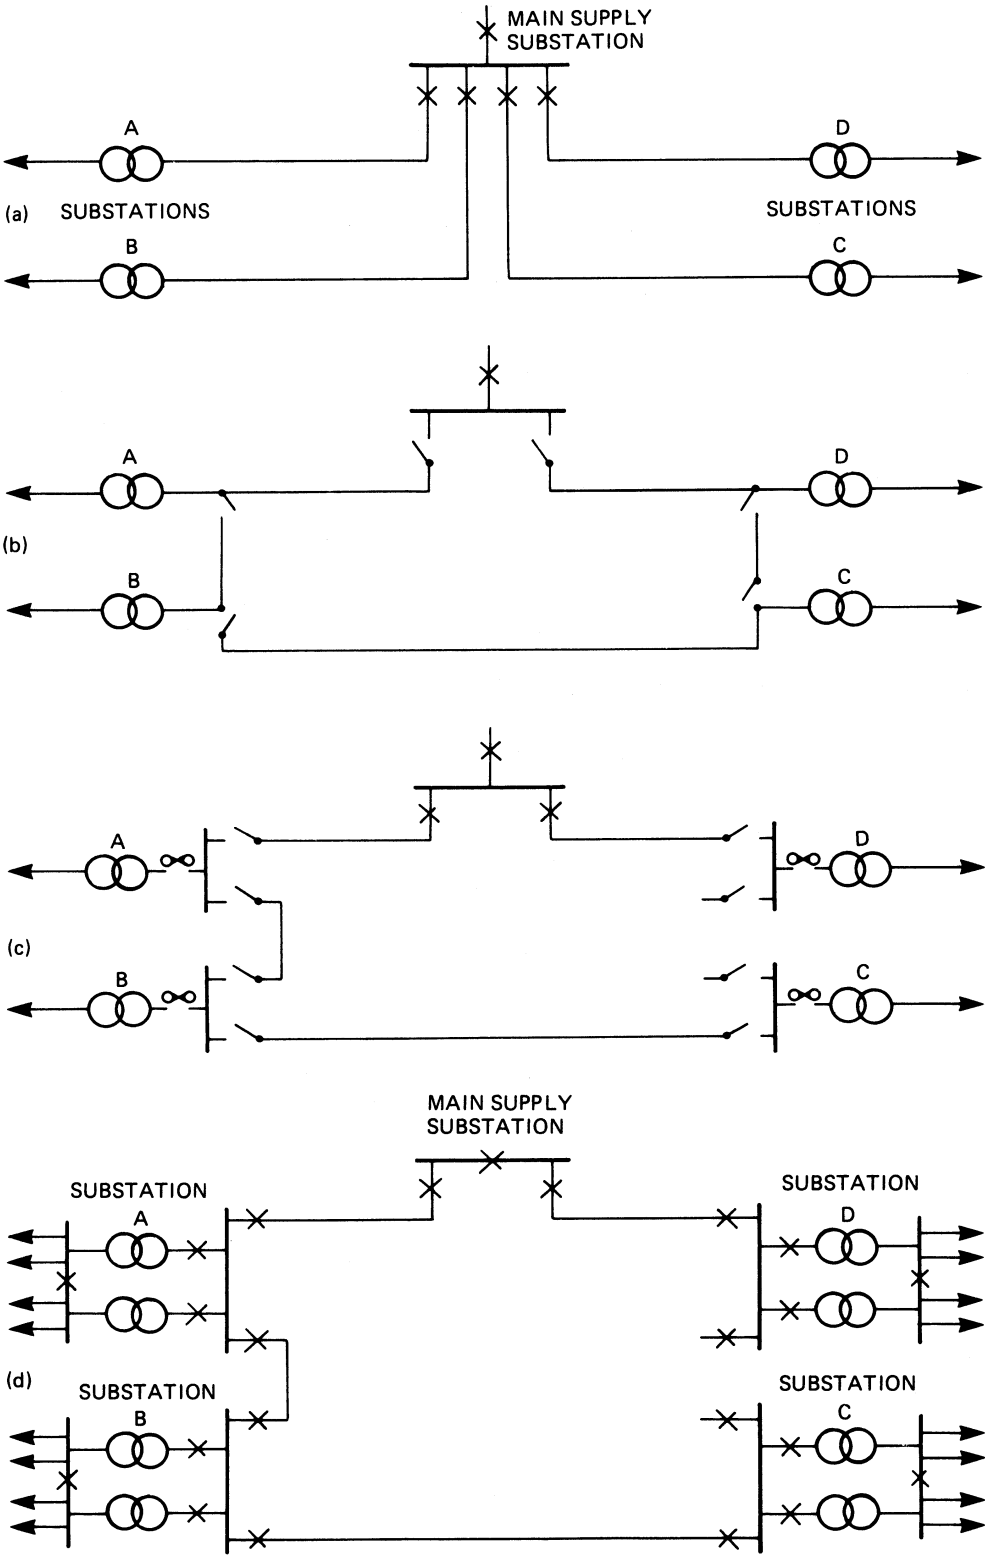

Calculation of the interrupting capacity  $S$  required at a point in a system is by assuming an arbitrary kVA/ $S_0$  in the system, and evaluating the voltage required to pass this load as a fraction  $x$  of the line-to-neutral voltage. Then  $S = S_0/x$ . The effective reactance of the system configuration involves summing branches in series and parallel and, in some cases, the application of the star/delta transformation technique. The availability of computer software that enables engineers to undertake fault analyses, protection and regulation calculations now speeds up the calculation process. *Table 38.1* gives typical values of reactance for generators and transformers.

## 38.5 Substations

The space requirements of a substation depend on the equipment to be housed, and on whether a new building can be erected for it or it has to be fitted into an existing building. In the latter case it may be difficult to achieve an ideal solution, but where no severe limitations are imposed the layout in *Figure 38.3* would prove satisfactory. This is suitable for a main 11 kV substation, also supplying local l.v. distribution, and it will be seen that it meets most of the following requirements:

- (1) There is adequate clearance around the equipment and space to withdraw circuit-breakers for maintenance.
- (2) Equipment operating at different voltages is segregated (advisable but not mandatory).
- (3) There is sufficient space for drawing in and connecting cables, and for the delivery and erection of additional switchgear: doorways are high and wide enough.
- (4) The walls can act as fire barriers. If a h.v. bus-section switch is included, a decision must be made as to the need for fire barrier walls between the sections. Even with oil circuit-breakers, this risk is small and many engineers disregard it.
- (5) Transformers are usually housed in open or semi-open compounds; but if an indoor location is essential, particular attention must be paid to its ventilation. The risk of a transformer fire is extremely small: nevertheless, an oil sump (usually filled with pebbles) should be provided to trap burning oil which could escape following a fire.

The substation design described above can be said to be traditional, but in recent years, with the almost universal use of vacuum and gas-insulated switchgear from 11 to 15 kV, and with the growth in availability of cast-resin

**Figure 38.2** Alternative supply system designs: (a) radial feeder; (b) simple ring main arrangement; (c) distribution substation with outgoing cables controlled by switch and fuses; (d) HV installation with automatic circuit-breakers

**Table 38.1** Typical per-unit reactances

45	—	0.10	0.11

distribution transformers, there has been a re-think on substation design for many applications. Over the past 20 years the concept of package substations was introduced whereby cast-resin transformers, low voltage switchgear, automatic power factor correction equipment and 11 kV switchgear is incorporated into a composite arrangement. It should be realised that there are savings in installation costs with possible improvements in safety as mentioned in 38.5.2. Today it is not unusual to find commercial buildings with electrical loads totalling tens of megawatts. The recent explosion of the IT industry and internet server installations has seen electrical loads in these bespoke buildings of up to 400 megawatts. The traditional approach of locating the transformers in the basement or in an outdoor compound with 415 V cabling to the l.v. switchboards may result in a very expensive distribution system. A new approach is to run 11 kV cables throughout the building to substations which incorporate the 11/0.415 kV transformer(s) as well as the 415 V switchgear. Typical of this is the combined board shown in *Figure 38.4*. In this illustration the transformer is of the dry insulated type, but increasingly cast-resin units are used. Both exhibit strong fire-resistance characteristics. This same approach can be as readily applied to industrial buildings.

To simplify the stock of spares and to ensure ready interchangeability between gear in different substations, as much standard equipment as possible should be used, even at the expense of varying from the ideal installation. In general, substations should be limited to a capacity of about 2000 or 3000 kVA, with individual transformers no larger than 1500 kVA, to allow for the use of commercial l.v. switchgear of about 43 kA rupturing capacity.

### 38.5.1 Low-voltage equipment

At substations the l.v. distribution gear consist usually of a circuit-breaker for each transformer with circuit-breakers, or switches and fuses for the outgoing feeders. L.v. feeders are usually supplied with ammeters and often with meters to

measure the energy consumption of the feeder. In many cases maximum-demand meters are included so that this feature can be periodically monitored—a useful facility in large industrial complexes. Intelligent l.v. switchgear is now available where strategically placed voltage sensors and circuit telemetry is monitored by a PLC. Thermal monitoring of bus-bars and connections using continuous infra-red detectors are also available.

Feeders radiate to the various sectional distribution centres, where they terminate at switchboards to which smaller sub-main cables are connected, supplying power to the various departments or shops by means of other small distribution boards. The most important feeders will again be duplicated or interconnected to some extent, to safeguard the supply, so that a l.v. breakdown will result only in a temporary shutdown of one section. With duplicate cables, one may be entirely spare or both cables may share the load, provided that they are both of sufficient capacity to carry the total current independently in emergency.

### 38.5.2 Packaged substations

In addition to the substation designs referred to in Section 38.5 the so-called 'packaged substation' has become increasingly popular. A typical design incorporates an h.v. SF<sub>6</sub> switch, a cast resin transformer and fused l.v. outgoing ways. They are popular with supply authorities partly because of their compact construction, which makes them attractive for installation where space is at a premium. They also require the minimum of site erection work. They can be supplied complete with a prefabricated enclosure, often of moulded reinforced fibreglass construction, or unclad and suitable for direct installation in a building.

### 38.5.3 Low-voltage distribution

From the substations described earlier, l.v. feeders run to subsidiary substations or load centres. These can include multi-motor starter boards, air-conditioning control boards, lighting and heating power distribution boards, vertical or horizontal bus-bars, street lighting supplies, etc. The range of alternatives is wide and the following paragraphs outline only some of the solutions available.

*Multi-motor starter boards* Large motors are usually supplied with independently separate feeders. Motor starter boards will probably have the facility for intelligent motor protection. This is advisable because of the heavy fluctuating load, which might otherwise cause disturbance to other plant on the same supply. However, where a number of small or medium sized motors are in reasonable proximity, it is convenient to group the starters in a multi-motor starter panel, which often includes one or more distribution boards for lighting.

*Air conditioning and ventilation control boards* These are variants of the multi-motor starter board. As well as starters for the fans and pumps of the system, they also include the specialist control equipment needed for the automatic control of the air conditioning and ventilation. Similar developments are found in many industries where plant process control equipment is incorporated into combined motor starter and small-power boards. These starter boards may also incorporate equipment for Building Management systems and communications capability to connect onto

**Figure 38.3** Typical 11/0.415 kV substation layout

circuit breakers and MCCBs which allows diagnostic data, indication signals and energy management to take place.

Intelligent motor control can be incorporated to monitor overload, overheating and earth faults.

**Bus-bar systems** In general, wherever there are continuous rows of machine tools to be fed, an overhead bus-bar system provides the required degree of flexibility. Used vertically, a bus-bar system offers simple and flexible provision of power in a high-rise building. Several manufacturers market

copper/aluminium bus-bars, embedded in epoxy cast resin, enclosed in steel trunking and provided with tapping points at intervals. Standard tees, bends and other accessories are available. At the tapping points it is possible to insert a tapping box, which can be safely applied or removed with the internal bus-bars live. When positions of machines have to be changed or new machines installed, it is easy to insert a tapping box at the appropriate point in the run of the bus-bar trunking. The maintenance cost is low, depreciation is minimal and there is a high recovery value if the trunking

**Figure 38.4** ABB 415 V switchboard, incorporating dry type 11/0.415 kV transformer, main incoming I.v. air circuit-breaker and outgoing I.v. circuits

has to be demounted and rerun. Earth continuity can be provided by an external link bolted between lengths of trunking, but for large ratings a separate earth conductor is necessary. No cables other than the bus-bars themselves may be included within the trunking. Fire barriers are required for vertical runs, and for long runs it is advisable to provide bus-bar expansion joints.

From the individual fuse switch (or circuit-breaker) units on the overhead bus-bar, cables in conduit or flexible metallic tubing are run to the machine tools. In the case of tools with more than one motor, distribution boards can be mounted at a convenient point on the equipment.

Vertical bus-bars are usually run in a vertical duct within the building. A lock-proof cupboard is formed at each floor level and the distribution boards and switches are accommodated therein, with the outgoing supplies fed to meet the lighting and power needs of the floor occupants. Where possible, it is preferable to use only one phase on each floor of the building, as this eliminates risk of voltages in excess of 240 V being encountered by personnel.

## 38.6 Wiring systems

The choice of wiring system for industrial, commercial and domestic installations depends on the structure, application, supply voltage, load, appearance and cost. An essential feature is a proper earthing system giving an earth continuity conducting path for protection and safety.

### 38.6.1 Steel conduit

Screwed steel conduit, either galvanised for corrosion resistance or black enamel, provides a potentially good earth

continuity, and makes it possible to enclose cables throughout their length with strong mechanical protection. The conduit is normally of a heavy-gauge welded construction.

Skill is required to achieve a proper system of good appearance. The conduit should be erected completely before cables are drawn in; tube ends should be reamed to prevent damage to cables; draw-in boxes should be amply proportioned and accessible; the conduit should be adequately supported by saddles or clips. There should be no more than two right-angle bends (or their equivalent) between successive draw-in boxes. The whole system should be mechanically continuous throughout, including connections to switches, fittings, distribution boards, motor control gear and the metal cases of other equipment; and it must be properly earthed.

Most conduit systems in factories are run on the surface, but in offices, or where conduit would be affected by corrosive fumes, it may be sunk in concrete in the floor or in walls behind plaster or cement. The layout must be carefully pre-planned, and joints must be tight, to prevent the ingress of wet concrete, cement or plaster. A draw wire should be pulled through as soon as possible after pouring or plastering, to remove any intrusive material before it hardens. The actual wiring is left until all is dry, and all wiring in one conduit must be drawn in at the same time.

### 38.6.2 Plastic conduit

In recent years there has been an upsurge in the use of plastic conduit. Polyvinyl chloride (PVC) components are generally unaffected by water, acids, oxidising agents, oils, aggressive soils, fungi and bacteria, and they can be buried in concrete or plaster. They provide slight resistance to heat and flame, and in this respect are inferior to steel conduit. Their mechanical strength is also much less.

Flexible heavy duty nylon conduit is also available for cable protection in installation systems. This system is self-extinguishing, free of phosphor, halogen and cadmium and is shock resistant.

They are not electrically conductive and separate earth continuity conductors have to be run, which on occasion can require a larger diameter than for a steel conduit. Expansion couplings may need to be included in long straight runs, as linear expansion of PVC gives it an extension of about 1.5 mm/m for a temperature rise of 20°C. On the other hand, the conduit can be readily cut by hacksaw and bent when gently heated. PVC conduit can be screwed using suitable dies, but jointing of lengths is commonly by a solvent welding compound. This is easier, quicker and provides an entirely watertight joint.

PVC conduit and fittings are marginally cheaper than the equivalent steel conduit components, but PVC is a by-product of the oil industry and its price comparison with steel conduit is likely to vary.

### 38.6.3 Trunking

Trunking is used to bunch numbers of cables or wires which follow the same route, with branches to motors, switchgear and lighting circuits by spurs in trunking or conduit. Trunking is made in various sections from 50 mm × 40 mm upward and in standard lengths. Tees, reducers, crossings, elbows and other fittings are made as shown in Figure 38.5.

Both steel and plastic trunking are used. With the former, low-resistance joints between lengths of trunking and fittings are essential. If the trunking is itself used as a 'protective conductor' under the requirements of the Wiring Regulation, its bonding and jointing are specified. Where conduits connect to the trunking, a clearance hole is drilled in the trunking wall and the conduit connected with a socket and male bush. Connections between trunking and switchboards and similar panels are generally effected by flanges securely bonded to the trunking and bolted to the switchgear.

Figure 38.5 Cable trunking

On a switchboard or distribution panel in which lengths of trunking enclose the various interconnecting cables, the units should be bonded to the trunking by a copper earth tape. In the case of vertical runs of trunking, internal fire barriers must be fitted at each floor level. These barriers must also be fitted in horizontal runs where the trunking passes from one zone of fire protection to another.

Plastics trunking is made in sizes similar to those for steel trunking, small sizes being extruded and large ones formed from PVC laminated sheet. Common fittings are available, but as PVC is easily 'formed', special fittings can be 'welded' with the help of a hot-air welding gun. The characteristics of PVC trunking make it particularly suitable for fume-laden atmospheres, humid tropical conditions and salt-laden coastal air. The material has the physical characteristics mentioned in Section 38.6.2 and for the same reason requires a copper conductor to be included to provide an effective earth. Screwed or snap covers may be used.

### 38.6.4 Cabling

Details of insulated cables or conductors are given in Chapter 31. The following cables have applications special to the wiring of buildings:

#### 38.6.4.1 Mineral insulated metal sheathed cables

A mineral insulated metal sheathed (MIMS) cable normally consists of high-conductivity single-strand copper conductors inside a seamless copper sheath packed with magnesium oxide powder as the insulant. As an alternative aluminium conductors and sheath are also available. The sheath acts as a robust and malleable conduit, capable of withstanding considerable mechanical abuse. It is strongly fire resistant, and when covered overall with an LSF sheathing can withstand chemical corrosion.

Because magnesium oxide is hygroscopic, the exposed cable ends must be sealed. The sealants are suitable for operating temperatures up to 70°C, but special oil-resistant and high-temperature seals are available for special applications.

Although dearer than the equivalent steel conduit installation, there are applications where MIMS cabling is superior and preferred. For example, some fire authorities insist on MIMS cables for all fire protection, detection and alarm circuits.

#### 38.6.4.2 PVC/PVC sheathed cables

For domestic installations, PVC insulated and sheathed cables are often used, run on the surface, or more usually buried in plaster. Since there is at least a perceived danger of buried cables being penetrated by a nail or screw driven into the wall, the IEE Regulations have since 1987 been amended to lay down strict rules as to the positioning of buried cables. For example, cable connected to any point or accessory on the wall must be run horizontally or vertically to the point or accessory; in this regard, the consumer unit is treated as an accessory.

In small industrial installations where cost is a prime consideration, it may sometimes be acceptable to run PVC sheathed cabling fixed by cleats spaced about 1 m apart. Cables should preferably not be concealed and must be protected where they run through floors, and also on walls if fixed at a level below about 1.6 m from the floor.

## 38.7 Lighting and small power

Whatever type of electrical installation is involved—be it for a factory, a public or commercial building, or domestic premises—supplies for electric lighting and small power will be needed.

### 38.7.1 Lighting circuits

There are two main ways of running lighting circuits, 'loop-in' and 'junction box'. Both can be used in the same installation. In the loop-in system (a) in *Figure 38.6* the terminals for joining the cable ends form part of the ceiling rose. The junction-box system (b) is used when the lighting fittings have no loop-in terminals, or to save cable when the lamp and the switch are far apart. The connections are similar to those in the loop-in system. The new 3 and 4 pin plug in lighting system now offers the installer greater flexibility and ease of installation especially with dimmable fluorescent lighting and emergency lighting circuits.

#### 38.7.1.1 Two-way switching

The two-way switch is a single-pole changeover switch. When interconnected in pairs, two-way switches provide control from two positions and are therefore installed on landings and staircases, in long halls and in any room with two doors. The arrangement is as shown diagrammatically in *Figure 38.7(a)*.

#### 38.7.1.2 Intermediate switches

Where there are long halls, corridors or passageways, with several doors, it may be convenient to introduce additional switching positions. The 'intermediate' switch enables any number of additional switching points to be introduced to the two-way switch circuit, as in *Figure 38.7(b)*.

#### 38.7.1.3 Master control switching

A master control switch is sometimes provided to give over-all control to a number of lamps which are, in addition,

independently switched, as in *Figure 38.7(c)*. A typical installation would be an hotel bedroom or suite, where a double-pole switch at the entrance to the room will switch off all lights on the occupants leaving the room.

In new office installations, increasing use is being made of master control switching, usually by way of sophisticated relay systems which allow groups of lights (sometimes whole floors) to be controlled by timer, or by measuring the ambient light conditions and switching lights 'off' or 'on' to suit.

More modern lighting controls will consist of internal and external illumination sensors connected to micro-processor controls which monitor and control luminaires, from the window line, to achieve energy savings and sophisticated lighting control via high frequency dimming for T5 fluorescent lamps.

The new generation of micro-processor based control units incorporate LCD touch panels to enable activation of pre-set lighting schemes together with adjustment of blinds, air conditioning and sound systems.

### 38.7.2 Small power circuits

The socket outlet is a safe and convenient means by which free-standing or portable apparatus can be connected to an electric supply. It is false economy to limit the number of socket outlets installed. Sufficient should be provided to match the predicted needs of the consumer, and should be located adjacent to the most convenient point of use of the apparatus.

Both radial and ring final sub-circuits may be used to connect socket outlets, although in the UK the 30 A ring-main system using BS 1363:1984 fused plugs has held sway for many years. With this system, the current-carrying and earth-continuity conductors are in the form of loops, both ends of which are connected to a single way in the distribution board. The conductors pass unbroken through socket outlets or junction boxes (or must be joined in an approved manner). The ring may feed an unlimited number of socket outlets or fixed appliances but the floor area covered shall not exceed 100 m<sup>2</sup>. In domestic premises particular consideration should be given to the loading in the kitchen, which may require an additional circuit.

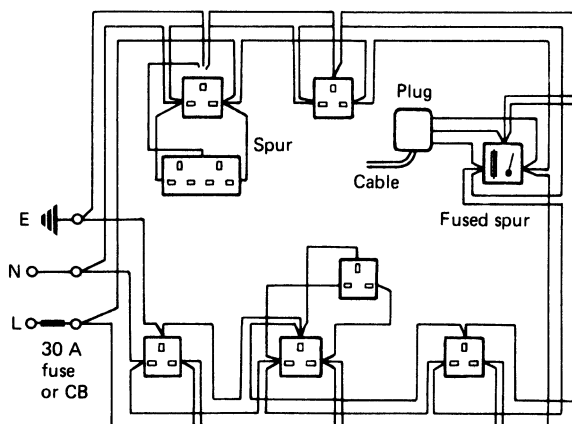

**Figure 38.6** Ceiling rose loop-in and junction-box wiring: (a) loop-in system; (b) junction-box system. —, Red, always live; ----, black, neutral except where returning from a switch; —, earth; —, flex to lamp

**Figure 38.7** Lamp switching: (a) two-way switching; (b) two-way and intermediate switching; (c) master control switching

In the UK an unlimited number of fused connection units may be installed in a ring circuit, but the number of *non*-fused connection units must not exceed the number of socket outlets, or one permanently connected item of equipment. A typical ring circuit is shown in *Figure 38.8*.

Portable apparatus is now normally supplied with moulded plugs. At the same time more and more consumer units are being equipped with miniature circuit-breakers in place of fuses. It is also obvious that 13 A socket outlets to BS 1363:1984; Pt 1:1995 are bigger, more obtrusive and more expensive than the Continental or American counter-

**Figure 38.8** Ring circuit for 13 A outputs. CB, circuit-breaker

parts. Is it perhaps not time that we give some thought in the UK to a reversion to radial circuits and to non-fused plugs?

## 38.8 Floor trunking

Floor trunking is used mainly as a flexible means of providing small-power and telephone facilities throughout an open floor area. The basic methods are underfloor, open-top and cavity-floor systems. All must have continuity between metal sections and be adequately earthed.

### 38.8.1 Underfloor trunking

The several proprietary brands available consist basically of a closed trunking with one, two or three compartments, laid in a grid pattern on the floor slab. Specially designed intersection boxes take care of the crossovers in the lines of trunking, and fixed outlet boxes from the trunking are installed to meet all possible future needs. When the trunking is screeded over, the intersection and outlet box lids are flush with the final floor level.

### 38.8.2 Open-top trunking

Open-top trunking is a more recent concept of floor trunking. As with the underfloor trunking it is laid on the floor slab before screeding, but in this case the heavy-duty cover plates of the trunking are flush with the final floor finish, which makes it easy for outlet boxes to be added anywhere along the length of the trunking as changing needs demand, hence giving a greater degree of flexibility.

### 38.8.3 Cavity-floor systems/dado trunking

This flexible system comprises wood or metal square plates resting on support jacks. The services are run in conduit or trunking on the surface of the floor slab under the floor plates. Flush surface boxes can be installed into holes cut almost anywhere in the suspended floor, and wiring to power and telephone outlets is routed via conduits or

**Figure 38.9** 'ALPHATRAK' cavity-floor trunking system. (Courtesy of Power Plan Systems Ltd)

trunking to central junction boxes. (A typical installation is shown in *Figure 38.9*.) There are now slim shallow products on the market with desk modules to connect to user power, voice and data appliances. Underfloor power distribution, available in 63 A, 40 A and 25 A is suitable for power to PC circuits and is available with clean and standard earthing systems.

Dado wall mounted cable management trunking consists of a series of single, twin and multi-compartment systems in various sizes produced in high impact UPVC. The trunking will accept wiring accessories and a bus-bar variant. The cable compartments are designed for power, communications and data outlets.

Data tray cable basket systems are manufactured from 50 mm × 50 mm wire mesh grid with the facility to provide take off or support positions throughout the length of the installation. The installed matrix system is ideal for most power, data, low voltage signal and some pneumatic systems.

## 38.9 Stand-by and emergency supplies

Provision for supply failure has sometimes to be considered, most commonly for emergency lighting in the form of (i) escape lighting (to ensure the provision of adequate illumination of emergency escape routes), and (ii) stand-by lighting (to enable normal activities to continue during the period of mains failure). The two most common systems of emergency lighting are: *maintained*, where normal lighting is fully maintained by automatic switching to an alternative source should mains failure occur; and *non-maintained*, where the emergency lamps are energised only when the normal lighting has failed.

Both systems are used extensively. The maintained system is essential in certain public buildings, and is the system preferred for 'stand-by' lighting.

Standards of emergency lighting are derived from the Fire Precautions Act 1971 and Fire Precautions Regulations Updates 1997. The CIBSE Lighting Code and BS 5266: Part 1 7:1999 also provides some useful guidance.

In the past, most emergency lighting systems were supplied from a central battery and charger unit, but self-contained emergency lighting luminaires have become readily available for both maintained and non-maintained systems. Each unit comprises a lamp, battery, charger and control equipment, and is wired conventionally into the normal lighting system. Usually a neon or diode indicator is incorporated to provide a visual indication that the battery is under charge. In general, where fewer than 20 fittings are involved, the self-contained luminaires are likely to give the more cost-effective solution. To be effective it is essential that emergency lighting is regularly tested and a maintenance procedure set in place. This can be done by semi-automatic and fully automatic testing.

## 38.10 Special buildings

### 38.10.1 High-rise buildings

With large high-rise buildings, the heavy electrical and mechanical services plant is usually located in the basement and/or basement and part-way up the building. However, there are occasions when air-conditioning chillers, stand-by generating plant and even boilers are located on the roof, and this can influence the positioning of the main electrical

switchboards. Nevertheless, since the main power supply enters at basement level, it is usual to locate the main transformer and the primary substation in the basement. Basement-mounted equipment will normally provide supply for 10–12 floors, for taller buildings additional substations are required every 10–15 floors.

When equipment is installed in buildings to be used as offices or apartments, particular attention must be given to preventing unnecessary vibration. Rotating plant should be provided with anti-vibration mountings. In a new building the architect and the structural engineer should co-operate in providing a 'floating' floor to support equipment liable to vibration.

### 38.10.2 Public buildings

In installations for large buildings and special establishments open to the public (such as theatres, cinemas, etc.) special precautions must be taken in the layout of the electrical equipment. National standards and any regulations formed by the local authorities must be strictly observed in planning the scheme. These deal more especially with the requirements necessary to avoid danger to the public from fire, explosion, electric shock, etc. and are also concerned with the question of dual supply or emergency lighting in the event of a breakdown of the power mains.

### 38.10.3 Domestic premises

Domestic premises are commonly connected to the street supply by a one-phase l.v. PVC cable, often with aluminium conductors. The incoming supply is rated at between 60 and 100 A and is capable of supplying the lighting, heating and cooking demands of the house or flat.

The incoming cable terminates in a service cut-out and connects via the house meter to a consumer's unit. There is an increasing desire with new housing to locate the meter in a position where the meter reader can read it without access to the house. The consumer unit is equipped with an incoming supply switch and outgoing ways using high rupturing capacity (HRC) fuses or miniature circuit-breakers. One or more 30 A ring mains for socket outlets will be provided. Immersion heaters fitted to hot-water cylinders in excess of 15 litre capacity should be supplied from an independent circuit. Electric cookers are fed by a final sub-circuit through a cooker control unit which may also include a 13 A socket outlet.

When the ratings of the protective devices or the quality of the earthing is such that an earth fault would not be cleared within the prescribed time, a residual-current device (r.c.d) should be fitted. It could cover a whole domestic installation, but there can then be a risk of spurious tripping caused by the normal leakage currents of healthy equipment.

An alternative would be to use one r.c.d on a socket outlet circuit. Certainly, if a socket outlet is used to connect garden tools, this should be protected by an r.c.d. The r.c.d can be incorporated in the consumer unit; a unit comprising one socket outlet and an r.c.d unit can be contained in a twin-socket box or a plug in unit.

## 38.11 Low-voltage switchgear and protection

Heavy switchgear is dealt with in Chapter 34. The term 'industrial switchgear' is generally applied to that used for

voltages not exceeding 600 V and controlling power from the l.v. side of a transformer to distribution boards which may include automatic circuit-breakers, or to fuse switches and contactors for motor-starting equipment. Consideration must be given to the prospective fault current at the point of installation, particularly as it may directly affect personnel, often unskilled and unaware of the danger should the apparatus fail to perform its function.

Today oil circuit-breakers are out of favour for operation at 415 V. Air circuit-breakers are still preferred by many engineers to moulded-case circuit-breakers, and for the higher current and fault levels they are essential.

### 38.11.1 Air circuit-breakers

For the larger industrial and commercial consumer the principal switchboard, and often subsidiary switchboards, will normally comprise a factory built cubicle assembly, incorporating conventional air circuit-breakers with ratings up to 4000 A. Air circuit-breakers now normally incorporate microprocessor electronic protection and management controls. Composite boards with a mix of air circuit-breakers, moulded-case breakers, fuse switches and contactor gear are also common. Segregation of components are via various forms of separation for the bus-bars, functional units and incoming or outgoing terminations. The forms of separation range from Form 1 to Form 4b, type 7.

#### 38.11.1.1 Forms of internal separation

##### The Standard

- Form 1 No Separation
- Form 2 Separation of bus-bars from functional units
- Form 3a Separation of bus-bars from functional units  
Separation of functional units from one another  
Separation of the outgoing terminals from the functional units  
*But*  
No separation of terminals from one another  
No separation of terminals from the bus-bars
- Form 3b Separation of bus-bars from functional units  
Separation of functional units from one another  
Separation of the outgoing terminals from the functional units  
Separation of terminals from the bus-bars  
*But*  
No separation of terminals from one another
- Form 4 Separation of bus-bars from functional units  
Separation of functional units from one another  
Separation of the outgoing terminals from the functional units  
Separation of terminals from one another

#### Form 4 – Type 1

Separation of bus-bars by insulated coverings, e.g. sleeving, wrapping or coatings  
Terminals in same compartment as functional unit

#### Form 4 – Type 2

Separation of bus-bars by metallic or non-metallic rigid barriers or partitions

Cables glanded elsewhere

Terminals in same compartment as functional unit

#### Form 4 – Type 3

*All* separation by metallic or non-metallic rigid barriers or partitions

The terminals for each functional unit have their own integral glanding facility

Terminals in same compartment as functional unit

#### Form 4 – Type 4

Separation of bus-bars by insulated coverings, e.g. sleeving, wrapping or coatings

Cables glanded elsewhere

Terminals *not* in same compartment as functional unit

#### Form 4 – Type 5

Separation of bus-bars by metallic or non-metallic rigid barriers or partitions

The terminals for each functional unit are separated by insulated coverings

Cables glanded in common cabling chamber

Terminals *not* in same compartment as functional unit

#### Form 4 – Type 6

*All* separation by metallic or non-metallic rigid barriers or partitions

Cables glanded in *common* cabling chamber

Terminals *not* in same compartment as functional unit

#### Form 4 – Type 7

*All* separation by metallic or non-metallic rigid barriers or partitions

The terminals for each functional unit have their own individual glanding facility

Terminals *not* in same compartment as functional unit

Where the switchboard manufacturer is not also the manufacturer of the air circuit-breakers, the customer should seriously consider the use of 'cassette' breakers. With this design each breaker is delivered to the switchboard builder complete in a sturdy 'box', i.e. the cassette. The breaker design will have been type tested in its cassette. Hence the user can be satisfied that the breaker will retain its certified test rating when fitted in a custom-built switchboard. This cannot be assumed with breakers offered to the switchboard builder in 'open cradle' form. At the same time, the switchboard builder can be absolved from having to carry out separate type tests to guarantee the requisite ASTA rating.

### 38.11.2 Moulded-case circuit-breakers

Of particular interest to the installation engineer are moulded-case breakers which find wide use in commercial and industrial applications. They are primarily intended for applications such as protecting main feeder cables, or acting as main circuit-breakers controlling large banks of other circuit-breakers. As such, their major function is to provide back-up protection to the sub-circuit protective devices. Overcurrent protection is a relatively secondary function. The moulded-case breaker is of more robust construction

than the miniature circuit-breaker and can often be provided with auxiliary items such as extended operating handles for assembly in multi-switch cubicles, mechanical interlocking with adjacent breakers, motor-operated mechanisms and shunt trip coils. Current ratings up to 1250 A and short-circuit capacities between 25 kA to 150 kA are readily available.

### 38.11.3 Miniature circuit-breakers

Miniature circuit-breakers usually embody both overload and short-circuit current tripping devices, the overload usually by a thermal device, the short circuit by a magnetic one. A trip-free mechanism is incorporated so that the contacts cannot be held closed against a fault, and the thermal element prevents continuous rapid reclosing of a circuit when a fault persists.

The primary function of a miniature circuit-breaker is to protect an installation or appliance against sustained overloading and short-circuit faults, but it will also give protection against earth faults provided that the earth fault loop impedance is low enough. As a secondary function the miniature circuit-breaker can be used as an isolating switch or for local control switching. Today they are widely used in place of fuses in domestic installations where householders find them more convenient.

A circuit-breaker used to protect a sub-circuit should have a current rating matched to its load. The circuit-breaker rating must not exceed that of the cable; also, the current causing effective operation of the breaker must not exceed 1.45 times the lowest current-carrying capacity of any of the conductors in the circuit. (This requirement of WR16 also applies to other protective devices such as fuses.)

Miniature circuit-breakers are available with current ratings from about 0.5 to 100 A, with a fault capacity of 16 kA although values of 9/10 kA are more normal.

### 38.11.4 Fuses

The first edition of the IEE Wiring Regulations in 1881 contained a note reading: 'The fuse is the very essence of safety'. Today, over 120 years later, fuses have to face competition from other devices, but in their many modern guises, though very different from their counterparts of the 19th century, they still play an outstanding role in the protection of electrical circuits.

The HRC fuse is the common type for general power system use. It was first introduced in the 1920s, and in the intervening years its design and performance have steadily improved, until today it has an unrivalled reputation as a short-circuit protective device. Its breaking capacity and energy and current-limiting ability are superior to those of any other protective device.

The design of the HRC fuse is described in Section 34.2.2.2. The most important design feature is the fusible link, usually of silver or silver/tin alloy, but often with the addition of other metal inserts. This enables the designer to achieve the desired time/current and other characteristics, striking a balance between conflicting requirements of minimum fusing current, low let through  $I^2t$  and peak current on short circuit.

BS 88 was revised and up-dated in 1988, and is now identical to IEC 269 and BS EN 60269:1:1999, 'Low voltage fuses'. It makes significant progress in the international standardisation of LV fuses. The aim has been to achieve safe electrical installations, particularly from the viewpoint

of avoidance of electrical shock, both in normal and fault conditions, and the provision of overcurrent protection to the electrical cables forming the fixed installation.

Some of the fuse link types used in some European countries have only partial range breaking capacity, i.e. they interrupt short-circuit fault currents, but are unable to interrupt overload currents safely. To distinguish these types from the much more widely used general-purpose fuse links, the concept of 'utilisation category' has been introduced in IEC 269, and in the revised BS 88:1988.

Each of the classes is identified by a two-letter code. The first letter indicates the breaking range of the fuse link:

- g A full-range breaking capacity.
- a A partial-range breaking capacity.

The second letter indicates the utilisation category:

- G A fuse link for general application, including the protection of motor circuits.
- M a fuse link for the protection of motor circuits.

The standards combine these letters to recognise three classes: i.e. gG, gM and aM.

Although harmonisation of the fuse dimensions as between the German, French, British and other systems has not yet been achieved, effectively there has been wide agreement on electrical parameters. This is a major achievement because it means that all general-purpose fuses, from whatever source, can be applied in the same manner. For example, for all fuses above 16 A rating, the fusing current shall not be less than  $1.25I_n$ , where  $I_n$  is the fuse rating.

Similarly, compliance with the specification results in a discrimination ratio between major and minor fuses of 1.6:1 based on pre-arcing characteristics. When fault current in an a.c. circuit starts to rise, the fuse element heats and begins to melt. This takes a finite *pre-arcing* time. As the element ruptures arcing occurs and shortly afterwards the break is complete, the arcing ceases and the current drops to zero. This is the *arcing* time. The sum of these two is the *total operating* time. In the past it was accepted that discrimination between major and minor fuses should be based on the vast majority of installation, under fault conditions with total operating times, but it is now argued that in modern fuses the arcing  $I^2t$  can be ignored. Even in three-phase circuits with relatively high power factors and fault levels up to 80 kA at 415 V, the 1.6:1 ratio is found to be valid, and this clearly provides economic benefits in any modern installation.

### 38.11.5 Prospective fault current

The prospective fault current at any point in a system is the current that would flow if there were a solid short-circuit at that point, and it represents the maximum current the protective device would have to interrupt. In practice, the actual current is usually much less than the prospective fault current because seldom does a solid three-phase short-circuit occur at the terminals of the protection device, and even short lengths of intervening cable reduce the fault current considerably. Nevertheless, knowledge of prospective fault current is necessary to ensure that the circuit-breakers, fuses, etc. in the system can deal with the fault current. If the fault level at the point is in excess of the rupturing capacity of the device, damage can be done to the installation and to the protective device itself, because of the amount of energy that passes before the current is completely interrupted. In such cases the protective device must be backed up by another breaker, or by fuses capable

of interrupting the fault and before the 'let-through' energy has built up. The total 'let-through' energy is identified by  $I^2t$ , where  $I$  is the fault current and  $t$  is the time for which the current flows before complete interruption.

### 38.11.6 Discrimination

A major consideration in designing a distribution system is the problem of ensuring effective discrimination. Ideally, the protective devices should be so graded that, when a fault occurs, only the device nearest the fault operates. The other devices should remain intact and continue supplying the healthy circuits. It is usually possible to assess, with fair accuracy, how effective the discrimination will be between combinations of circuit-breakers and fuses, but there are several practical considerations to be taken into account: (i) manufacturing tolerances in components, and (ii) operating conditions such that the devices do not conform to the published data. Over a period of time a fuse may be subjected to high currents causing it to 'age', and this can have an adverse effect on its behaviour.

In any medium to large installation, the supply is subdivided for distribution, and hence there will be protective devices (sometimes several) between the final device and its source of supply. At the other end of the scale, as in a domestic ring circuit, there may be fuses further down the line backed by miniature circuit breakers. The primary objective is to ensure that the device in question will deal with faults up to its breaking capacity, the back up device taking over above this level. (These other protective devices may be circuit-breakers or fuses.) This, theoretically, is the ideal condition, but in practice—to allow for the discrepancies mentioned above—it is usually advisable to aim for back-up protection taking over at a fault-current level not exceeding about 70% of the circuit-breaker breaking capacity. The need to comply with this requirement will automatically set the upper limit to the current rating of the back-up device. The lower limit of current rating is usually set by the need to avoid loss of discrimination.

Where miniature circuit-breakers in sub-circuit distribution boards are concerned, the miniature circuit-breaker should be the device to operate for all fault levels up to 1000 A, i.e. the great majority of sub-circuit fault currents. If the zone in which the back-up fuse tends to take over from the circuit-breaker is below 1000 A, discrimination troubles may be experienced, but provided that it is not below about 700–800 A, operating experience indicates that little trouble will be met on this score. If the zone is above 1300 A, the installation should be relatively free, in practice, from any form of discrimination trouble.

If fuse time/current characteristics are available, the probable position of the take-over zone can be addressed quite readily. The total time taken by a miniature circuit-breaker to clear a short-circuit fault is usually about 10 ms. If, therefore, the prearcing or melting time of the back-up fuse—at a given level of fault current—is less than 10 ms, it is reasonable to assume that at that level of fault current a m.c.b. will not consistently discriminate against the back-up fuse. Thus, the current at which the fuse prearcing time/current characteristic crosses the 10 ms line will give a working guide to the position of the take-over zone.

The family of time/current characteristics shown in Figure 38.10 is for a typical range of quick-acting HRC fuses. From this diagram it will be seen that the 63 A characteristic crosses the 10 ms line at about 1000 A. From this it is reasonable to assume that the take-over zone, i.e. the range of current over which there is a possibility of loss

**Figure 38.10** Time/current characteristics for HRC fuses and MCSs. HRC fuses ----; HRC fuse; 30 A MCSs —

of discrimination, will probably extend from about 800 to 1000 A. For fault currents less than 800 A there should be no trouble with the back-up fuse. With an 80 A fuse the zone will probably extend from about 1100 to 2500 A. Hence, if a quick-acting HRC fuse is used for back-up, ideally it should not be rated at less than 80 A, and preferably at not less than 100 A.

The use of readily available computer programs to undertake a full discrimination study would enable the engineer to add, select, change and delete a device with reference to fault levels, in rush conditions and measuring the grading margin.

### 38.11.7 Motor control gear

A motor starter may be an individual item of equipment, or one of several in a multi-motor starter panel. In general, the supply authority lays down the limits of starting current permissible. Small motors are normally switched direct-on-line, but larger machines may require starting methods that limit the starting current and power factor.

#### 38.11.7.1 Isolating switches

The Electricity at Work Regulations and the IEE Regulations WR16 require that every motor be provided with a means of disconnecting the motor and all its auxiliary equipment, including any automatic circuit-breaker. The isolating switch should be mounted nearby and is often incorporated in the same case as the starter itself. The switch must be capable of making and breaking the stalled current of the motor and under normal conditions it remains closed. The switch often incorporates auxiliary contacts which (among other functions) isolate the control

circuitry in the starter, to ensure that the starter and its control circuit are isolated before the door is opened and maintenance work begun. The regulations do allow an isolating device to be located remote from the motor, but under these circumstances provision must be made so that the means of isolation can be secured in the open position.

### 38.11.7.2 Contactor starter

For the smallest motors, a manual mechanical switch is acceptable; however, the Regulations require that means must be provided to prevent automatic restarting after stoppage (due to drop in voltage or failure of supply) where unexpected restarting might cause danger. Where such a device is provided, it is logical that it should also be used to operate the switching contacts, and this is the reason for the popularity of electromagnetically operated contactor starters. Many other advantages, such as easy control by relays, limit switches and other light current devices, follow the adoption of contactor starters.

There are two basic types of contactor—the electrically held-in and the latched-in type. With both, the contactor should close when the voltage is as low as 85% of nominal. With the electrically held-in type, should there be a transient failure of the supply, the contactor will drop out. With certain types of drive this can be embarrassing, and a latched-in contactor may be preferred. With this type, the 'close' coil energises the contactor, which then latches in, and the 'close' coil is de-energised. The contactor is opened by energising an 'open' coil or by the operation of a protective device.

### 38.11.7.3 Motor protection

Motor starters are usually fitted with a trip device which deals with overcurrents from just above normal running current of the motor to the stall current. The aim should be for the device to match the characteristics of the motor so that full advantage may be taken of any overload capacity. Equally, the trip device must open the starter contactor before there is any danger of permanent damage to the motor.

Contactors are not normally designed to cope with the clearance of short-circuit conditions, and it is therefore usual for the contactor to be backed up by HRC fuses or by circuit-breaker.

The arrival on the scene of very compact motor starters and the need to provide proper back-up protection to them has posed a problem. BS EN 60947-4-1 (1992) (previously BS 4941) 'Motor starters', describes three types of co-ordination, the most onerous condition (type C) requiring that under fault conditions there shall be no damage to the starter or to the overload relay. The usual back-up device will be the HRC fuse. It is important that the user check with the manufacturer's catalogue to ensure that the correct fuse is used to secure this co-ordination.

### 38.11.7.4 Remote control of motors

When the starter is mounted remote from its motor, care must be taken in positioning the control push-buttons. Accidents can occur when the operator cannot view the motor from the control position; it may then be necessary to mount pilot lights adjacent to the motor to indicate to local personnel that it is about to start. In some cases, particularly with large complex machines, it may be necessary to give audible warning that the equipment is about to be started.

When an emergency stop button is located adjacent to the motor, it should be of the lock-off variety, so that when operated, not only does the motor come to a standstill, but also it cannot restart until the lock-off push-button has been released.

### 38.11.7.5 Braking and stopping machines

When it is necessary to stop a machine very quickly, some form of braking must be employed. An ordinary friction brake, the simplest device, should be held off against a spring or counterweight, so that it is applied automatically if power should fail. Electrodynamical braking is ineffective at slow speeds: it is therefore a useful addition rather than an alternative to a friction brake. Torque reversal (plugging) is very effective, but in many cases a reverse rotation cut-out will be required.

Care must be taken with the connection to the brake. Some motors tend to generate during run-down, and the brake circuit must therefore be interrupted positively to ensure that the friction brake is applied. A particular danger arises when rectified current is used for the brake solenoid on large machines. It may be found that the rectifier acts as a low-resistance shunt across the brake coil and prevents the magnetic flux collapsing quickly, making the brake action sluggish. In this case it is necessary for the main contactor to have separate contacts in the brake-magnet circuit.

When heavy machines are controlled by plugging, a problem will arise if the power supply should fail, for this would leave the machine uncontrolled, unless there is back-up emergency braking.

### 38.11.7.6 Limit switches

Limit switches are generally used to initiate a control sequence at the correct point in the mechanical duty cycle of a machine. For example, they may signify the end of a crane travel and initiate the stop sequence. Limit switches must be of robust construction—well protected against the ingress of fluids, dust or dirt. They are frequently used on machines expected to have a long life, and it is essential that the limit switches be equally generously designed. The current-carrying capacity of the electrical contacts should also be generously rated, since they may well have to handle in-rush current.

### 38.11.7.7 Inching control

When frequent inching is required, it is preferable that a separate contactor be employed. However, the motor circuit should still be taken through the overload protection device, to ensure that the motor is not allowed to overheat. At the same time the use of the separate contactor does restrict wear on the contacts of the main contactor.

## 38.12 Transformers

Most transformers used in industrial and commercial applications are either oil-filled or dry cast resin, natural-cooled and suited for mounting out of doors. The transformer is contained in a tank, plain or with cooling tubes or fins. Tanks may be equipped with small wheels, but more usually have a flat bottom for mounting on a concrete plinth. The modern transformer is reliable and tolerant of its location. In oil filled transformers, fires are infrequent but there is

still some reservation with regard to siting oil-filled units indoors.

For such locations transformers with the mineral oil replaced by a non-toxic, biodegradable dielectric fluid, such as MIDEI, may be used. The use of polychlorinated biphenyls (PCBs) (Askerels) is now totally banned because of their toxicity as their perceived carcinogenic nature.

With the increasing need for transformers to be located indoors there has been a growth in demand for dry-type units, initially these were what used to be called class C type: i.e. with windings vacuum impregnated with silicone varnish, and with insulation and varnish selected to avoid the propagation of fire, and the emission of smoke and toxic fumes.

More recently, the demand has been for cast-resin transformers where each phase of the winding is encapsulated in epoxy resin. These units are usually supplied in ventilated sheet steel enclosures with lift-off access panels or lockable cubicle doors. Where access to a site is particularly difficult, these transformers can be dismantled before delivery and re-assembled *in situ*, but obviously this is not a favoured activity.

As an optional item axial flow fans can be supplied to boost the output of the cast resin transformer by up to 25%. This feature can be useful, particularly where one of two units operating in parallel has to be taken out of service for maintenance. The boosted output of the remaining unit enables it to take up the additional load, probably without affecting the total load normally being supplied from the two units. Using the fans for regular day-to-day use is not recommended.

Whatever type is supplied, and wherever located, heat loss from a transformer makes ventilation important. Even at an efficiency of 99% there can still be many kilowatts of heat to be dissipated in a confined space!

It is usual for a transformer to be delivered ready for service, and it is recommended that the installation engineer does not remove the lid unless there is evidence of some abnormality. If, however, there is doubt, the check testing below is carried out.

- (1) *Voltage ratio*—apply a low-voltage three-phase supply to the h.v. winding and measure the l.v. output voltage.
- (2) *Phase grouping*—connect one pole of the h.v. and l.v. windings together (Figure 38.11): then by applying a three-phase l.v. supply to the h.v. windings, voltages can be measured and the grouping determined from the results.

It will be readily seen that in both the above tests it is imperative that the test l.v. supply be connected to the h.v. winding.

Figure 38.11 Checking the phase group of a transformer

It is seldom that a small or medium-sized transformer is shipped without oil; but if this should happen, or if the transformer has been in store, it may be necessary to dry out the windings before commissioning the unit. If carried out at the manufacturer's works, this would be done in a drying chamber, but on site it should be done by circulating currents in the transformer windings. It is then preferable that the oil be circulated through a filter plant at the same time. During the drying-out test, regular readings of the insulation resistance of the winding should be taken and checks made on the electric strength of the oil. The drying-out process is likely to take several days.

Where large transformers are concerned (say above 10 MVA), it would be foolish to proceed with any pre-commissioning or commissioning tests without enlisting the aid of the manufacturers.

### 38.12.1 Installation

Before connecting the transformer to the supply, several precautions are necessary. First, the tank should be efficiently earthed. In the case of a transformer with off-load taps, the correct tapplings should be chosen.

With self-cooled units fitted with radiators, the valves at the top and bottom of the headers should be open. In the case of artificially cooled units, all the valves must be open and the correct quantities of oil and water should be circulating. Where the transformer is of the type employing forced oil circulation with a water-cooled cooler, the pressure of oil in the cooler must be greater than that of the water, so that, if there is any leakage, water will not be forced into the oil. In the case of transformers with fan coolers, these should be checked and tested, and the setting for the cutting-in of the fan checked.

Breathers, where used, should be fully charged with the drying agent. The jointing of the cable boxes should be checked, and where the transformer is fitted with bushings, these should be examined for cracks or chips, and if fitted with arcing horns, the gaps should be checked and set.

If the transformer is required to operate in parallel with another unit, it should be 'phased in', i.e. the phase sequence on the secondary, with the primary excited, should be identical with that of the other unit before the secondary is connected to the common outgoing supply. In a number of three-phase transformer connections there is a phase displacement of the secondary line voltage, as for example in a delta/star connected transformer. If the primaries of this be paralleled with the primaries of a star/star transformer, then it is not possible to run the secondaries in parallel, for the line voltages in the two cases have a phase displacement of  $30^\circ$ . A delta/star group may be paralleled with a star/delta or a star/interconnected star group, but not with a star/star or delta/delta group. A grouping commonly found in industrial and commercial work is the delta/star, either a Dy 1 or a Dy 11. In normal circumstances it is not possible to parallel Dy 1 and Dy 11 transformers, since, when the primaries are connected to the h.v. supply, there would be a  $60^\circ$  phase displacement between the l.v. connections. However, this can be corrected by crossing two of the h.v. connections on one of the transformers and the corresponding pair of l.v. connections.

After switching in and applying full voltage successfully, it is desirable to have the transformer operating in this no-load condition for as long as is practicable. The heat due to core loss warms the coils and the oil gradually; this minimises absorption of moisture and also allows trapped air to be removed by the circulation of the oil.

Inspection of naturally cooled transformers should be made annually; artificially cooled units should be inspected every 6 months. It is always advantageous to take a sample of oil and test it for electric strength. This gives an indication of the presence of moisture or other impurities in the oil. At all times oil levels should be maintained correctly and breathers should be recharged regularly.

### 38.12.2 Transformer protective devices (oil filled)

The practicable indication of the temperature rise of a transformer in service is the top oil temperature. There is a temperature differential between the winding and oil temperatures, and the winding temperature responds much more quickly to changes of load, but the winding temperature cannot readily be monitored.

On larger units it is usual to fit an instrument on the tank to read the sum of the oil temperature and an analogue of the winding gradient. The instrument comprises a normal dial thermometer, the bulb of which is surrounded by a heating coil, with thermal characteristics similar to those of the transformer windings and fed from the secondary of a current transformer. In this manner the dial reading gives an indication approximating to the temperature of the windings.

Winding temperature indicators are fitted with alarm contacts, so that warning can be given should the windings reach dangerous temperature.

The Buchholz relay is a mechanical device fitted in the pipe between the transformer tank and the conservator. It usually consists of two floats with contacts: one to an alarm circuit, the other to a trip circuit. Any breakdown in transformer insulation is accompanied by the generation of gas in the oil. A serious fault results in the rapid generation of gas, and as this rushed through the pipe, it operates the float and closes the trip contacts. Alternatively, if the fault develops slowly, gas is generated slowly but is sufficient to operate the alarm float and contacts.

## 38.13 Power-factor correction

Most industrial loads have a lagging power factor, and since most electricity tariffs are constructed to penalise low power factors there is a good commercial reason for installing power factor correction equipment.

Design is usually straightforward. There are three points where the correction can be applied; at the individual piece of plant; for a group of plant items (say in one workshop in an industrial complex); or at the main supply. Only the user can determine the optimum solution.

The common method of correction is by means of static capacitors, generally oil-impregnated and oil-cooled and with a paper dielectric. The loss in a capacitor is less than 2 W/kVAr, and the temperature rise does not exceed about 15°C above ambient. Maintenance is negligible, and it is unnecessary to filter or replace the oil during the life of a capacitor. No special foundations are needed. Capacitors are available for direct connection to systems up to 33 kV at power frequency, and can be installed indoors or outdoors.

An alternative power factor correction method is the use of synchronous machines with over-excitation. Operated at a leading power factor, the machine can correct the lagging power factor of the rest of the system. However, the method is applicable only when the synchronous machine is required for a specific duty and when system conditions are such that the motor is not shut down while the rest of the system is still in operation.

Figure 38.12 Power-factor correction

### 38.13.1 Capacitor rating

In order to evaluate the capacitor requirements, the system power factor must be known: it can be obtained from a power factor meter, or calculated from active, reactive and apparent power indicators.

Let a load of active power  $P$ , reactive power  $Q_1$  (lag), apparent power  $S_1$  and power factor  $\cos \phi_1$  require correction to a lagging power factor  $\cos \phi_2$ , corresponding to  $P$ ,  $Q_2$  and  $S_2$ . The correction is shown in Figure 38.12 with specific reference to a three-phase 415 V 50 Hz load of  $P=100$  kW and a power factor of  $\cos \phi_2=0.9$ , both lagging. For the two conditions:

Power factor 0.5:

$$P = 100 \text{ kW} \quad S_1 = 200 \text{ kVA} \quad Q_1 = 173 \text{ kVAr}$$

Power factor 0.9:

$$P = 100 \text{ kW} \quad S_2 = 111 \text{ kVA} \quad Q_2 = 48 \text{ kVAr}$$

The required capacitor rating is therefore  $Q_a = Q_1 - Q_2 = 125$  kVAr. With a delta-connected 3-phase bank, each branch is rated at  $125/3 = 42$  kVAr. Table 38.2 gives the rating (in kilovars per kilowatt of load) to raise a given power factor to a selection of higher values. To obtain power factors approaching unity, the capacitor rating tends to be large, and it is usually uneconomic to correct to power factors greater than about 0.95.

For a rating  $Q_a$  (in kilovar) the capacitance  $C$  (in micro farads) required is:

$$C = (Q_a / 2\pi f V^2) 10^9$$

where  $f$  is the frequency (in hertz) and  $V$  is the line voltage (in volts).

## 38.14 Earthing

Earthing an electrical system is the process of connecting all metalwork (other than the electrical power conductors themselves) to the main body of earth. The aim is to convey to earth any leakage of electrical energy to the metalwork without hazard to personnel or equipment. An earthing system has two distinct but related parts: (i) a low-resistance conductor bonding the metalwork, connected to (ii) an electrode or array of electrodes buried in the ground. A 'good' earth may be difficult to achieve. The main factors in (ii) are the form and configuration of the electrode assembly, and the electrical resistivity of the soil.

**Table 38.2** Capacitor rating (kVA/kW of load)

$\cos \phi_1$	Correction to $\cos \phi_2$				
	0.85	0.90	0.95	0.98	1.0
0.40	1.67	1.80	1.96	2.08	2.29
0.45	1.36	1.50	1.66	1.78	1.99
0.50	1.11	1.25	1.40	1.53	1.73
0.55	0.90	1.03	1.19	1.32	1.52
0.60	0.71	0.85	1.00	1.13	1.33
0.65	0.55	0.68	0.84	0.97	1.17
0.70	0.40	0.54	0.69	0.81	1.02
0.75	0.26	0.40	0.55	0.67	0.88

0.85	—	0.14	0.29	0.42	0.62
0.90	—	—	0.15	0.28	0.48

### 38.14.1 Earth electrode

The ideal electrode is a conducting hemisphere. Current entering the ground from the hemispherical surface flows in radial lines, with concentric hemispherical equipotential surfaces decreasing in potential from the electrode. Such an electrode, or radius  $r$  in soil of resistivity  $\rho$ , has a resistance to the main body of earth given by:

$$R = \frac{\rho}{2\pi r}$$

Most of this resistance is located near the electrode surface, where the current density is greatest.

Practical electrodes are usually rods, plates or grids, and have a non-uniform current distribution in close proximity, but the more remote from the electrode system, the closer does the current distribution resembles that of the hemisphere. Formulae for estimating the value of  $R$  for typical configurations are given below. In each case  $\rho$  is the soil resistivity.

*Single rod* of diameter  $d$  and buried length  $l$ :

$$R = \frac{\rho}{2\pi l} \left[ \log_e \frac{8l}{d} - 4 \right]$$

*Multiple rods*: it is seldom that a single rod can provide a low enough resistance and so arrays of rods have a relevance and are commonly used for substation earthing. The following formula is due to Tagg.<sup>1</sup>

For a group of  $n$  rods, each of resistance  $R_1$ , in a hollow-square configuration with a spacing  $s$  between rods:

$$R = \frac{R_1}{n} (1 + \alpha)$$

where  $\alpha = \frac{r_h}{s}$ , where  $r_h$  is the radius of the equivalent hemisphere for one rod, and  $k$  is a factor depending on  $n$ .

Figure 38.13(a) gives values for  $r_h$  for 25 and 12 mm diameter rods buried to varying depths. Variations in diameter have little effect on the overall resistance.

Figure 38.13(b) gives values for factor  $k$  for varying numbers of rods.

*Buried horizontal wire*: buried wire or strip conductor is often used for earthing, particularly where ground conditions, as in hilly and mountainous country, make the driving of rods difficult or impossible. Formulae for the calculation of resistance values are complex, and it may be more helpful to quote values for particular conditions and leave the reader to make his own extrapolations.

**Figure 38.13** (a) Equivalent hemisphere radius v. length of rod electrode; (b) Factor  $k$  for hollow-square multiple-rod earthing array

For a conductor 2.5 cm in diameter, and buried about 1 m deep the resistance values shown in Figure 38.14 would apply. Resistivity is assumed to be 10 000  $\Omega$ -cm. Within reason, neither the depth of burying nor the diameter of conductor make significant difference to the resistance.

Since it is not always possible to lay an unlimited length of conductor in one direction, alternative configurations are

**Figure 38.14** Resistance of buried horizontal conductor

often employed. For a total length of the above conductor of 150 m the resistance values would be as shown below. Note that for other values of  $\rho$  the figures in curves and tables should be multiplied by  $\rho/10\,000$ .

Arrangement	Resistance ( $\Omega$ )
Straight wire	1.4
Right angle	1.45
Three-point star	1.49
Four-point star	1.6
Six-point star	2.0
Eight-point star	2.31

**Plate electrodes:** In the past considerable use was made of plate electrodes, but in general they are not as efficient or economical as rod or strip electrodes. When used, plate electrodes should be buried vertically with the top of the plate not less than 0.5 m below the surface. A simplified formula for the resistance of a plate electrode is:

$$R = \frac{\rho \rho_s}{223} \sqrt{\frac{1}{A}}$$

where  $A$ , the area of the plate is in square metres.

The addition of coke having a relatively low resistivity, to a distance of 250 cm all round an iron plate electrode may reduce the resistance to earth by up to 50%, but coke is liable to increase corrosion both by chemical and electrolytic action. It must not be used with copper electrodes, and cables should not be run within about 6 or 7 m of the plate electrode.

All the above formulae for resistance values of earth electrodes should be viewed with caution, but once the value of the soil resistivity has been established they do provide the engineer with guidance as to the best method to adopt in any particular application. The following section deals with soil resistivity and its measurement, but it should be recognised that a major problem in pre-determining a value for earth electrode resistance is that in practice soil is seldom

homogeneous, and values can vary widely, even within the fenced area of one substation.

Computer programs are now available to be used to design complex earthing systems.

### 38.14.2 Soil resistivity

The quality of the soil (sand, clay, gravel, rock, etc.) and its homogeneity determine its resistivity. Typical values ( $\Omega$ -m) are:

Rich arable soil, wet or moist	50
Poor arable soil, gravel	500
Rocky ground, dry sand	3000

The resistivity is greatly affected by (i) moisture content, (ii) temperature and (iii) the presence of chemical contaminants. Thus, the resistivity rises substantially when the moisture content is below 30% and also when the temperature falls below about 10°C; but the presence of salts in the soil lowers the resistivity. It is evident that when soil is subject to considerable seasonal changes of climate, earthing electrodes should be deeply buried. In practical terms this suggests the adoption of rod electrodes, which can be driven to a depth where the moisture content and the temperature are more stable.

### 38.14.3 Electrode installation

For toughness and resistance to bending, driven electrodes are of steel rod, either galvanised or with copper molecularly bonded to the surface (*Figure 38.15*). Rods of diameter 15–20 mm can normally be satisfactorily driven. For adequate depth, rods supplied in standard lengths can be connected by screwed couplers or special connectors. In an installation requiring few rods, manual driving is easy and economic, but for hard compacted soil, and where many rods are concerned, it is preferable to use a power hammer.

**Figure 38.15** Typical earth-rod electrode

**Table 38.3** Earthing-rod fusing currents (kA)

Rod section area (mm <sup>2</sup> )		Duration (s)		
Copper clad	Equivalent steel	0.25	0.5	1.0
62	72	15	11	8
98	115	24	17	12
113	132	28	20	14
126	147	31	22	16
158	183	39	27	19
235	271	57	41	29
422	522	110	78	55

Each rod should be driven until a minimum resistance reading has been reached, as described later. If the overall resistance of a given rod assembly is not low enough, additional rods may be driven, spaced typically at double the depth.

An earth electrode system must resist corrosion. Both galvanised and copper-clad steel rods have good corrosion resistance. The system must also retain its ability to carry large currents repeatedly throughout its life (30 years or more). Individual rods can deal with currents up to the fusing values, indicated in *Table 38.3* for three typical durations.

**Plate electrode** This has lost favour, being more expensive to install, more liable to corrosion, and buried in top layers of soil where stable soil-resistivity conditions are not readily achieved.

**Grid electrode** Where the ground is rocky and the soil resistivity high, the only practicable method of obtaining an adequately low earth resistance may be by installing a grid of buried conductors.

**Addition of chemicals** In general, this is of limited application, as chemicals tend to leach out, but where earthing is difficult, gypsum (a form of calcium sulphate) may be employed, mixed into the top soil or spread on the surface. Its value lies in its relatively low solubility in water. With moderate rainfall, gypsum percolates through the soil and continues to keep down the earth resistivity for the life of the electrodes. It has minimal corrosive effect, but sulphates do attack concrete.

#### 38.14.4 Resistivity and earth resistance measurement

The soil resistivity must be known for the design of an earthing system to be determined and the earthing resistance of the system must be checked after installation. Both measurements involve passing current through the soil and measuring the volt drop. Composite instruments are available. *Figure 38.16(a)* shows the measurement of resistivity. The test prods are pushed into the ground to a depth not exceeding  $s/20$ , where  $s$  is the spacing between prods. The greater the spacing  $s$ , the greater the volume of soil concerned in the measurement. By repeating the test with various values of  $s$ , the uniformity of the soil can be assessed: reasonably constant values indicate good soil homogeneity.

Testing *electrodes*, individually or in an array, is shown in *Figure 38.16(b)*, using the same test set with  $C_1$  connected to  $P_1$ . Prods  $C_2$  and  $P_2$  should be far enough from the electrode system for accurate readings of resistance to be obtained. Provided that there is an adequate distance between  $C_1$  and  $C_2$ , there should be a zone within which the potential prod  $P_2$  gives a constant reading.

#### 38.14.5 Protective conductors

The earthing conductor connects the consumer's main earth terminal to the earth-electrode system, but such disconnection must require the use of tools.

Under the IEE Regulations WR16, the *circuit protective conductors* (formerly the 'earth-continuity conductors') are those that join the consumer's main earth terminal to all the exposed conductive parts of the system. The circuit protective conductor provides a low-impedance path for fault current, but must also ensure that no dangerous voltage can occur in metalwork in the vicinity of the fault. This is achieved by the connection of all extraneous metalwork to

**Figure 38.16** Measurement of (a) soil resistivity and (b) earthing resistance

the main earth terminal: the provision covers such items as water and gas pipes, accessible structural steelwork, and central heating pipework, a requirement termed *main equipotential bonding*. The connections should be made as close as possible to the point of entry to the building concerned. Additionally, *supplementary bonding* is the connection of extraneous conductive parts that are accessible simultaneously with other conductive parts but are not electrically connected to the equipotential bonding: e.g. water taps, sink and bath waste outlets, central heating radiators.

The cross-sectional area ( $S$  in square millimetres) of the circuit protective conductor may be calculated as

$$S = (1/K) \sqrt{I^2 t} \Leftarrow$$

where  $I$  is the current (in amperes) for a fault of negligible impedance,  $t$  is the operating time (in seconds) of the disconnecting device, and  $K$  is a factor depending on the material of the conductor, the insulation, and the initial and final temperatures. The operating time is usually  $t = 5$  s for fixed

and  $t = 0.4$  s for portable equipment. A quick rule-of-thumb alternative to the formula is:  $S$  is the same as the cross-sectional area of the phase conductor where the latter is  $16 \text{ mm}^2$  or less;  $S = 16 \text{ mm}^2$  for phase conductor sections between  $16$  and  $35 \text{ mm}^2$ ; and  $S$  one-half of the phase conductor section for larger areas.

For main equipotential bonding conductors, the area shall be not less than one-half of the main earthing conductor of the installation, with a minimum of  $6 \text{ mm}^2$  (10 mm for protective multiple earthing (PME)). In general, supplementary bonding using  $4 \text{ mm}^2$  bare or  $2.5 \text{ mm}^2$  mechanically protected conductors should be acceptable.

### 38.14.6 System earthing

WR15 introduced a new designation for electricity supply systems to identify the type of earthing in use. WR16 continues this system, using a three or four letter code as follows:

*First letter*—‘supply’ earthing arrangement. T indicates that one or more points of the supply are directly earthed. I indicates that the supply is nowhere earthed, or is earthed through a fault-limiting impedance.

*Second letter*—‘installation’ earthing arrangement. T indicates that all exposed conductive metalwork is connected directly to earth. N indicates that all exposed conductive metalwork is connected directly to the earthed supply conductor (usually the neutral).

*Third and fourth letters*—earthed supply conductor arrangement. S indicates separate neutral and earthed conductors. C indicates combined neutral and earth in a single conductor.

In a TT system the exposed conductive parts of the installation are connected to an earthing electrode which is independent of the supply earth.

In a TN-S system the consumer’s earth terminal is connected to the supply authority’s protective conductor, usually the cable sheath and armouring, and so provides a continuous metallic path back to their earth electrode. The majority of installations with an underground supply are of this type.

In a TN-C system the neutral and protective functions are combined in a single conductor throughout the system. Typical is a system using earthed concentric wiring. If fed from a public supply authority, this system can only be used under special conditions and with the authority’s permission.

In a TN-C-S system the supply neutral and protective functions are combined and earthed at several points, often with an earth electrode at or near the consumer’s incoming terminals. The exposed conductive parts of the installation are connected to the neutral and to the supply neutral/earth at the consumer’s main earthing terminal. This system is also referred to as *protective multiple earthing*.

In an IT system the exposed conductive parts of the installation are connected to the consumer’s earth electrode, while the supply is either isolated from earth or connected to earth through an impedance. This form of supply cannot be used for public supply in the UK.

## 38.15 Inspection and testing

On completion and before energising, every installation must be inspected and tested to ensure that it complies with the appropriate regulations.

### 38.15.1 Inspection

WR16 calls for an inspection to be made of each installation before it is energised to ensure that the requirements of the regulations have been met. This must confirm that all electrical equipment is in compliance with the appropriate national standards, has been correctly selected and installed, and is in a safe working condition. The inspector/tester should understand how the installation functions and, to this end, he should ensure that his inspection covers such items as the identification and checking of the size of conductors, and the labelling of circuits, fuses, distribution boards and other switchgear. Finally, he should insist on the availability of diagrams, charts or tables describing the system under inspection.

### 38.15.2 Testing

Testing is required to ensure that the installation has been designed and installed (i) to give protection against electric shock during normal operation and during fault conditions, (ii) to ensure that it provides protection against overloads and short-circuits, and (iii) to provide protection against thermal effects—in particular, against fire and burns.

The IEE Regulations WR16 are quite specific regarding the items to be tested, and in particular they cite the following items which, where relevant, shall be tested.

Initial tests should be carried out in the following sequence:

- (1) continuity of protective conductors, main and supplementary bonding;
- (2) continuity of ring final circuit conductors;
- (3) insulation resistance;
- (4) site-applied insulation;
- (5) protection by separation of circuits;
- (6) protection against direct contact, by a barrier or enclosure provided during erection;
- (7) insulation of non-conducting floors and walls;
- (8) polarity;
- (9) earth electrode resistance;
- (10) earth fault loop impedance;
- (11) operation of residual-current-operated devices.

Tests must be carried out in the correct sequence. For example, it is important that the continuity (and, therefore, the effectiveness) of the protective conductors be checked before insulation tests are carried out, because an open-circuited protective conductor coupled with a low insulation resistance reading could make the whole system live at the test voltage during the insulation test.

In general, the application of any voltage to a system prior to connection to the mains must be done with care, to ensure that no danger to persons, property or equipment can occur, even if the tested circuit is defective. There is an increasing use of electronic components in present-day installations, and these can be damaged by relatively low voltages. Therefore the insulation resistance tests should be undertaken before the components are fitted, or they should be removed before testing commences.

#### 38.15.2.1 Continuity

To check continuity it is not sufficient that a measurement be made across the end terminals. In the case of final ring

circuits two measurements need to be made. Appendix 15 of WR15 detailed these, but in the bid for harmonisation this appendix has been dropped from WR16. The appendix proposed two acceptable methods, both assuming that an outlet is installed at or near the mid-point of the ring.

In method 1 the resistance of each pair of like conductors is measured with the two ends separated. After reconnecting the two conductors, a measurement is taken between the distribution board and the mid-point. After measuring and deducting the resistances of the test lead, it should be found that the first reading is four times the second reading (see Figure 38.17(a)).

In method 2 no long lead is needed to make contact with the mid-point of the ring. The continuity of each conductor of the ring circuit is measured between the ends of the conductor when separated, as for method 1. The conductors are then reconnected at the origin, all the connections at the mid-point outlet are short circuited and the continuity is measured between the phase and neutral terminals at the distribution board. This value should be one-half of the previous reading. Finally, the continuity is measured between the phase and the earth (see Figure 38.17(b)).

Continuity tests in protective conductors, particularly steel conduit, require the application of a current approximately 1.5 times the normal design current, using a voltage not exceeding 50 V a.c. or d.c. (If d.c. is used, verify that no inductor is included in the circuit.)

It will be appreciated that the resistances being measured in the continuity test will be small (e.g. between 0.1 and 0.5  $\Omega$ ), and it is suggested that a testmeter with a range between 0.005 and 2.0  $\Omega$  would be useful.

### 38.15.2.2 Earth electrode

Methods of testing earth electrodes are described in Section 38.14.4 and illustrated in Figure 38.16.

### 38.15.2.3 Insulation resistance

Insulation resistance tests are carried out to verify that the insulation of the conductors and electrical accessories is satisfactory. A low reading would indicate a deterioration in the insulation, and a very low reading a total failure.

The test meter should provide a d.c. voltage of not less than twice the nominal voltage of the circuit under test (r.m.s. value for an a.c. circuit), but the test voltage need not exceed 500 V d.c. for installations between 500–1000 V.

Insulation resistance testing involves test of insulation resistance between conductors of different polarity and between all conductors and earth, and the value must not be less than 1 M $\Omega$ . A large installation may be tested by dividing it into groups, each containing not less than 50 outlets; the minimum insulation resistance demanded of each group is 1 M $\Omega$ . The term 'outlet' includes every point and every switch, except where the switch is incorporated in a lighting fitting, socket outlet or power-consuming apparatus.

During the insulation test to earth of a whole installation, all fuses should be in place and all switches closed, including the consumer's main switch (if practicable). For the test (Figure 38.18) all conductors are bonded together at the load terminal of the main switch by means of a copper wire. The bonding wire is then connected to the 'line'

Figure 38.17 Measurement of the continuity of a ring circuit: (a) method 1; (b) method 2

Figure 38.18 Insulation resistance testing

terminal of the tester, the other terminal being solidly connected to the consumer's earthing terminal. (When it is required to test to earth a live installation, the consumer's main switch must be opened and the supply from the mains disconnected.) Portable apparatus should not be connected to the system, as it can be tested separately. Any item of fixed apparatus may be disconnected if desired and tested separately. With the test set connected as described above, the insulation resistance is measured. Where two-way switches are included in the circuits, two test readings should be taken, one switch in each pair being changed over for the second test to include the strapping wires in the test.

If the insulation resistance value exceeds the specified minimum, the system can be passed; but if not, further sectional tests will have to be made to locate the faulty section.

For insulation testing between conductors, if practicable all switches and circuit-breakers should be closed, and all lamps removed, together with all fixed appliances.

Any equipment disconnected before the tests are done, and having exposed conductive parts, should itself have an insulation value of not less than 0.5 MΩ.

#### 38.15.2.4 Polarity

It must be checked that all fuses and single-pole circuit-breakers and switches are in the 'line' side, that the wiring of plugs and socket outlets is correct, and that the outer contacts of concentric bayonet and screw lampholders are in the neutral (or earth) side.

#### 38.15.2.5 Earth-fault loop impedance

If a fault of negligible impedance should occur from a phase conductor to earth, the supply voltage will provide a fault current through the earth-fault loop. The significance of the earth-fault loop impedance is that it determines the current, and this, in turn, determines whether or not the protective device will operate quickly enough to meet the requirements of the relevant regulations.

Take, for example, the arrangement shown in Figure 38.19 and assume a fault to occur in an item of consumer's equipment. The fault current  $I_F$  will flow from the transformer, through the fuse and then via the casing of the equipment to the consumer's earth, and thence back through the earth path to the transformer, such that  $I_F = V_s/Z$ , where  $Z$  is the loop impedance. From  $Z$  calculations

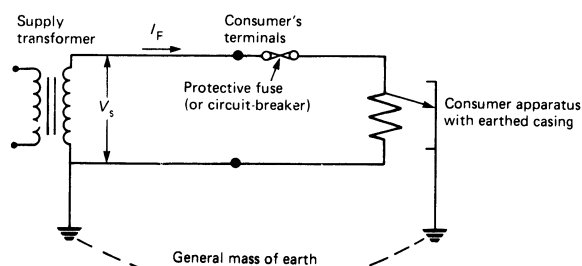

Figure 38.19 Earth-fault loop impedance

can be made for the overall performance of the system under fault conditions. For example, WR16 calls for all equipment connected to socket outlets to be cleared in 0.4 s or less when faulted. Other circuits supplying only fixed equipment are acceptable if the fault is cleared within 5 s. The regulations give tables of  $Z$  to meet these conditions.

In practical terms, a phase-to-earth loop can be tested by connecting a known resistor  $R$  between the phase and protective conductors when the system is live with  $R$  typically 10 Ω. Measuring the volt drop  $v$  across it gives the current  $I = v/R$ . If the supply voltage is  $V_s$ , then  $V_s = I(Z + R)$  or  $Z = (V_s/I) - R$ , giving the required loop impedance.

The loop impedance must be tested using a *phase-earth loop tester*, which gives a direct reading in ohms. (The neutral-earth loop tester previously specified is no longer acceptable.) A dual-scale instrument covering 0–2 and 0–100 Ω is suitable.

#### 38.15.2.6 Residual-current devices

Where the loop impedance is such that the required tripping times cannot be achieved, and in special cases (e.g. where the socket outlet in a house is used to supply gardening tools, or where the supply authority does not provide an earth terminal), a *residual-current* device must be fitted. It usually comprises coils on a magnetic circuit to carry the phase and neutral currents in opposing directions. In balanced conditions no magnetic flux is set up; but if a fault occurs on the system, even one of high resistance, the phase and neutral current imbalance induces an e.m.f. in a third coil (Figure 38.20), tripping the circuit.

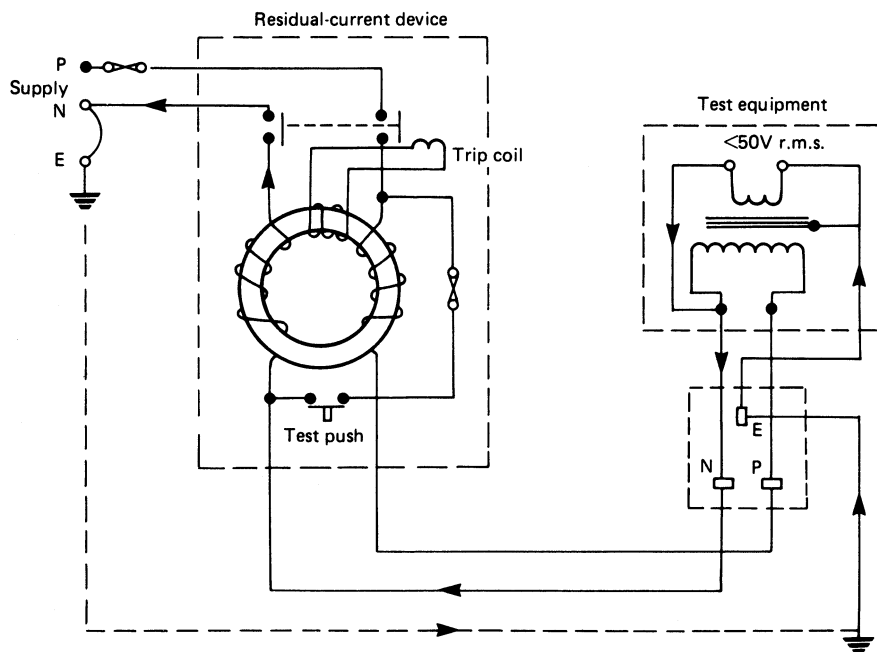

To test the device, an a.c. voltage not exceeding 50 V r.m.s. obtained from a mains-fed double-winding transformer, is applied across the neutral and earth terminals. The device should immediately trip.

Fault-voltage operated circuit-breakers may alternatively be used, but are subject to tripping when faults occur outside the protected zone. If used, however, the earth-fault loop impedance including earth-electrode resistance must not exceed 500 Ω.

Whether or not this simple go/no-go test is sufficient is debatable. Test sets are available to measure the effectiveness of the RCD which simulates an appropriate fault condition with respect to time.

#### 38.15.3 Test gear

Because the testing requirements of WR16 are stringent, the UK Electrical Contractors' Association has suggested that the tester should equip himself with the following instruments, incorporating the features itemised.

**Figure 38.20** Residual-current device, showing test connections. The arrows show the path of the test current

*Insulation-resistance/continuity tester*—with 500/1000 V selector, analogue scale down to 0.01  $\Omega$ , battery power, push-button operation.

*Digital milliohmmeter*—with battery power, push-button operation, voltage protection indicator.

*Polarity/earth-fault loop-impedance tester*—with mains power, polarity indicator lamps, analogue low-resistance scale.

*Residual-current-device/fault-voltage-device tester.*

*Earth-electrode/soil-resistivity tester.*

## Dedication

This section of the *Electrical Engineer's Reference Book* is dedicated to Jimmy Milne, BSc (Eng), C Eng, FIEE who has recently passed away and was not able to read my transcript of the updates from his original comprehensive work. I first met Jimmy when he was a Partner with Kennedy & Donkin Ltd, now Parsons Brinckerhoff Ltd, and I was an employee in the International Division. I am sure that all his professional colleagues will miss him.

## 39.1 The changing electricity supply industry (ESI)

Electrical power systems have developed over the 20th century to become the supplier of electrical energy to almost every household, factory, commercial building and activity in the developed world. Developing countries strive to emulate this achievement through attracting finance to build up their own infrastructure to stimulate their economies and to improve the quality of life for their inhabitants.

As with all industries, changing and improving technology through innovation, research and development has led to a change in the way power networks are planned and operated, initially as comparatively small local generation and supply networks, followed in the developed nations by more and more connections between local networks culminating in large continent wide grids with numerous large generating plant and components, high voltage systems and a supply to everyone requiring electrical energy. It has only been in the last 15 years from about 1985 that smaller operating units and private ownership of parts of the system has been seen to be an advantage.

### 39.1.1 Central planning

Power networks grew in capacity and extent in most industrialised countries through a centrally (government) controlled industry, often founded by treasury loans or sanctioned loans from the financial markets. This meant that with government involvement it was necessary to make a good case for the finance to be forthcoming to add to the present system or build anew to meet expected increase in electrical energy demand for all purposes. Consequently, centrally planned systems needed expert forecasting of demand at least 5 years ahead to design, manufacture and commission the necessary equipment and connections by cable or overhead line. Throughout the world the problem over many years was to achieve good forecasts which turn out to be dependent upon economic cycles and gross domestic product (GDP) which are well known for being extremely inaccurate, particularly in the 5 year time scale. The inevitable result has been that the ESI in most countries has been underdeveloped and never matches supply to demand, or overdeveloped where plant has been underutilised leading to inefficiencies and a higher price for energy than necessary. After 30 or 40 years from the 1940s to 1980s of attempting to make central planning work, the concepts of economic efficiency and plant installation by funding through the principles of the investment market—as in the oil and gas industries—was seen to provide a more acceptable way of achieving the desired objectives. This has produced a movement by many governments to deregulate and restructure the ESI such that central planning is no longer the norm, but private finance is encouraged to take the risk of getting a return on investment.

### 39.1.2 Vertical integration of generation and supply

Under central planning and government control, it was considered necessary to plan and operate the network as a unity such that the production, distribution and sale of electricity was either organised and run by one utility or each part had statutory obligations to ensure fairness and constraint on profit taking. Most countries, including the USA, ensured that utilities could not act as monopolies but only charge a reasonable tariff to obtain a regulated return on capital invested. It became the practice for utilities to serve defined

areas or populations without fear of competition and to purchase energy from their own generation or interconnected power network. This was known as 'vertical integration' and prevented other suppliers encroaching on the supply territory of another utility. If tariffs were set by governmental edict or statutory control, there was obviously little incentive for utilities to innovate or compete on price. To overcome this obstacle, many industrialised countries with a mature and reasonably adequate energy infrastructure looked for ways of using market competition to reduce energy tariffs and to provide an improved service to the consumer. This has produced 'deregulation' of the ESI.

### 39.1.3 Deregulation and restructuring

These are the 'buzz' words for a world-wide movement to improve consumer service and reduce prices in mainly the industrialised nations. It also means that controlled planning is no longer required—the necessary improvements in service, quality and price to produce satisfied customers being obtained through 'market' forces. It was quickly realised that if generating plant could be allowed to compete country wide on price and the transmission and distribution network could deliver the commodity (energy) to any part of the country, then competition to supply individual consumers could also be encouraged. Consequently, the break-up of the generation utility monopolies by selling shares (if government owned) or trading generation ownership on the stock market would achieve the desired ends. On the supply side allowing suppliers to encroach into others' territory would also produce competition with (hopefully) low prices and improved service. This was the desired deregulation and restructuring with no government involvement in setting prices provided that 'level playing field' competition could flourish.

Unfortunately, the power system network which enables the generator owner to sell energy to the suppliers was almost a natural monopoly in that it would be prohibitively expensive for another entrepreneur to construct an alternative supply network. Hence a *regulator* would be needed to ensure that fair prices were charged by the owners of the power network for energy transportation. The net result appears to be that generation and supply through private or market investment has obviated any planning needs through government forecasting but the power system can be made adequate for consumers through risk management implemented through many utilities.

### 39.1.4 Least cost planning

With a deregulated ESI, no longer is there a planning authority but all investors need to plan for their own investments and expected returns. This implies that companies who are thinking of financing a venture into the ESI, must consider all options open to them and estimate the risk and return on investment by considering the following aspects:

- the minimum cost investment to meet the desired objectives over a given period;
- the robustness of the proposal against likely changes in market rates, social climate, environmental constraints, etc.;
- likely level of co-operation between the company and the customers being served; and
- the financial viability of the whole proposal, including the attitude of the shareholders, the regulator and the government.

In theory, any investment in new plant (generator, transmission facility, supply services) should not occur until the cost of alternative measures to achieve the same objectives is equivalent to new plant costs. In practice, new plant investment may be required because of new developments, economic boom, improved supply security, availability of new technology etc. It is against these criteria that new investment will need to be measured.

## 39.2 Nature of an electrical power system

### 39.2.1 Electricity supply

All countries now have available some supplies of electricity to connected consumers. In many industrialised countries a nationwide grid or distribution system is installed so that generating plant can be 'pooled' through interconnections to supply customers from industrial/factory complexes down to the smallest residential consumer, perhaps with a single light or TV set. As electrical energy is not easy to store, except by converting it to some other form of easily stored energy e.g. water pumped to a higher reservoir, the generating plant output must always match instantaneously the demand of the loads plus the losses (hopefully less than 10%) in transporting and delivering demanded energy (units of kWh). For many good reasons, most small consumers require their supply at a low voltage (230 V in Europe,

110 V in USA for example) whereas to keep losses low, electricity needs to be transmitted over any distance at a high voltage (400 kV in Europe, up to 700 kV in US/Canada). Generation, on the other hand, is most economically done at around 20 kV thereby requiring a step-up in voltage to the transmission system and a step-down in voltage for distribution to the myriad of small (mainly residential) consumers. This transformation is readily done by high efficiency *transformers* which require, due to Faraday's law, an alternating voltage at 50 Hz in Europe, Japan, Australia, etc. and 60 Hz on the American continent. To keep material costs to a minimum, transmission and distribution is best done using a *3-phase* system but only a *single-phase* supply is required by small consumers. Large and intermediate consumers such as industrial processes, factories, large buildings and hospitals etc. are most economically supplied at a higher voltage than to small consumers, at between 10 to 20 kV.

Consequently, many distribution systems consisting of step-down transformers, cable or overhead lines operate at this voltage and only the final, comparatively short connections to individual small consumers, operate at 230 V or 110 V, usually by tapping off from a 3-phase system.

### 39.2.2 Transmission

Part of a typical generation and transmission network is depicted as a single line diagram as in *Figure 39.1*.

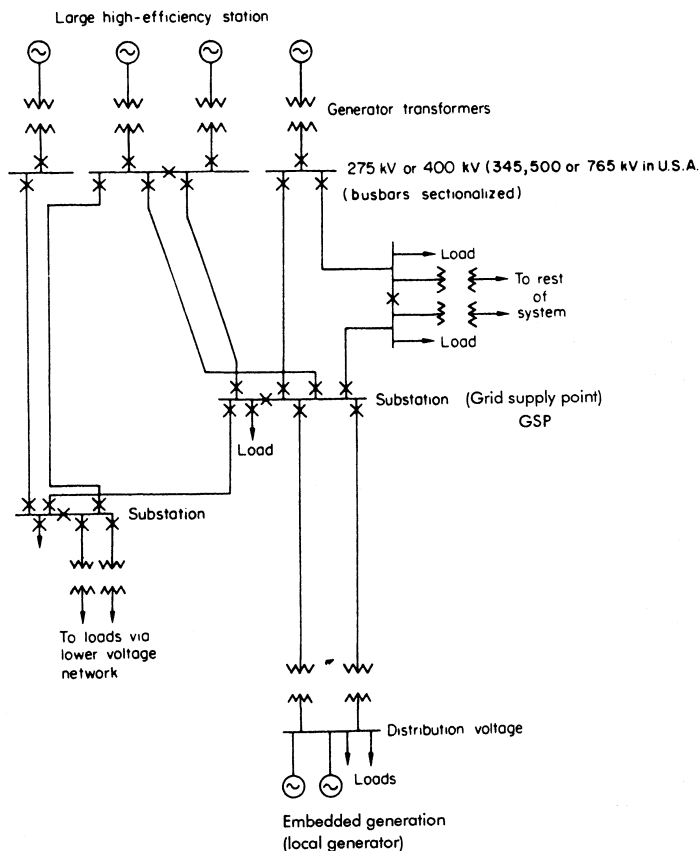

Figure 39.1 Part of a typical generation and transmission network. (Reproduced by kind permission of John Wiley & Son, Ltd)

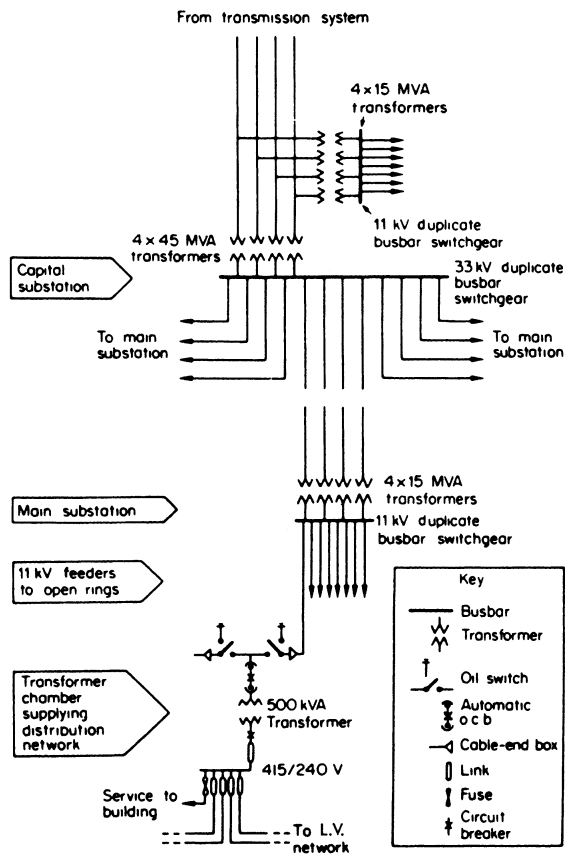

It should be noted that generators are interconnected by a 3-phase system and it is essential that they run in synchronism with each other. If a generator cannot remain in synchronism due to a fault, then it must be disconnected by its circuit-breaker otherwise the whole system could collapse. In the figure, substations enable circuits to be switched and alternative routes are available if a circuit needs to be withdrawn for repair or maintenance. Distribution systems are fed from the high voltage network through step-down transformers and increasingly there are smaller generators 'embedded' in the distribution network adding to the combined energy output of the synchronised system.

In a deregulated ESI, the generators could be owned and operated by different utilities, the transmission lines and substations owned by other investors and the supplies to the distribution systems bought under contract to private distributors or suppliers.

Increasingly, for undersea connections or for connections between networks not in synchronism, high voltage direct current using semi-conductors as a rectifier one end and inverter the other is being used. Such connections should be considered as alternatives to a.c. connections.

### 39.2.3 Distribution

Medium and low voltage distribution systems vary in their design and layout depending upon the locality being served.

**Figure 39.2** Typical arrangement of a supply to an urban network in UK. (Reproduced by permission of the Institution of Electrical Engineers)

In urban areas, where consumers are numerous and concentrated, an underground network with closely spaced step-down transformer substations are installed sized to meet the maximum expected demand after taking into account the average diversity of customer use. *Figure 39.2* depicts a typical urban network where each single line represents 3 phases contained within a single under road cable.

Because of the complexity of protecting the system if it was fully interconnected, it is usual to operate it as a radial system fed from the primary substations but allowing circuits to be supplied by alternative connections if any circuit is disconnected under fault or maintenance conditions.

For rural areas with sparsely sited consumers in farms or small villages, most supplies are stepped down by small pole-mounted transformers as close to the consumer as possible fed from a radial circuit. Fuse rather than relay operated circuit breaker protection is employed for cheapness and reclosing circuit breakers in the primary substation ensure that supplies can be quickly restored to healthy circuits once a fuse has blown because of a fault.

*Figure 39.3* shows a typical rural distribution system in which section points allow manual reswitching to restore supplies after fuse disconnection. Overhead lines, either 3 phase or single phase, is the norm thereby allowing quick repair with a suitably equipped crew.

### 39.2.4 Loads

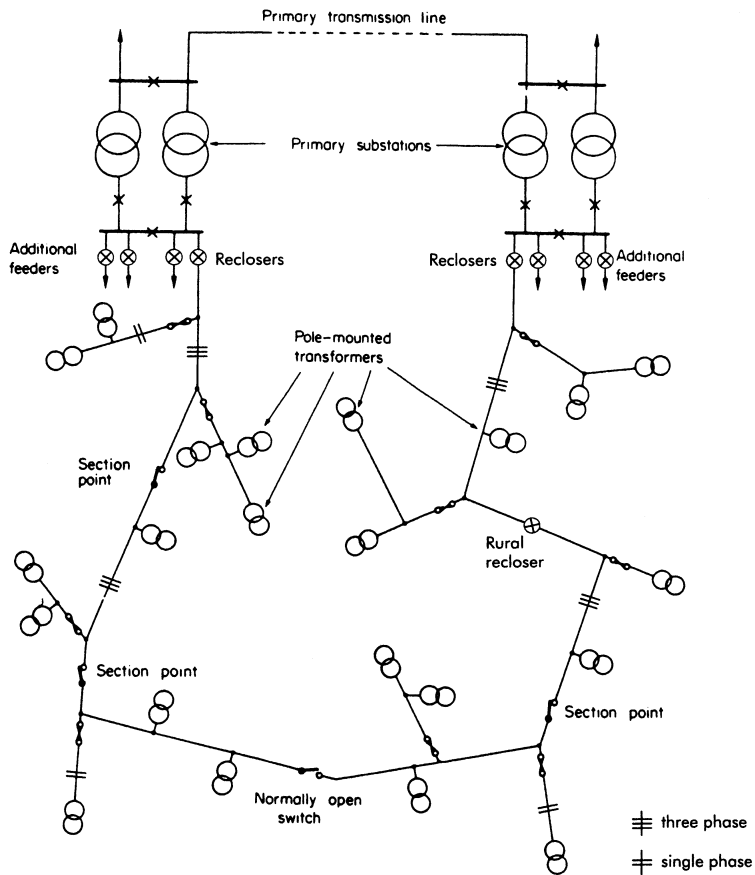

Consumer demand in a power system is often called a load and, of course, it will vary from hour to hour, day to day and season to season. Typical daily load curves aggregated over the whole England and Wales system are shown in *Figure 39.4*.

As previously remarked, the total generator output must match this demand and this requires the generators to be flexible. In practice, to maintain as high an efficient output as possible generators wish to run at full output or be off-line so the system operator instructs plant to synchronise and desynchronise at pre-planned times worked out by some economic scheduling algorithm. At times when the demand is expected to fluctuate by  $\pm 5\%$  or so within minutes (as could happen in a countrywide event when kettles or cookers are switched on/off in co-ordination by a TV programme) then a number of generators, particularly those with quick response, will be scheduled.

If the demand curve of *Figure 39.4* is plotted in descending order of magnitude as in *Figure 39.5*, the resulting diagram depicts a *duration curve*. Over a year of operation this curve indicates the *load factor* at which various kinds of generating plant can be expected to operate.

Normally the plant having the cheapest price per kWh would operate at base load and the peaking plant would operate on very small load factor around the peak demand. Other plant, depending on its characteristics and production costs, would be expected to run at the intermediate load factors, probably generating during the day and shutting down at night (known as *two shifting*).

In interconnected systems or power pools where energy trading is allowed, the operation of the system is much more complex. In this case, existing generating plant may find that it is unable to rely on base or intermediate load operation and must be installed and run according to its contracted output portfolio rather than in any economic sense. Plant without sufficient contracts to sustain their operation could therefore be isolated and eventually shut down, whereas newly installed plant with long term contracts could take its place. The availability of long term

**Figure 39.3** A typical rural distribution system at 11 kV with step up and step down transformers, the latter protected by fuses

**Figure 39.4** NGC summer and winter demands for 1995/96 (not weather corrected). (Reproduced by permission of NGC)

**Figure 39.5** Demand duration curve for typical winter demand on 04.01.96

contracts on both the fuel supply side and the output energy side is likely to be the dominant feature of planning in the future.

### 39.3 Types of generating plant and characteristics

Details of particular types of generator are given in other sections of this volume. Here, the main characteristics for planning purposes are summarised to provide a comprehensive picture.

#### 39.3.1 Steam turbine

The steam turbine, running at 3000 rpm for a 50 Hz output or at 3600 rpm for a 60 Hz output is the traditional work horse in most power systems.

It can be built in sizes up to 1200 MW when fuelled from coal, oil, gas, or nuclear sources. Coal fired plant requires quite expensive delivery, stocking and handling facilities compared with oil or gas thereby making it more difficult to finance initially although since the fuel is abundant in many countries and can perhaps be quarried rather than deep mined, the cost per MWh of output can be very competitive. Since most solid fuels contain sulphur, flue gas desulphurisation equipment may have to be statutorily fitted adding approximately 20% to the overall cost of the plant. The disposal of ash and gypsum (from the desulphurisation process) also has to be considered.

On the other hand, oil firing could also require some flue gas clean-up if sulphur is present but except in oil producing countries oil is relatively expensive compared to coal, but it is useful as a quick start (30 mins) source for peak lopping. Direct gas firing to raise steam is now a strong competitor to oil or coal, particularly if connection to a gas pipeline is

inexpensive and gas can be used in a dual fired boiler to back-up coal firing dependent upon arbitrage costs. The problems of using nuclear reactors for steam raising are well known although some of the steam driven turbine generators are the largest units constructed.

All steam driven turbo-generators require cooling water to create a high vacuum in the low pressure turbine for maximum efficiency, some of which can reach 40% dependent upon the highest temperature and pressure that materials can tolerate. It should be noted that combined cycle gas turbines (see later) also depend for their high operating efficiency on pass-out steam turbines with cooling water condensers as in traditional steam raising plant. An abundant source of make-up water and water recirculation in the sea or inland lake for cooling purposes can often be an advantage compared to the need for large cooling towers or fan driven coolers in smaller plant.

#### 39.3.2 Gas turbine and diesel

Since about 1980 the development of gas turbines running at 6000 rpm plus in 100–200 MW sizes because of the advances in high temperature blade material has enabled this combined cycle form of plant to generate at efficiencies of up to 60% and in comparatively small sizes. As this type of turbine is considerably smaller than a steam turbine of comparable power output, it can be started and stopped much more rapidly thereby producing the potential of being used as intermediate generation. As the site area necessary is also much smaller than required for steam boilers and turbines, it can be sited much closer to load centres or inside the curtailage of industrial complexes, thereby reducing the need for transmission to energy over some distance with consequent losses.

In the 1990s, combined cycle gas turbine (CCGT) had begun to provide the base load because of the comparative cheapness of gas as a fuel and the high operating efficiency.

As coal fired and nuclear plant had reached the end of its economic life, CCGT plant was being used more to supply base load, but during the early 21st century with the increasing installation of CCGT displacing older plant, intermediate (two shift) loading is becoming more usual. With two or more gas turbine driven generators whose waste heat raises steam for conventional generators, the flexible output obtained by varying the number of GTs is of prime importance to meet contracted varying output over the daily cycle. As the CO<sub>2</sub> produced by a CCGT with gas firing is only 55% of that of a similarly rated coal or oil fired plant, its popularity with environmentalists is evident. Note also that 10% overload for short periods is possible to meet short peaks and/or aid system recovery following a generation loss. Added to all these advantages is the comparatively low cost and short (2 years) installation time, particularly for CHP schemes, its use in power system planning is assured. An alternative to GTs in small CHP schemes (up to 50 MW) is that of diesel plant running at slow speed but overall efficiency of 90%.

### 39.3.3 Renewables

#### 39.3.3.1 Hydro power and pumped storage

Until fuel cells or rechargeable batteries become economic and reliable, the well known water turbine driving a multi-pole generator at comparatively low speed is still a valuable fast response unit that can act as reserve or regulating output, particularly at peak periods. Combined with pumping action, either using the coupled turbine in reverse mode or a separately coupled pump, water can be stored in a high level reservoir at low energy cost periods for use during peaks or emergencies. Overall the combined pump-generate cycle can run at up to 70% efficiency, implying that provided the difference between peak and off-peak energy cost is 35% or more, a pumped storage plant can be run at a profit. Retrofitting hydro-plant with pumping equipment is another possible option, particularly as the first cost of hydro can be very high. Storage is essential if the renewable energy source is intermittent as described in the next subsections.

#### 39.3.3.2 Wind generation

A popular renewable source of energy is from the wind, particularly in temperate zones where most days have a wind blowing. The economics of wind energy depend upon the range of wind speeds between the minimum 'cut-in' speed for the wind generator and the maximum speed that the wind blades are designed to withstand. A high average wind speed as usually found on exposed high ground is obviously an advantage, indicated on charts by 'isovent' contours. The visual impairment of any scheme needs the preparation of impact statements to satisfy the local environmental lobbies and the connections into what is essentially a rural distribution network requires careful design in conjunction with the distribution owner. Problems of voltage control, reverse current protection, safety of distribution personnel when sources of energy other than from the primary transformer are present in the network, all require consideration. Wind farms consisting of 20–30 wind turbines mounted on 30–50 m masts having 2 or 3 bladed sails, rotating at 100–150 rpm to produce up to 600 kW per turbine are now common. Reliability has increased and the cost per kW reduced as experience has been gained and selection of appropriate materials has improved. The output cost

per kW in year 2000 is now, on average, twice that of coal or gas fired plant, but as the energy (when available) is fed directly into the local distribution system, thereby avoiding both transmission and the bulk of the distribution losses and use-of-system costs, the energy price to the small consumer is becoming competitive. It is possible that consumers are willing to pay a premium for energy said to come from a renewable source. In the UK, a good site can produce 1800 kWh of energy per kW installed in a year.

#### 39.3.3.3 Solar power

In tropical areas and favourable temperate zones, power from the sun is becoming more and more flexible, either by using mirrors focused onto a steam raising boiler driving a conventional turbine or through the employment of solar panels with power electronic conditioning equipment to convert direct current into alternating current. The mirrors require angle positioning and tracking equipment for economic output and the area occupied can be comparable with that for a solar panel photo-voltaic array. Maintenance of mirrors and solar panels is required especially in dusty/desert zones. Installation of 10 MW or so are now becoming economically viable. Many of the considerations for wind energy installations apply to solar also.

#### 39.3.3.4 Tidal, ocean temperature gradient and wave power

Tidal power in large estuaries where a suitable tidal range is available requires horizontal, two-way flow turbines for energy production. It is comparable in cost to hydro-electric schemes, implying that long construction times and up-front financing is necessary. It has not been a great success anywhere in the world because of the impairment of the natural environment likely to ensue. Using the temperature difference between surface water and that at 500–800 m deep could produce energy from a specially designed turbine at 3 to 4% efficiency but would require vast quantities of piped sea water needing large underwater structures not yet attempted. Wave energy, close to rugged shorelines is a prime example of an obvious and visual source if only it could be reliably and economically harnessed. The variations in wave height and strength over the seasons are well known and the ability to cater for the severest storm conditions by man-made structures is fraught with difficulty. Research into robust shore structures using the inflow and outflow of the wave energy to drive air through a reversible turbine is continuing.

#### 39.3.3.5 Other renewables

There is some uncertainty as to exactly what should be regarded as a renewable resource. Wood or straw burning boiler plant for steam raising is acceptable—provided the wood is obtained from a managed forest where replanting on a scheduled basis is undertaken. Refuse incineration and landfill gas driven plant may or may not be classed as renewable depending upon the source of the bio-fuel. Such plants are increasing in number and extent and their assimilation into the local electricity supply system must be planned. Sources such as geothermal energy are valuable in suitable locations and as drilling becomes possible in deeper boreholes at reasonable cost, such 'renewable' sources using the heat of molten magma within the earth's crust become attractive.

### 39.4 Security and reliability of a power system

In industrialised countries, a high level of reliability of supply is expected amounting, on average, to not more than 60 min loss of supply (blackout) per year. In addition, voltage sags (dips), momentary interruptions or voltage surges should not cause interference with a consumer's installation. This condition is becoming much more onerous with the increasing use of power electronic equipment in which nuisance tripping can lead to shut-down of an entire industrial process. Consequently, considerable attention is now focused on *power quality* and the elimination of unwanted harmonics in the system. Many consumers with sensitive electronic equipment are encouraged to safeguard their vital equipment with an auxiliary uninterruptible power supply (UPS) using a battery or fly-wheel generator store. In general, the reliability of supply from generator to consumer depends upon the *availability* of generation plant, transmission and distribution equipment, the ability of the ESI to install sufficient generators to maintain a suitable margin of reserve capacity taking into account maintenance and forced outages and the design of the transmission system for security and continuity of supply to the consumer. On availability, all plant requires periodical planned outage for maintenance purposes and hopefully this aspect of planning will be done in conjunction with the system operator. Maintenance procedures are best developed from careful diagnostic measurements and statistical records including breakdown incidents plus advice from manufacturers. An increasing and desirable trend is towards more on-line diagnostic measurements from which possible breakdown occurrences can be predicted, particularly if this leads to longer periods between maintenance or forced outages.

On the transmission system, networks should deliberately be designed to provide alternative paths for energy flow in the event of one (or sometimes two) of the  $n$  circuits being forced out because of a fault, lightning disturbance or vandalism. This is known as  $n-1$  ( $n-2$ ) security and could be a condition laid down by the regulator in granting a transmission licence. Incidentally, this 'overprovision' of circuits compared to that of a just 'adequate' system leads to fewer losses and hence reduced cost of operation.

On the distribution system, the expense of providing duplicate circuits is not justified except perhaps in densely populated areas such as cities and industrial complexes. Again statutory requirements or the regulator will lay down the 'target' frequency of interruptions and the time allowed for restoration, usually by designing the system for back-up re-switching through strategically placed isolators or circuit-breakers. The target 'restoration' time should account for proficient remote monitoring and alarming of supply conditions and the deployment of standby repair crews. Most countries have standards on demand levels and the security required dependent upon the MW disconnected through circuit outages.

### 39.5 Revenue collection

Of prime importance is the ability to meter and collect the dues from the various parties in the generation and supply chain. In a vertically integrated or government controlled power system, the most important revenue to be collected is from the final consumers. This is usually achieved through the reading of a customer meter, belonging to the power authority, and the sending out of a bill according to

the agreement between the authority and the customer. Tariffs can be for units (kWh) consumed between the meter readings according to some scale, or, for the larger consumers, kVAh or kVAh and peak kW can be included. It must be emphasised that in a restructured ESI the final consumer may be supplied by an organisation who own no physical equipment but who make bulk purchases on the energy market and retail it at a negotiated price. For small (mainly residential) consumers this price must be published, but for larger (commercial or industrial) consumers this contract may be confidential.

The supplier must, of course, pay the transmission and distribution system owners for the delivery of the energy, thereby requiring not only metering in all parts of these systems but also an approved use-of-system charge as set by a government authority or a regulator. Finally the generators must collect revenue from the suppliers for their contracted energy as metered by an independent authority and assessed through an appropriate regulated formula. It is obvious that the measurement and collection of revenues is now a complex business requiring careful organisation and the taking of many millions of measurements each day for half-hour or hourly slots. Automated meter reading and formulaic calculation is absolutely necessary to reduce the costs of collection and billing if the final price of energy is to be restrained.

A continuing problem is the balance between introducing 'smart' meters with a communication channel between consumer and supplier or continuing with manual meter reading on a periodic basis perhaps interspersed with estimated readings. The former with all extra costs included can amount up to 20% of a residential consumer's bill although for larger consumers with bills of £1000 p.a. or more the cost of the new meter and associated communications can soon be recovered in the tariff. A meter reader can be expected to call on 100 to 150 customers a day dependent upon density of housing whereas a smart meter with two-way communication can be interrogated at least once a day and the payment notified immediately to the customer followed by direct debt to an agreed bank account. It was the practice to install pre-payment meters for poor paying or rapid turnover customers but the cash collection adds to costs and makes it difficult to give discounts and thereby reduce bills to the poorer members of society.

In developing countries where energy per household is extremely small, a fixed standing charge with fuse limitation of maximum demand is possible to save on collection costs. Where demand is for fixed and calculable times, such as street lighting etc., then an agreed monthly payment is preferable to avoid metering costs.

### 39.6 Environmental sustainable planning

No power system plan for a 'green-field' site or extension to an existing network can avoid careful and in depth consideration of the effect on the environment. It is expected that most governments have introduced or will introduce a strategy for reducing carbon dioxide and polluting gas emissions from electrical energy producers. This strategy not only requires energy producers to be more efficient than in the past but also expects the consumers—both large and small—to reduce considerably energy use of all kinds. Unfortunately, electrical energy is perceived to be the most polluting source because of the large power stations evident around the country and also because of the relative inefficiency of end use in all kinds of industrial plant, air conditioning and cooling, freezers, refrigerators and home heat

losses. Estimates of possible reduction in CO<sub>2</sub> emission per kWh of electrical energy over the next 10 years are up to 20% and by careful design and encouraging awareness of the problem, more reductions could be possible.

Although pollutants produced by electrical energy production can be mitigated by design, the extra cost must be borne by the purchaser e.g. flue gas desulphurisation on a large power station can add 20% to its capital cost plus about 10% to the running costs, making it uneconomic compared to existing stations. One answer, now being introduced by many governments, is the purchase of an emission limit licence for each installation, which if not fully taken up each year can be traded like any other asset. The aim would be to control total emissions such that local atmospheric conditions could be stabilised and reduced.

For carbon dioxide emissions leading to global warming a similar 'carbon tax' on fuel use is proposed. Whilst the cost of CO<sub>2</sub> entrapment at source is tremendously expensive at present (+80% estimate for a power station) the tax

would pay for more research and development leading eventually to power products such as renewables and fuel cells in which no CO<sub>2</sub> is emitted. The aim is to move towards non-polluting producers, including zero CO<sub>2</sub>, and to use resources that will sustain the ecology of the planet and continually improve the quality of life for all.

## 40.1 Introduction

Power system operation and control are guided by the endeavour of the utility to supply electric energy to the customer in the most economic and secure way. This objective is underlined by the fact that the electric energy system is a coherent conductor-based system in which the load effects the generation without delay. Energy storage can only be realised in non-electrical form in dedicated power-stations, so that each unit of power consumed must be generated at the same time. It is therefore necessary to maintain all the variables and characteristics designating the quality of service, such as frequency, voltage level, waveform, etc.

The power system is operated continuously and extends geographically over wide areas, even over continents. The number of generators supplying the system and the number of components contributing to the objective are extremely high. However, the task of system operation is alleviated by the fact that there are not too many different types of component (if the intricacies of power-stations are excluded). In the transmission system the components that are quite easily managed are lines, cables, breakers, disconnectors, bus-bars, transformers and compensators. In the power-stations the generator commonly used is the synchronous machine. The prime mover is a turbine driven by steam or by water. Overlooking the details, there are similarities in the operation and control of turbines and generators that permit a certain uniformity of approach; however, many details have to be considered when it comes to design, failure modes, actual performance, quality of service, etc.

The mechanism of power flow in the system, which is a key issue in all considerations of operation under normal and disturbed conditions, is governed by the Ohm and Kirchhoff laws. Higher voltage at an appropriate phase angle will cause more power flow when a suitable path is available. To draw power from a system is extremely simple: the consumer's load is just connected to a three-phase bus-bar, where the voltage is regulated so that the load can be supplied. The system includes control actions by which the power is allocated to various generators, but there is little interaction in the transmission system.

For economic and secure operation, the actions are quite sophisticated. Control can no longer be performed in a single location by observing a single variable. The control system becomes a multivariable, multi-level system with real-time and prophylactic interventions, either manual or automatic. Thus, the control system is a hierarchical system where the levels and corresponding functions can be characterised as follows.

### *Decentralised control*

- (1) In the power-station: control of voltage, frequency, active and reactive power.
- (2) In the substation: control of voltage (tap-changer on transformers), switching of lines and cables, protection.

### *Centralised control*

- (1) Regional control centre: switching, start-up and shut-down of generating units, unit commitment, reactive power control and load frequency control.
- (2) Utility control centre: economic load dispatching, security assessment, load frequency control (automatic generator control), power exchange with other areas, security monitoring, security analysis and operational enhancement.

A hierarchical control system needs extensive communication. Hence there is an extensive telemetering and telecontrol

system which provides data to the various control levels and executes control actions at a particular location that have been initiated in a control centre.

The following material is organised in such a way that the objectives and requirements of system operating and control are given and discussed first (Section 40.2); they underline the motivation for the development of modern complex systems. A way of presenting components and subsystems is given in Section 40.3. Data acquisition and telemetering are then treated (Section 40.4) these are prerequisites for power system control.

Decentralised control is divided into *excitation* control (Section 40.5), *turbine* control (Section 40.6) and *substation* automation (Section 40.7), which are the most important control functions at a local level. Pulse controllers for tap-changers are also considered (Section 40.8).

Centralised control is dealt with in Section 40.9, where the hardware and software aspects of computer-based system operation are considered. With the various systems and functions to hand, present-day system operation is characterised in Section 40.10. Changes in the system operation due to liberalised energy markets are also pointed out in the Section 40.11. The new focus on distribution automation and demand side management is touched upon in Section 40.12. Finally, the reliability of system control is considered in Section 40.13.

## 40.2 Objectives and requirements

The often-cited objectives of economy and security have to be considered in various time-scales and in different system conditions in order to achieve a systematic approach to power systems operation, particularly when computer-based systems are involved. Before we go into details, it should be noted that system operation as considered here is a problem within the framework of a given power system. Planning problems and problems of procuring the primary energy are omitted.

Any objective or requirement is derived from the basic task of supplying electric energy to the consumer with the least expenditure of economic effort, measured over a long period. Hence a variety of cost items and even some intangibles such as environmental effects are involved. These items range from generating costs, losses, the cost of outages and the cost of damages, to risks and the amount of emissions, etc. Stated thus, these items are still too general to be converted immediately into an objective upon which a control function could be built. Different objectives apply for decentralised and centralised control; moreover, within a centralised control system it is necessary to distinguish various conditions to which particular objectives apply.

The most widely used concept for the realisation of a systematic control approach in centralised control is the concept of *states*. A state of the power system is characterised by reserves, by the ability of the system to override a disturbance, by the presence or absence of overloads, etc. The starting point is a series of considerations concerning the security of the system. However, considerations of economy can be easily added.

The four states with some rough characterisations are as follows:

- (1) *Normal (N) state*: the system has no overloads and a good voltage profile; it can withstand a line or generator outage and is stable.
- (2) *Vulnerable (V) state*: the system has no overloads and a good voltage profile; line or generator outage causes

- overloads and/or voltage droop; there is a low stability margin.
- (3) *Disturbed (D) state*: the system still supplies its loads, but overloads are present and there is a low voltage profile.
  - (4) *Emergency (E) state*: the system cannot supply all of its loads, overloads are present, there is a low voltage profile and part of the system is disconnected.

There are inadvertent transitions between the states caused by faults, human error and dynamic effects. However, control actions will return the system to the normal state. A thorough understanding of system operation will show that appropriate objectives and corresponding control functions will effect this return in a logical manner. These mechanisms are illustrated in the schematic of *Figure 40.1*, which shows (upper part) a state diagram with various transitions. The lower part of the figure gives transitions associated with a number of objectives. These pertain to control actions only. It is clear that the objective of full load coverage has to be met first before the vulnerable state can be reached. Further, all vulnerable conditions have to be eliminated before economic dispatching can be initiated.

At the decentralised level the objectives are much simpler and easier to understand. A state concept is not necessary since the objectives are expressed in terms of errors or time sequences in a straightforward manner. As an illustration, let us consider protection and excitation control.

In protection the objective is to keep fault duration or outage to a minimum. The fault itself cannot be avoided, but the adverse effects, possibly leading to a disturbed or emergency state, can be. Thus protection supports the aim of security on the decentralised level.

Excitation control maintains the voltage at a given location of the system and supports the stability. It is the stable voltage, with all its implications, that is at stake. A stable

voltage is a very important prerequisite for system security. For its realisation many detailed considerations are required since it is system dynamics that determines the performance of excitation control. Beyond that, an excitation system has many monitoring functions, i.e. limit-checking and even protective functions. The objectives of decentralised control, which become recognisable in terms of set-points, time periods and the like, must be co-ordinated. This co-ordination is performed either in the planning or operational planning phase (e.g. for protective relays), or in real time (e.g. for economic dispatching).

In power system operation and control it must be recognised that the control functions have a certain time range in which they are effective. Thus the corresponding objective has its validity within this time range only. As *Figure 40.2* shows, there is a complete hierarchy of functions ordered in terms of their effective time range. This hierarchy in time is also responsible for the functional hierarchy of the control system.

### 40.3 System description

In describing an electric power system we must distinguish the network (responsible for transmission and distribution) and the generating stations, as well as the loads.

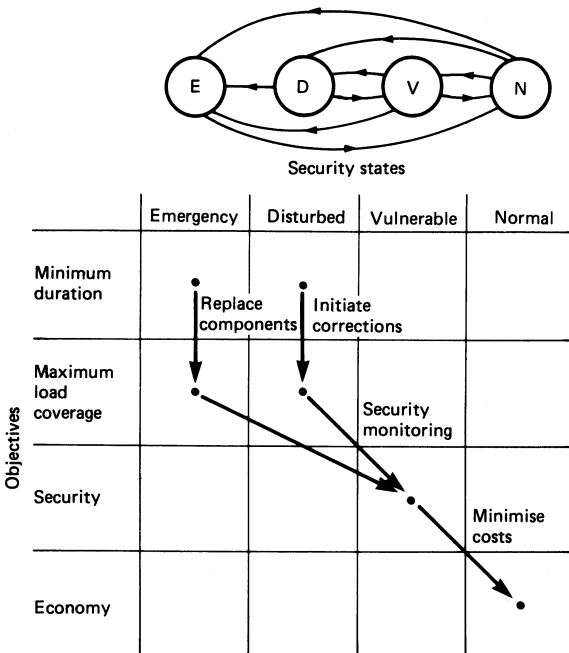

The network is amenable to description by topological means such as graphs and incidence matrices as long as the connection of two nodes, by a line or cable, is of importance. Thereby it is implied that the connection is made by a three-phase line which is itself described by differential equations. This topological description is always inherent and necessary. In routine work, however, it may not always be obvious what the true background is. Hence it is worthwhile to consider these topological means as a starting point.

Graphs and incidence matrices are equivalent and describe the way in which nodes are connected. A graph is a pictorial representation, whereas the incidence matrix is a mathematical formulation which can be interpreted by a computer. An example will illustrate the correspondence between these two descriptions. *Figure 40.3* shows a graph derived from an electrical network. The connections between nodes have been marked by arrows; this fixes the way of counting and thereby orientates the graph. *Figure 40.4* is the incidence matrix corresponding to the graph. The way of counting is indicated by the sign of the entries. Both the graph and the matrix describe the same network. The graph, however, is much easier to grasp.

The incidence matrix is the base for two processes, both of which are important for systematic description. The first is the reading of network data, wherein the way in which lines are connected is already implied. The second is the establishment of admittance and impedance matrices.

Consider the graph in *Figure 40.3* where the nodes have a particular numbering. This numbering permits the specification not only of a connection between two nodes but also of the type of connection. Assume that the connections consist of simple series impedances. Then the following description, which is machine-readable, is possible:

Connection	Impedance	Connection	Impedance
1-2	$0.05 + j0.68$	3-6	$0.06 + j0.75$
2-3	$0.06 + j0.75$	3-5	$0.03 + j0.35$
1-4	$0.03 + j0.35$	4-5	$0.04 + j0.50$
1-5	$0.04 + j0.50$	5-6	$0.05 + j0.65$
2-5	$0.05 + j0.70$		

**Figure 40.1** Security states and objectives: state diagram (above) and controlled transitions (below) following given objectives

Figure 40.2 Response times and cycle times for plant management, monitoring protection and control functions. AGC, Automatic generation control;  $P$ , active power;  $Q$ , reactive power;  $f$ , frequency;  $V$ , voltage

Figure 40.3 Oriented graph describing the structure of a six-node network: 1–6, nodes; a–i, lines

The first column specifies the nodal connection, the second the complex impedance. Each line of the list corresponds to a connection or a line of the network.

The generation of the nodal admittance matrix can be explained by a multiplication of the primitive admittance matrix  $p$  (diagonal matrix) by the corresponding incidence matrix and its transpose from left and right respectively:

$$Y = A^T Y^p A$$

The nodal admittance matrix contains all the information necessary (topology, impedance) to describe the network.

Loads and generators are connected to the nodes of the network. The description of the nodal constraints depends on the way the network is employed in an analysis or decision-making process.

	1	2	3	4	5	6
a	+1	−1				
b		+1	−1			
c	+1			−1		
d	+1				−1	
e		+1			−1	
f			+1			−1
g			+1		−1	
h				+1	−1	
i					+1	−1

Figure 40.4 Nodal incidence matrix  $A$  corresponding to the graph in Figure 40.3. The matrix establishes relationships between line and nodal quantities (currents and voltages). The arrow leaving a node determines the positive sign of the entry (+1)

For the purposes of load-flow calculations the specification is done in terms of  $PQ$ - or  $PV$ -nodes, where  $PQ$  means that the active power  $P$  and reactive power  $Q$  at the node are constant (i.e. independent of voltage), and  $PV$  means constant active power and constant voltage.

**Figure 40.5** Schematic diagram of a generator and a speed governor: G, generator; T, turbine; R, regulator/speed governor;  $f$ , measured frequency;  $f_s$ , set-point of frequency

For dynamic analysis more complex models for the nodal description have to be added. On the load side, the frequency dependence or, if necessary, a set of different equations is needed. For the generating unit, differential equations are comprehensive, but not always transparent. Hence, a block diagram is used to specify forward and feedback paths, wherever appropriate. As an example, the signal flow and the generation of torque within a turbo-generator are given by the block diagram in *Figure 40.5*. The dynamics of a synchronous machine would also be amenable to such a description, but in practice a description by differential equations (two-reaction theory) is usually preferred. Details of controllers and regulations are described by block diagrams, as is common in control engineering.

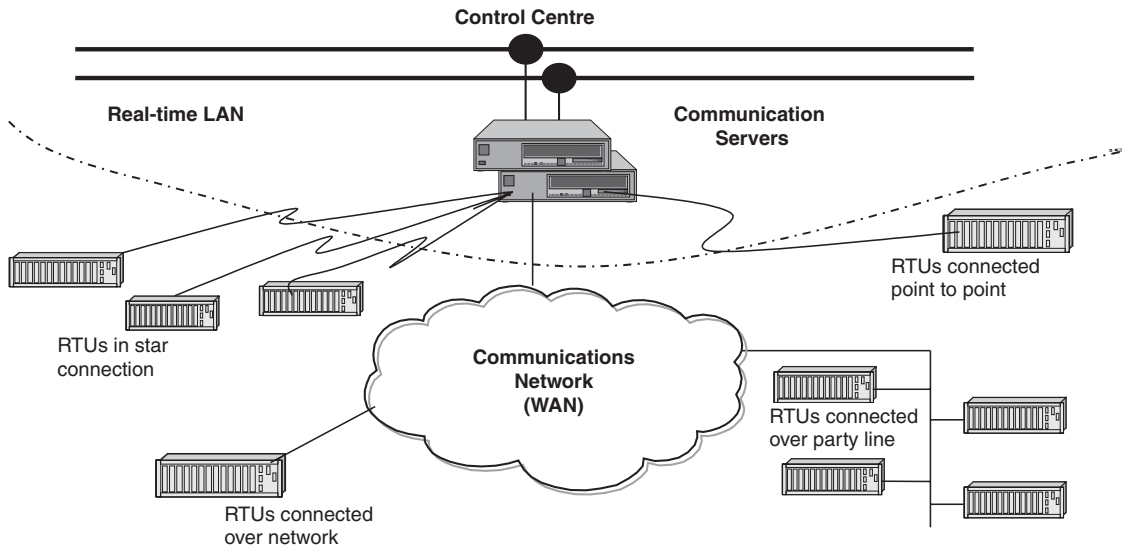

## 40.4 Data acquisition and telemetering

### 40.4.1 Introduction

To be able to supervise and control a power system, the network control engineer requires reliable and current information concerning the state of the network. This he obtains from the power flows, bus voltages, frequency, and load levels, plus the position of circuit-breakers and isolators; the source of these data being in the power stations and substations of the network. As these are spread over a

wide geographical area, the information must be transmitted over long distances. Thus the electrical parameters and switch states must be converted into a suitable form for transmission to the control centre. A telecontrol system is also required to transmit these data using communication channels which were historically limited in capacity and were shared with other facilities such as speech, protection and, perhaps, also telex communication. Speed of data transmission was therefore often limited, and the telecontrol network was configured to optimise the use of the available bandwidth on the carrier channel. The modern communication is based on fibre optical or wireless communication networks, which provide a powerful broad band communication. The classical power line carrier communication technology has also been improved with the use of digital technology. It is almost mandatory that all the new HV and EHV lines be laid with fibre optical core in the ground wire, as the incremental cost is quite low. The trunk routes may have dedicated logical links for speech, data and protection signal in addition to the data and voice network for telecommunication purposes.

The telecontrol system comprises a master station communicating over communication channels with remote terminal units (RTUs) located in the power stations and switching stations. Normally the RTUs are quiescent, i.e. they only send data after a direct interrogation from the master station; thus more than one RTU can be connected to a transmission channel as the channel can be time shared. A telecontrol network can be configured as a point to point, star (radial) or multi-point (part line) system as illustrated in *Figure 40.6*. The transmission can be either duplex, half-duplex or simplex (in the case where data traffic is unidirectional). The newer generation of RTUs can remain quiescent and can report the data on their own initiative using a slave to master communication protocol. The use of standard telecontrol protocols is also being promoted to facilitate use of equipment from different suppliers. International Electrotechnical Commission (IEC) has recommended IEC870-5-xxx group of protocols, which allow certain amount of openness in the system. The state of the art RTUs can communicate over data communication networks providing a large bandwidth with good reliability.

**Figure 40.6** Transmission network configuration

#### 40.4.2 Substation equipment

The data-acquisition equipment in a substation is usually a microprocessor-based RTU, equipped with both program-mable read-only memory (PROM) and random-access memory (RAM). The data-acquisition program and the transmission program are loaded into the PROM, which is non-volatile (not corrupted during a power supply failure). All the system modules are connected to the system bus (see *Figure 40.7*) which is structured to facilitate data transfer from the information source to its destination, under the control of the program. The microprocessor function is monitored by the watch-dog module. The RTU is configured to suit the substation requirements. A typical configuration is shown in *Figure 40.8* with the input/output

for one high-voltage (h.v.) circuit only. The input modules fall into three main categories: digital input, analogue input and pulse input.

##### 40.4.2.1 Digital inputs

Digital input modules are used for inputting contact states indicating breaker positions, isolator positions and alarm contact operation. The contact states are continually monitored but are not transmitted unless a contact state has been changed. Under program control, the module is cyclically interrogated to see whether it has a change of state to report: if the reply is negative, the program moves to another module; if it is positive, the change of state is

Figure 40.7 RTU bus structure: I/O, Input/output

**Figure 40.9** Digital input circuit

written to the memory. The input circuits are decoupled from the power system equipment by electromagnetic relays or opto-couplers and are filtered to eliminate the effect of contact bounce. A digital input circuit is illustrated in Figure 40.9.

#### 40.4.2.2 Analogue inputs

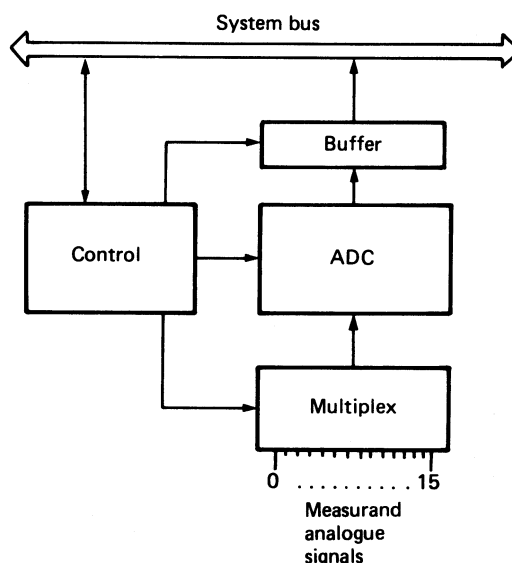

The electrical measurements are converted from current-transformer and voltage-transformer levels to analogous direct-current (d.c.) milliamper signals by suitable transducers. These convert voltage, current, active and reactive power, frequency, temperature, etc., into proportional d.c. signals which are fed into an analogue input module. This module (Figure 40.10) has a multiplexer for scanning multiple inputs (usually 16) and an analogue-to-digital converter (ADC) which converts the d.c. signal into a digital code (usually binary or BCD). The local scanning rate of the measurands is less than 0.5 s, with an accuracy of conversion for normal requirements of 1% for bipolar (7 binary bits + sign) values and of 0.5% for unipolar values. For higher accuracy requirements an accuracy of 0.1% is used (11 bits).

#### 40.4.2.3 Pulse inputs

Energy or fuel consumed can be measured by integrating meters giving a proportional pulse output. The pulses are integrated in a pulse input module which is periodically scanned, e.g. at 15 min intervals. The consumption over that period is then the difference between the last two readings. Special measures are taken to ensure that the reading does not interfere with the pulse integration or vice versa.

#### 40.4.2.4 Digital output

Digital output modules convert a coded message, received from the control centre, into a contact output, e.g. to trip or

**Figure 40.10** Analogue input module

close a circuit-breaker or to raise or lower a tap-changer. Obviously, the transmission of these signals must be very secure, and checking that the correct output is given must be rigorous. Echo checks are made to ensure that the correct code has been received by the module, and additional circuits can be added to detect stuck contacts and to prevent more than one command being output at a time.

#### 40.4.2.5 Analogue output

Set-points are output via analogue output modules that receive a coded message which they convert into a d.c. analogue signal; this is output e.g. as a turbine-governor setting.

#### 40.4.2.6 Clock

An optional feature of the RTU is a clock module, which enables the events in the substations to be arranged and transmitted in chronological order and the time at which an event happened to be added. The clock is capable of giving a 10 ms time resolution in event sequence recording and the time in hours, minutes, seconds and hundredths of a second.

#### 40.4.2.7 Printer

A further option can be included to print the alarm and event sequences locally at the substation by adding memory, serial-parallel interface, a printer and additional program. If the memory capacity is limited, the output is either coded or abbreviated; however, with adequate memory the print-out can be in clear text.

### 40.4.3 Data transmission

The substation data are locally scanned and memorised in the RTU ready to be transmitted to the control centre. When an instruction is received from the master station, the processor prepares to send the data to the control centre. To every message containing data, it adds check bits

that enable the master station to ensure that the message has not been corrupted during transmission. Similarly, to any message output from the master station, check bits are added to enable the RTU to verify that the received message has not been corrupted. The data are then output to the communication channel via the parallel-to-serial converter and the modulator-demodulator (modem) which converts d.c. pulses into keying frequencies in the voice-frequency (v.f.) range. Normally two v.f.-range frequencies are used to represent '1's and '0's of the message code and to modulate the carrier of the transmission channel. At the receiving end, the modem converts the keying frequencies into d.c. pulses and the serial-parallel converter module reassembles the message into a parallel word including the check bits. The message can then be checked for errors induced during transmission.

There are various methods of checking for errors in a message telegram. The error-detecting capability of a checking system is often described as a Hamming distance. The Hamming distance between two binary words is the number of bit positions by which they differ, which is undetectable by the error-checking system. For most purposes in tele-control, the minimum Hamming distance is 4, i.e. all 3-bit errors are detected. An example of a modified Hamming code error-checking system is shown in *Figure 40.11*.

The advantage of this system is that in addition to detecting the same number of error patterns as equivalent error-checking systems of the same size, the introduction of odd parity in one check-bit position and even parity in the others forces at least two changes in bit settings in the telegram. This considerably reduces the risk of loss of synchronism when the word is being read. The Hamming distance of this code is 4: i.e. all patterns of 3-bit errors are detected, as well as all odd numbers of bit error patterns and over 92% of all even numbers of bit error patterns.

#### 40.4.4 Transmission system

The data transmission system must be designed to allow all the RTUs to transmit their data to the control centre in a reasonable time without imposing impractical demands on the communication system. The data transmission can be divided into several parts, each of which can comprise one or more RTUs. Each part system is completely independent of the others; thus they effectively operate in parallel.

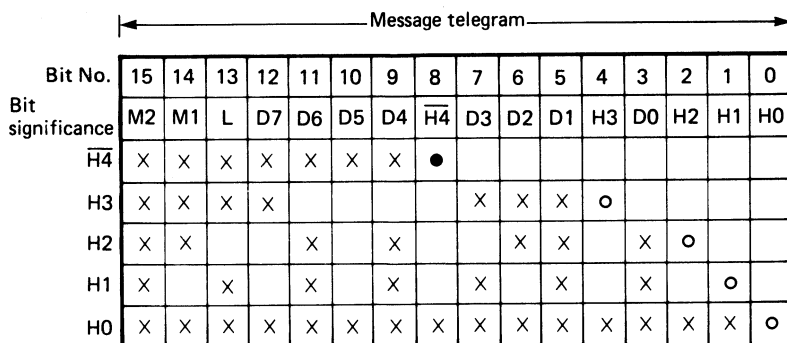

Three basic systems are possible: point-to-point, radial or multi-point (see *Figure 40.6*). Combinations of radial and multi-point are also possible.

With point-to-point systems, the transmission can be simplex (where the RTU sends data continuously to the master station) or half- or full-duplex (where data can be transmitted in both directions).

With radial or multi-point systems, the dialogue between the master station and the RTU is entirely controlled by the master station to avoid two or more RTUs sending data simultaneously. The master station transmits instructions to the RTU, which, in complying with the instruction, acknowledges it. The RTU takes no initiative in transmitting data and sends data only after receiving a specific instruction to do so from the master station. Thus all data in a part system are transmitted from each RTU in turn and response times are a limiting feature of a part system configuration.

There are two basic forms of data to transmit: even-controlled data which appear at random intervals, and data that must be transmitted cyclically as they are liable to be continually changing. The cyclically transmitted data, e.g. measurands which require frequent updating at the control centre, take up most of the transmission time; however, as the RTU is quiescent, periodically it must be asked whether it has any spontaneous data to transmit. To save transmission time, this is made in a 'broadcast' interrogation to all RTUs in the part system simultaneously. If no RTU answers positively, the normal cycle sequence is resumed; however, if one or more RTU answers that it has spontaneous data to send, the normal cycle is interrupted and each RTU is interrogated in turn until all the spontaneous data have been transmitted and received at the master station. In order that the detection of spontaneous data (e.g. a breaker trip) is transmitted in a reasonable time, the spontaneous data interrogation is interjected between the transmission of groups of measurands (say 16). An example of a transmission sequence is given in *Figure 40.12*. The spontaneous data can be sent in chronological order of events taking place and also with the time at which each event happened.

The response times are dependent on the transmission speeds, and a choice of speed is available. Standard speeds of 50, 100, 200, 600 and 1200 bit/s are available within the v.f. band. The choice of speed is then dependent on the response times required and the bandwidth available on the communication channel. As an example of response times, a part system comprising four RTUs each having measurands would have a measurand and indication interrogation scan time (with no changes of state to transmit) of approximately 6.5 s, using a 200-baud channel. To decrease this time, either the number of RTUs in the part system

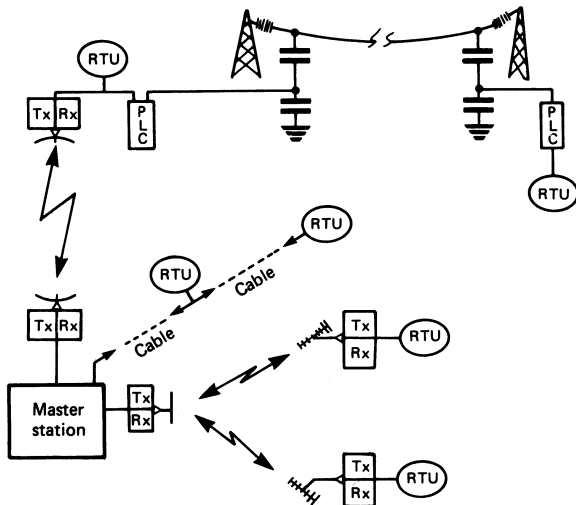

**Figure 40.11** An example of message telegram organisation: ●, odd parity check; ○, even parity check; x, bits supervised by Hamming bits; D, data bits; L, message sequence complete; M, message-type definition; H, Hamming bit

**Figure 40.13** An example of a data transmission system. Tx, Rx, radio transmitter and receiver; PLC, programmable logic controller

would have to be reduced or the speed of transmission would have to be increased.

#### 40.4.5 Communication channels

The transmission of the frequency-shift keying signals requires a four-wire circuit communication channel, which can be telephone-type cable, power line carrier equipment, radio transmission or any combination of these media in series or parallel. *Figure 40.13* gives an example of a possible combination of different types of communication channels.

Often the telecontrol signal must share the v.f. band with other transmissions such as speech, telex, protection or even another telecontrol part-system transmission. An example of the frequency multiplexing of the v.f. band is given in *Figure 40.14*. The multiplexing equipment is normally available with the power line carrier. The frequency-shift keying takes place within the frequency bandwidth indicated in *Figure 40.14*: e.g. for a 200-baud modem the lower keying frequency is  $-90$  Hz and the upper is  $+90$  Hz of the channel centre frequency. The total bandwidth required is 360 Hz.

### 40.5 Decentralised control: excitation systems and control characteristics of synchronous machines

#### 40.5.1 Introduction

A synchronous generator operating on an interconnected grid requires a fast-response excitation system to ensure its

stable operation. This system must be able to adjust the level of magnetic flux in the generator according to the grid network requirements. Since the parameters of the generator will fall into a fairly narrow range according to the type of generator (salient pole or turbo), the excitation system must be designed to bring the generator flux (i.e. excitation current) to the required level in the shortest possible time, notwithstanding the long time-constants of the generator transfer functions.

Brushless excitation equipment has been developed to meet these requirements on various types of synchronous generator—particularly on smaller turbogenerators—and has given excellent results in service. The control characteristics of this system, however, are dictated largely by the exciter and the rotating diodes rather than by the voltage regulator (d.c. exciters are not used in modern excitation systems).

For large generators a static excitation system represents the best solution since, in principle, it imposes no limit on the ceiling voltage. In the per-unit system the ceiling voltage is the ratio of the maximum excitation voltage to the excitation voltage for nominal open-circuit voltage at the generator terminals. Values of 10 or 15 p.u. are quite often used. A great advantage of static excitation is that the total field-voltage range is available with practically no time delay. This speeds up not only field forcing but also field suppressions when required, by change-over to inverter mode.

#### 40.5.2 Brushless excitation systems

Brushless excitation systems are mainly employed either where the control requirements are not too stringent or where the atmosphere is chemically aggressive. The main generator excitation is provided by an auxiliary exciter generator mounted on the main generator shaft.

This exciter is a salient-pole synchronous generator with a three-phase winding on the rotor and a d.c. excitation winding on the stator. The alternating currents produced by the rotor winding are rectified by rotating diode bridges mounted on the shaft, the resulting d.c. being fed to the field winding of the main generator. The excitation for the exciter stator winding is supplied by a thyristor regulator which comprises voltage regulators and limit-value controllers. Field suppression of the exciter machine is also carried out by the regulator (*Figure 40.15*).

The controlled rectifiers and the electronic circuitry of the regulator are supplied either from a permanent magnet (p.m.) generator on the main shaft or through a transformer fed from the main generator terminals. In the latter case, compounding equipment is available for the required selective switching (short-circuit duration in excess of 0.5 s) which is then combined with the standard regulators.

In its basic form the regulation system contains the continuously active elements for automatically controlled operation, which are:

- (1) a voltage regulator;
- (2) a reference-value potentiometer for remote adjustment;

Figure 40.14 Allocation of communication functions to a 4 Hz channel

Figure 40.15 Voltage regulation system with manual control facility: 1, current transformer; 2, voltage transformer; 3, exciter; 4, generator; 5, voltage regulation; 6, reference value; 7, supply transformer for the voltage regulator; 8, field switch/discharge resistor; 9, change-over switch; 10, rectifier; 11, variac with motor drive

- (3) a supply transformer;
- (4) a field-breaker and discharge resistors; and
- (5) diode monitoring consisting of the manual control device, i.e.
  - (a) a variac transformer,
  - (b) a diode bridge, and
  - (c) a change-over switch (auto to manual).

### 40.5.3 Static excitation systems

On generators with difficult regulation requirements a rotating exciter should not be used. Here the excitation is supplied either directly from the generator terminals via a transformer and a controlled rectifier bridge (Figure 40.16) or by an auxiliary generator.

The main components of a static excitation system are:

- (1) an excitation transformer (or auxiliary generator);
- (2) a static converter;
- (3) a field suppression system;
- (4) control and firing circuits; and
- (5) a protection and monitoring system.

The capacity of the excitation system is dependent on the generator specification and on the requirements of the power system. The rating of the excitation transformer or exciter in particular is determined by the maximum continuous current rating of the rotor winding and the required ceiling voltage. In designing the converter circuits, which have much shorter thermal time-constants, the ceiling current and short-circuit current capacity must also be considered.

The voltage of the transformer secondary (or of the auxiliary generator) is determined by the maximum ceiling voltage,  $V_c$  of the excitation system, and its current by the maximum continuous current  $I_{fm}$  of the generator field winding. A simple approximation to the rating of a three-phase excitation transformer is  $1.35 V_c I_{fm}$ .

The static converter comprises one or more fully controlled thyristor bridges, which are almost always cooled

Figure 40.16 Block diagram of a voltage regulator with static excitation (without manual control): 1, instrument transformer; 2a, transducer; 2b, voltage regulator; 2c, PID filters; 3a, firing-angle control; 3b, filter; 3c, voltage relay for control of excitation field flashing; 4, pulse amplifier; 5, reference-value setting unit; 7, generator; 8, main excitation rectifier; 9, excitation transformer; 10, field suppression device; 11, field flashing device; 12, overvoltage protection

by forced air. The number of parallel bridges and the number of series elements in each bridge branch are determined by the technical data (current rating and inverse voltage) of the thyristor bridges, the maximum exciting current, the transient overload (due, for example, to a system fault) and the ceiling voltage. An extra redundant bridge is normally included (in parallel) so that, even if one bridge fails, the full operational requirements can still be met. To ensure selectivity, it is necessary to have at least three bridges in parallel. This is because a faulty thyristor together with a healthy branch can form a two-pole short circuit that persists until the fuse in series with the defective element blows. If only two parallel bridges are provided then the short-circuit current in the healthy branch is shared by only two thyristors; the fusing integral of both the corresponding fuses may then be exceeded, resulting in an excitation trip.

The rectifier can have either a block structure or be arranged phase by phase. In the block arrangement, one or more bridges are grouped together and gated from a common pulse amplifier. Blocks are normally provided with individual fans, but common cooling is also possible.

The arrangement of the converter in phase groups reduces the risk of an interphase short circuit. All parallel thyristors of one phase are brought together in a single rack. A separate cooling system for each rack is inappropriate in this arrangement and common cooling is employed, consisting of two fans each capable of supplying the full cooling-air requirement.

With the phase-by-phase arrangement, the excitation transformer is usually composed of three one-phase units; this will always provide a higher degree of safety against interphase short circuits.

The field suppression system comprises essentially a two-pole field-breaker and a non-linear field discharge resistor. The component ratings are so chosen that neither the permissible arcing voltage at the breaker nor the maximum permissible field-circuit voltage is exceeded, even with the maximum possible field current (following a terminal short circuit on the generator). A 'crowbar' is included in the discharge-equipment cubicle as additional overvoltage protection. This comprises two antiparallel thyristor groups which are triggered by suitable semiconductor elements such as breakover diodes (BODs). If, for instance, a voltage is induced in the rotor field circuit owing to generator slip, this voltage can rise only to the threshold of the BOD element. If this value is reached, the element triggers the thyristors, and the rotor circuit is connected to the discharge resistance, allowing a current to flow which immediately causes the induced voltage to break down.

#### 40.5.4 Automatic voltage regulator and firing circuits for excitation systems

The voltage regulator for brushless exciters as well as for static excitation systems constitutes the central control element in a modern plant. This unit uses a voltage transformer to measure the actual value, rectifies it and compares it with the reference value. The difference-voltage is fed to an amplifier with a lead-lag filter (the response characteristics of which must be carefully adjusted to suit the particular generator and grid parameters) and the amplified value is brought to the gate control unit. Using additional reactive current compensation it is possible to adjust the reactive current behaviour of the generator with regard to the network.

The voltage regulator has normally to be supplemented with parallel-connected limiters which function before

corresponding generator protection relays are activated. Depending on requirements, rotor-current, load-angle and stator-current limiters may be employed. Their features are described later.

If the limitation control causes a reduction in the excitation current (on over-excited operation), time-delay elements are incorporated to allow high transient currents. For underexcited operation there is no time delay.

Stabilising equipment can be used to damp power oscillations that may arise under exceptional network conditions.

The voltage regulator may be supplemented with an overriding system for controlling the power factor or the reactive power flow, as required. All voltage regulators are provided with manual control (changeover from closed-loop to open-loop control). A separate redundant gate control unit is often provided (double-channel type). In case of a fault in the 'automatic' channel, a follow-up control system ensures a smooth transition to manual operation.

The amplified difference signal is transformed into pulses with the appropriate firing angle by the gate control unit. The firing pulses are amplified in an intermediate stage and led to the individual output stages which are assigned to the various converter units. The output stages shape the pulses to the steep slopes necessary to ensure simultaneous firing of all parallel thyristors. The pulses from the output stages are fed via impulse transformers to the thyristor gates.

The transfer function of the automatic voltage regulator (AVR) including the gate control system is

$$\frac{\Delta V_f}{\Delta V_g} = A \frac{(1 + pT_1)(1 + pT_2)}{(1 + pT_3)(1 + pT_4)} \frac{1}{1 + pT_M} \frac{1}{1 + pT_E}$$

where  $T_M$  is the measuring time-constant,  $T_E$  is the exciter time-constant,  $T_1, \dots, T_4$  are the equivalent lead-lag time-constants,  $A$  is the amplification, and  $p$  is the operator  $d/dt$ .

#### 40.5.5 Limiting the excitation of synchronous machines

Ever-increasing demands on power system reliability led to the development of ancillary equipment (limiters), to inhibit the tripping of protection gear when this was not wanted and to make, within the permissible limits, better use of the synchronous machine. These limits are clearly depicted in the power chart of a turbogenerator shown in *Figure 40.17*.

The limit of active power output (line CE) is determined by the prime-mover, and is disregarded. A factor connected directly with excitation current, however, is the permissible temperature rise in the rotor winding, represented by the arc CD with centre A corresponding to the non-excited condition. This thermal limit is defined by the ageing of the insulation. It may therefore be exceeded for a short time—a requirement essential for the stability of the power system.

In the underexcited mode, operation of the synchronous machine is limited by the airgap torque necessary for the active power transfer, the steady-state condition being represented by a definite, permissible rotor displacement angle (line AE). This limit has mechanical and dynamic characteristics, and calls for instantaneous intervention as soon as it is exceeded, to prevent the generator from falling out of step.

Another important condition governing the limits to be introduced is the requirement that these do not interfere with the normal operation of the voltage regulator, and that neither intervention nor return to voltage regulation leads to disturbances.

The demands to be met by the rotor-current limiter are best explained with reference to the voltage and excitation controller when a short-line fault occurs. The voltage regulator reacts to the drop in voltage with surge excitation. The controller is not intended to impede this, but merely to determine the ceiling current  $I_{fm}$ . Although the clearance normally takes place in a few hundred milliseconds, the longest duration (back-up protection) of 2-3 s will be assumed. When, after the fault has been cleared, nominal voltage is attained with a permissible continuous excitation current, the thermal controller will not intervene. However, when because of, for example, breaker failure the fault is not cleared, or when generated reactive power no longer suffices to maintain the voltage level, overexcitation will continue to be present. The limit controller now aims to reduce the excitation current before any of the protection

gear is tripped. A further important aspect is that this also causes the short-circuit power of the system to be reduced, which, in turn, will diminish the extent of the damage resulting from failure of a breaker or other protective gear.

The condition in which the maximum continuous excitation permissible is present might persist for a long time, and experience has shown that further short circuits appear relatively frequently during this time. When these secondary disturbances occur, it becomes necessary to deliver the maximum reactive current to the system once more, especially to retain system stability. This means that limitation has to be cancelled again for a short time. The characteristic which trips the reset is the steep drop in voltage,  $dV/dt$ .

A further requirement results from the fact that today most of the large excitation equipment is fed from the generator terminals. The necessary ceiling excitation current is normally already available at 90% of the rated voltage. This means that at 120% of the rated voltage, a ceiling current which is 33% higher than the necessary value will flow when an instantaneously acting excitation limiter is not provided.

The limitation signal can be introduced as a reference-value variation of the voltage regulator. However, two facts suggest applying the signal to the voltage regulation output for use as dominant parallel limitation. These are: (i) the limitation is absolute and thus fully effective even when the actual value for the voltage regulator is lost (voltage-transformer fuses blown); and (ii) the limit controller can be adapted to the dynamic conditions of the field-current controller and become independent of voltage-regulator response.

As has been mentioned, limitation to the permissible continuous excitation current should be delayed in order to first give the voltage the maximum support possible. The permissible continuous current in the excitation circuit is determined by the thermal stressing of the field winding, the supply transformer, or the thyristors or diodes. The overload capacity of these elements can usually be represented by integration of the current. A slight overrun of the set limit for the continuous current is then tolerated correspondingly longer. It can be argued, however, that the ceiling excitation will be required only as long as fault clearance is still taking place, in which case a fixed timing element is provided. In both cases, it is usually desired that ceiling excitation should be available again in the event of secondary disturbance.

Based on previous experience, improved rotor-current limit controllers were developed to cater for the many varied applications met with in practice; these controllers can be easily adapted to the particular protection method used.

A maximum-current limit controller, instantaneous acting and always available, ensures that for terminal-fed excitation the desired ceiling current is not exceeded over the entire operating voltage range.

In the case of the simple integrator mode, the speed at which reduction to the limit value takes place is relative to the magnitude of the overcurrent. The integrator is reset only when the limit for the continuous rotor current is underrun.

With the switching mode, reduction to the limit begins after a set delay  $T_v$  of several seconds. Every time there is a sharp drop in voltage, maximum-current limitation begins anew and the timing element is reset.

A method frequently used in the combined mode: here, integration of the overcurrent is combined with resetting of the integrator by each succeeding voltage drop.

The actual current can usually be measured with a current transformer in the alternating-current (a.c.) power supply prior to rectification by the thyristors or diodes. A d.c./d.c. converter makes connection to a shunt also possible.

When partial failure of components in the excitation circuit causes the permissible continuous current to be reduced, change-over to a pre-set second current limit set-point is possible.

#### 40.5.5.2 Load-angle limitation

For a number of years it has been standard practice to provide protection gear that detects excitation failure or loss of generator synchronism and trips the generator breaker. Inadequate excitation can, for example, also be caused by a change in the system configuration due to a fault, by reference-value failure or by other faults in the voltage regulator. The load-angle limiter obviates unnecessary disconnection by the under-excitation protection device in all these cases.

The limit angle is set intentionally to a value considerably smaller than the pull-out limit. For turbogenerators, for example, the angle lies between  $70^\circ$  and  $85^\circ$ . For salient-pole machines the actual stability must be taken into account and a suitable response limit determined. Thus, an adequate angle difference exists for the acceleration of the generator during clearance of a nearby short circuit. This reserve is directly related to the time allowed for clearing the fault.

The principle of analogue simulation of the phasor diagram using stator voltage and current is applied. This method is notably simpler than the direct measuring processes. In the event of a transmitter on the shaft providing the rotor position, the same device may be employed for further evaluation. The angle between the two simulated phasors, rotor voltage  $E_p$  and the infinite bus voltage  $V_s$ , is converted into a d.c. signal in a solid-state angle discriminator. When transients appear, the angle generated by the simulation leads the true load angle slightly. This is advantageous as this limiter should intervene at an early stage. Such a procedure has been shown to be reliable in practice.

#### 40.5.5.3 Stator-current limitation

The stator-current limit, which is governed by thermal considerations, normally lies beyond the operating range of the synchronous generator. Thus, stator-current limitation is employed only in special cases. To illustrate this point, actual applications of a stator-current limit controller, usually in conjunction with limit control of the load angle and excitation current, are given below.

- (1) With gas turbo-sets, for example, the useful output can be raised at times to cover peak demands, so that the limit is governed partly by the stator current.
- (2) In coastal areas it is necessary to reduce the system voltage at certain times of the year because of salt vapour; there is thus an increase in stator current for the same power.
- (3) In the case of reactive power compensators the under-excitation limit can be attained only with a stator-current limiter.
- (4) With synchronous motors, a practical utilisation limit can appear that will be detected approximately by a stator-current limit controller.

### 40.5.6 Control characteristics for synchronous machines

As far as the system of synchronous generator and network is concerned, there is a strong similarity between the speed and active-power control system on the one hand, and the voltage and reactive-power control system on the other.

To understand control by characteristic it is useful to compare the two systems (*Figure 40.19*). As long as the set is operating at no load, or on isolated duty, the appropriate value is controlled by the corresponding control system, i.e. the speed (frequency) or generator voltage. This is no longer the case, however, in parallel operation with a live network. Frequency and voltage are already present and can be changed by the set only to a limited extent. Secondary controlled variables are involved here, and it is imperative that they are controlled in parallel operation. These secondary variables are the active and the reactive power.

On what is this two-fold nature of the control system based? In isolated duty, only one control system is acting on any control loop. In parallel operation, however, many loops are coupled through the common controlled variable. The primary control task is distributed over a large number of control points. Selective stable distribution is of decisive importance. The overall task here is to maintain frequency and to produce active load, or to maintain voltage and to produce reactive load. The familiar solution is to provide the regulator with a drooping characteristic, i.e. the set-point of the primary controlled variable drops as the secondary controlled variable rises. The point of intersection of this characteristic of the network rating defines the corresponding operating conditions. Any set-point can also be set for the secondary controlled variable by parallel displacement of the characteristic. The gradient of the characteristic is usually expressed as a droop of the form  $S_n = \Delta n/n$  or  $S_v = \Delta V/V$ , i.e. as the percentage deviation in the primary controlled variable that is necessary to bring the secondary controlled variable from zero to the rated value.

While the frequency of the network is the same throughout, in the case of voltage this applies only to the imaginary voltage of an infinite bus-bar. The true network represents roughly a variable 'mountain landscape' of voltages defined by its line impedances and feed-in or feed-out at a large number of junction points. This true network must first be accessible by reducing it to a simple equivalent circuit (*Figure 40.20*).

Each individual generator feeds through transformer and line impedances into the 'finite bus-bar' formed by the sum

**Figure 40.19** Characteristics for parallel operation: (a) speed/active-power control; (b) voltage/reactive-power control. 1, Generator breaker; 2, generator; 3a, speed regulator; 3b, voltage regulator; 4, turbine; 5, rotor winding; 6, network;  $P$ , active power;  $Q$ , reactive power;  $n$ , frequency;  $V$ , voltage

**Figure 40.20** Impedances and voltage drops: (a) equivalent circuit diagram; (b) phasor diagram.  $V_s$ , Voltage of infinite system;  $V_N$ , system voltage;  $V_G$ , generator voltage;  $I$ , generator current;  $I_p$ , active component;  $I_q$ , reactive component;  $X$ , external (short-circuit) reactance;  $X_T$ , transformer reactance;  $X_D$ , direct-axis reactance of generator;  $E_E$ ,  $R_T$ , active resistances;  $Z_L$ , load impedance;  $G$  generator;  $\Sigma G$ , sum of all other generators;  $R$ , voltage regulator

of all the other generators. As can be seen from the phasor diagram in *Figure 40.20*, which may be considered as qualitative, the products of the reactances and reactive components of the current are decisive for the magnitude of the voltage drop  $|\Delta V|$ . The drop in active voltage and the phase displacement of the voltage phasor can here be ignored. The reactances between the generator terminals and the infinite network thus produce a natural drop in the reactive current, whereas the drop of the speed-control system is always synthetic. The generator reactance  $X_D$  is within the control loop and therefore need not be taken into account for quasi-steady-state phenomena. The effect of the natural drop in reactive current, and its increase or decrease by artificial means, is the main theme to be discussed from various viewpoints in the following.

#### 40.5.6.1 Parallel operation in a power-station

Parallel operation in a power-station is illustrated in *Figure 40.21*. As virtually all large generators are operated in unit connection, the transformer reactance between the terminals and the h.v. bus-bar causes a natural reactive current drop of 8–12%. This accurately defines the reactive power output. Conditions are very different in the case of low-voltage (l.v.) generators, which must operate in parallel direct at the machine terminals. Here there is no natural droop, and even the smallest difference in the voltage values will lead to undesirable mutual exchange of reactive power between the machines, without resulting in a defined distribution of demand. It is not until an artificial droop is introduced by applying reactive current in the measuring loop of the voltage regulator that the reactive load distribution becomes stable; initially it is immaterial whether the generators themselves define the voltage at a purely consumer network, or coincide with the voltage given by a live network.

**Figure 40.21** Parallel operation in a power-station: (a) basic circuit diagram; (b) characteristics. 1, Generator breaker; 2, generator; 3, voltage regulator; 4, voltage transformer; 5, current transformer; 6, bus-bar; 7, unit-connected transformer;  $V_N$ , system voltage;  $V_{G1}$ ,  $V_{G2}$ , generator voltage characteristics;  $V_0$ , no-load voltage;  $Q_{G1}$ , reactive power output of generator 1

Electronic controllers have no dead-band and permit closed-loop gains of between 100 and 200 in accordance with a proportional range of 1–0.5%. Consequently, in isolated duty a satisfactory distribution over the parallel generators is achieved even with a 3–4% artificial droop. For reasons discussed later, there are various factors that make higher droop values more suitable for interconnected systems. The polygon connection used previously in some power-stations for distributing the reactive load has therefore lost its significance to a large extent because total elimination of changes in the steady-state voltage had to be bought at the cost of complicated circuitry.

#### 40.5.6.2 Principle of current bias

The principle of phasor addition of a current-proportional voltage to the generator voltage has been known in various forms for some time (Figure 40.22). All three-phase voltages should be measured in each case to keep ripple and filter time-constants small. As shown in Figure 40.22, a one-phase current bias can be applied. In the case of controllers for large generators, the extra cost for symmetrical three-phase bias is justified.

The summation is made such that the overexcited reactive component of the current increases the actual voltage. This method of falsifying the actual value in relation to an unchanged set-point results in a drooping characteristic. In a steady-state condition the effect is the same as that of a reactance. A subtractive current bias causes a rising

**Figure 40.22** Current bias: (a) basic circuit diagram; (b) phasor diagram; (c) characteristics. 1, Three-phase voltage transformer; 2, current transformer; 3, load resistance  $R_B$ ; 4, rectifier; 5, voltage regulator; 6, generator;  $V_c$ , V. r.m.s. voltage;  $I_{Rp}$ , active current in phase  $R$ ;  $I_{Rq}$ , reactive current in phase  $R$ ;  $I_q$ , reactive current, superexcited;  $I$ , reactive current droop; II, no effect; III, reactive current compounding

characteristic, i.e. a compounding. The effect of a true reactance can be reduced by compounding. In simple circuits the reactive current droop is accompanied by a slight compounding in the active current, but in most cases this is useful and under no circumstances is it a disturbing influence.

It should also be noted that the current bias curve is not entirely linear but slightly progressive. This is of virtually no significance. The current bias can be varied between zero and maximum by altering the load resistance. Nearly all voltage regulators are issued with this equipment.

As mentioned above, the current phasor is chosen in most cases so that an almost purely reactive load effect is created.

However, an active-load effect or a mixture of the two effects can be achieved by selecting a different phase angle. Consequently, in medium-voltage networks, additional active current compounding has shown itself to be a suitable means of improving the operating behaviour.

#### 40.5.7 Slip stabilisation

Power transmission between synchronous machines and the load centre must remain stable even over long distances and under complex conditions. Experience has shown that certain network conditions can cause excessive hunting. Analysis indicates that hunting can be effectively reduced only by the introduction into the voltage control circuit of transient stabilising signals derived from the machine speed/frequency or produced by a change in the electrical output of the generator. Knowledge of the origin of the instability and the means of intervening in the controlled synchronous machine are essential for applying additional signals.

If the synchronous machine is connected to a rigid network through a reactance, it can be easily seen from the phasor diagram that the terminal voltage of the machine and the electrical torque alter with the rotor angle and with the main flux. The changes in terminal voltage, torque and main flux are given by differential quotients. In order to be able to make a quantitative statement for a given duty point, small changes are observed and the transmission functions and their representative factors are linearised about the duty point (index 0). This gives simple expressions, and a block circuit diagram (Figure 40.23) can be drawn which characterises the response of the synchronous machine at the rigid network. Let

$$\Delta M_{dE} = k_1 \Delta \delta \psi - k_2 \Delta E'_q$$

$$\Delta E'_q = k_3 \Delta E_p + k_4 \Delta \delta \psi$$

$$\Delta V_t = k_5 \Delta \delta \psi - k_6 \Delta E'_q$$

$$k_1 = \frac{\Delta M_{dE}}{\Delta \delta \psi} = \frac{V_0 \cos \delta_0}{x_q + x_e} E_{q0} + \frac{x_q - x'_d}{x'_d + x_e} V_0^2 \sin \delta_0 \frac{1}{x_q + x_e}$$

$$k_2 = \frac{\Delta P_d}{\Delta E'_q} = \frac{V_0 \sin \delta_0}{x'_d + x_e}$$

$$k_3 = \frac{\Delta E'_q}{\Delta E_p} = \frac{x'_d + x_e}{x_d + x_e}$$

$$k_4 = \frac{x_d - x'_d}{x'_d + x_e} V_0 \sin \delta_0$$

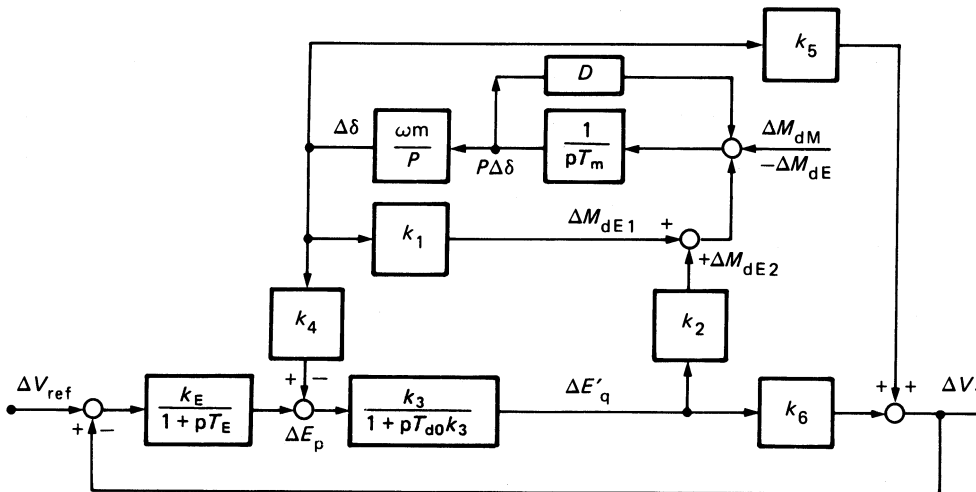

$$k_5 = \frac{\Delta V_t}{\Delta \delta \psi} = \frac{V_d}{V_t} V_0 \cos \delta_0 \frac{x_q}{x_q + x_e} - \frac{V_q}{V_t} V_0 \sin \delta_0 \frac{x'_d}{x'_d + x_e}$$

$$k_6 = \frac{\Delta V_t}{\Delta E'_q} = \frac{V_q}{V_t} \frac{x_e}{x'_d + x_e}$$

The relationship between change in torque and change in rotor angle in a closed voltage-regulator loop is therefore

$$\frac{\Delta M_{dE_2}}{\Delta \delta \psi} = \frac{k_1 k_3 k_5 + k_2 k_4 (1 + p T_E)}{1/k_2 + k_6 k_E + p(T_E/k_2 + T'_{d0}) + p^2 T_E T'_{d0}}$$

The factors,  $k_1, \dots, k_6$  have a considerable influence on the damping of the synchronous machine and its behaviour, as follows.

**Figure 40.23** Block circuit diagram of a synchronous machine connected to a rigid network:  $D$ , damping constant of synchronous machine;  $k, k_E$  proportionality factors;  $M_{dE}$ , electric torque;  $M_{dM}$ , mechanical torque;  $T_{d0}, T_E$ , time-constants;  $T_m$ , moment of inertia;  $\omega_m$ , angular velocity of synchronous machine;  $p$ , operator  $d/dt$ ; other symbols, as for Figure 40.17. For linearisation of transfer functions assuming small changes:

$$k_1 = \frac{\Delta M_{dE1}}{\Delta \delta \psi} \quad E'_q = \text{constant}$$

$$k_2 = \frac{\Delta M_{dE2}}{\Delta E'_q} \quad \delta \psi = \text{constant}$$

$$k_3 = \frac{\Delta E'_q}{\Delta E_p} \quad \delta \psi = \text{constant}$$

$$k_4 = \frac{\Delta E'_q}{\Delta \delta \psi} \quad E'_q = \text{constant}$$

$$k_5 = \frac{\Delta V_t}{\Delta \delta \psi} \quad E'_q = \text{constant}$$

$$k_6 = \frac{\Delta V_t}{\Delta E'_q} \quad \delta \psi = \text{constant}$$

- $k_1$  is generally positive and can assume negative values only at correspondingly large network reactances, but it is then no longer possible to transmit stable power. In the normal range, however, this factor has a stabilising effect, i.e. damping.
- $k_2$  is always positive and has a stabilising effect.
- $k_3$  is independent of the rotor angle and responds only to changes in excitation.
- $k_4$  is negative and reduces damping in the system, an effect that can be markedly reduced by high gain in the voltage regulator. The negative electric torque generated by  $k_4$  is synchronous with the torque achieved with  $k_1$  and is compensated by this.
- $k_5$  comprises two components. With large system reactances  $x_e$ , i.e. where the rotor angle is large anyway, the expression can become negative. A torque that reduces damping is generated and is further enlarged by the gain at the voltage regulators. Active-load hunting commences with large amplitudes and leads to the machine losing synchronism and being shut down. Only with slip-stabilisation equipment can the effects of this component be eliminated and stable power transmission restored.
- $k_6$  is independent of rotor angle and therefore of no significance as far as hunting is concerned.

It can be seen from the block circuit diagram that the damping-reducing influence is introduced through the difference between set-point and actual values at the voltage regulator. Provided that the synchronous machine is not equipped with static excitation, it is recommended to feed the stabilising signal to the mixing point of the control amplifier. Where static excitation equipment is provided, mixing is also possible direct at the entrance of the gate control system of the power stage of the excitation equipment. To damp the rotor oscillations, it is essential that more active power is delivered at the stator terminals when the rotor is accelerated, and less when it is braked.

There are various means of measuring speed and acceleration, and their corresponding effect on the rotor motion. One simple method is to measure the active power. Assuming that the prime-mover power is constant, changes in the active power cause corresponding acceleration or deceleration of the rotor. Measuring the active power fluctuations gives the first derivative of speed. The actual speed can be determined by integration. The accuracy of the method is adequate for this purpose. However, the reaction

to load changes at the drive end is entirely false. Any danger to operation can safely be eliminated by limiting the effect of the stabilising equipment on the voltage control and by introducing an additional signal that is also proportional to frequency.

Thus the use of  $\Delta f$ , i.e. the angular frequency ( $\Delta\omega$ ), instead of integration of  $\Delta P$  represents a considerable advance in this field. The base signal combination ( $\Delta\omega$  plus  $\Delta P$ ) arrangement therefore gives the best arrangement for damping of oscillations (Figure 40.24). Test results have fulfilled all expectations in respect of the stabilising signal. Peaks in the signal, which occur when breaker operations take place in the network, are of such short duration that they have no effect upon the excitation. The load/frequency system combines the advantages of load and frequency measurement without any detrimental side-effects.

#### 40.5.8 Adapted regulator for the excitation of large generators

The excitation of a generator is in principle controlled by automatic voltage regulators, and improvements have been achieved in several respects. The original purpose of the feedback arrangement was *voltage regulation*. This basic requirement is important for maintaining stable synchronous operation of the generators in the power system and for controlling the voltage supplied to customers. Further advantages have been obtained since *static* (power semiconductor) *excitation* systems have been used. Through these fast-acting devices, the regulator may contribute to the *transient stability* after faults (keeping the generator from falling out of step) and to the *damping* of electromechanical rotor oscillations. Furthermore, stabilising signals have been introduced with pre-set amplification gains as a compromise to various operational points. These features are now provided by many commercial regulators. The adapted regulator improves the performance one step further. The main result is the good damping provided for a wide region of operating points, and the smooth voltage regulation.

For better understanding of the benefits of an adaptive control on a network, the one-machine system is presented in Figure 40.25. The generator is connected to the 'infinite bus'  $V_\infty$  over two transmission lines with circuit-breakers.  $V_\infty$  is an ideal three-phase voltage source, and the lines are represented by pure reactances.  $X_e$  denotes the equivalent reactance between the generator and  $V_\infty$ . This configura-

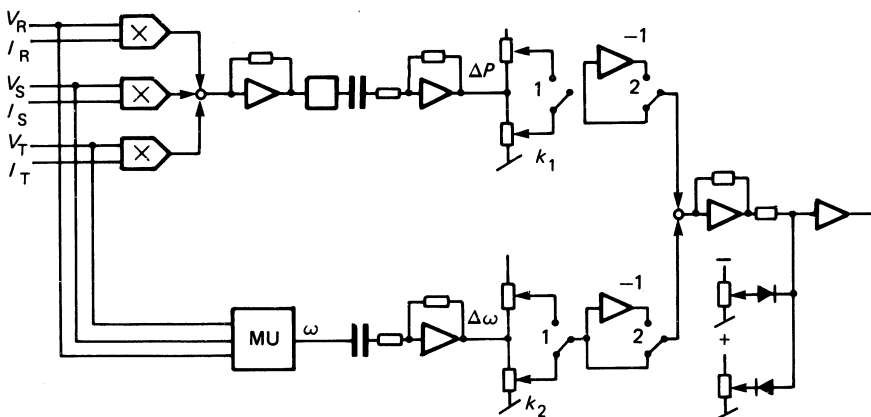

Figure 40.24  $\Delta\omega + \Delta P$  base signal combination arrangement for damping of oscillations, MU

Figure 40.25 Power system model

tion corresponds to the realistic case of a remote power-station supplying a distant load centre.

The control quality of the synchronous machine is assessed in terms of the steady-state behaviour and the dynamic performance in the presence of disturbances. Two kinds of *disturbance* must be considered.

- (1) short circuits in the network, line switchings;
- (2) changes of operating point (power, voltage, network parameters).

Therefore in the design of the voltage regulator the following performance criteria must be considered.

- (1) Regulation of the generator terminal voltage with regard to: (i) smoothness (no ripple during steady-state operation); (ii) speed of response (to avoid overvoltages after load or topology changes); and (iii) accuracy.
- (2) Ability to keep synchronism after a fault. This requirement means simply that the excitation voltage should be at the maximum during faults and during dangerous rotor accelerations. The excitation may return to normal after the first peak of the rotor swing.
- (3) Damping of rotor oscillations.
- (4) Criteria (1)–(3) for a wide region of operating points of the generator (power loading, voltage).

The voltage regulator used here corresponds to the present-day conventional regulator as described earlier. However, the stabilising signals derived from power and frequency measurements are introduced via variable gain factors (Figure 40.26).  $P$  and  $\omega$  feedback are regarded as additional signals, the purpose of which is to produce damping (stabilisation) of rotor oscillations.

The gains for the power and frequency feedback are determined by using the D-decomposition technique.

D decomposition (or domain separation) is a method based on the characteristic equation of the linearised model. It produces curves of constant damping in the plane of the gains  $G_1$  and  $G_2$ , at a certain operating point ( $P = \text{constant}$ ,  $Q = \text{constant}$ ) and constant line impedance  $X_e$ . The method is combined with an optimisation procedure to generate optimal gains (optimal damping of the dominant poles). However, as already stated, the gains that are adequate for the best damping of rotor oscillations depend on the operating point of the generator. Owing to the non-linearities in the system, the operating point itself may vary in time, depending on the loading, voltage and network topology ( $X_e$ ).

Three quantities are sufficient to define the operating point: active power  $P$ , reactive power  $Q$  and the reactance  $X_e$  of the network.  $P$  and  $Q$  are measurable directly, while  $X_e$  can be identified from local measurements by system response. When the three quantities are known, the linearised model of the generator is fully defined (assuming  $V_\infty = 1 \text{ p.u.}$ ) and the adequate gains can be adjusted automatically.

However, two situations must be considered: steady-state operation and transient operation (short circuit, rotor oscillations). In the steady state, the gains  $G_1$  and  $G_2$  should be reduced for better voltage control, but they may be larger during transient operation.

The resulting adaptation scheme is shown in Figure 40.27. The entries of the look-up table are computed off-line.  $G_1$  and  $G_2$  are adjusted whenever major events occur or the parameters have drifted significantly. Updating of the gains is only permitted once every few seconds in order to secure the stability of the adaptation. The identification of  $X_e$  is based on a simple curve-fitting procedure. The adaptation scheme (Figure 40.27) is implemented on a digital

Figure 40.26 The analogue regulator (present-day Brown Boveri Cie (BBC) regulator). - - -, Alternative connection required by some customers

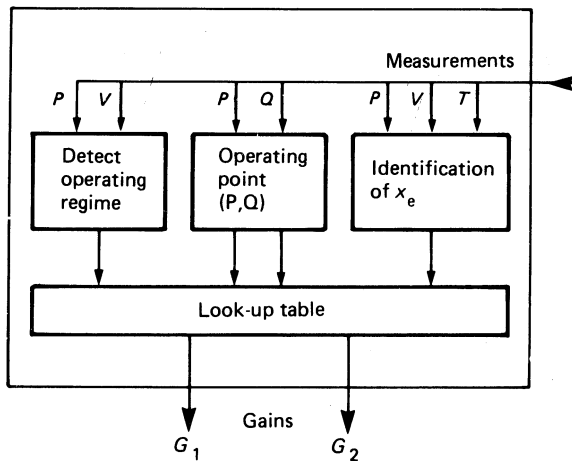

Figure 40.27 The adaptation scheme

Figure 40.28 Steady-state stability limits of the generator: —, Unadapted regulator; —, adapted regulator

microprocessor. The gains  $G_1$  and  $G_2$  are then applied to the analogue regulator of Figure 40.26.

The need for adaptation at critical operating points is demonstrated in Figure 40.28. Two sets of gains are used, each designed for a specific operating point. The graphs show that the gains designed for one case may not be used in the other. When the wrong gains are used, instability occurs after a disturbance or in the form of self-induced oscillations. Figure 40.28 shows the region of stable operating points for two typical values of  $X_e$ . The stability boundary is evaluated using the linearised model.

#### 40.5.9 Static excitation systems for positive and negative excitation current

Hydroelectric power-plants are usually remote from the load centre, and the power produced is transmitted over

long three-phase transmission lines to the consumer. Depending upon the active power to be transmitted (light- or heavy-load operation), the transmission line will supply or consume reactive power, which must be absorbed or supplied by generators at two ends of the line or by reactive current compensators (var sources). Owing to the great distance of transmission along the line, the excitation equipment of such synchronous machines must be designed for high ceiling voltages and negative excitation currents in conjunction with stability of operation. Static excitation equipments with controlled static converters connected in antiparallel and subject to circulating current are capable of satisfying these requirements for hydroelectric generators and synchronous compensators; they improve the capacity of these machines for absorbing reactive load, while retaining optimum control and operating characteristics not merely for steady-state operation but also for dynamic and transient conditions in the network. The circuit diagram for an excitation device is shown in Figure 40.29.

The maximum continuously permissible positive excitation current is defined by the maximum continuous load of the synchronous machine for a given power factor. The short-term loadings due to ceiling current and load-independent short-circuit current at the rotor in the event of a fault must also be superimposed upon this value. The maximum continuous current of an excitation device for hydroelectric generators is therefore about 1.5 times the rated excitation current, if redundancy design is ignored. On the other hand, the maximum negative excitation current that must be applied to maintain the voltage of the synchronous machine under extreme capacitive load is determined solely by the design, and therefore by the machine parameters, of the synchronous machine.

A salient-pole generator of terminal voltage  $V$  operating at a load angle  $\delta$  with an internal field electromagnetic force (e.m.f.)  $E_p$  supplies a reactive power  $Q$  given by

$$Q = \frac{E_p V}{X_d} \cos \delta \psi - \frac{V^2}{X_d} \left( 1 + \frac{X_d + X_q}{X_q} \sin \delta \psi \right)$$

where  $X_d$  and  $X_q$  are the direct- and quadrature-axis reactances, respectively. If the load angle  $\delta$  and the excitation  $E_p$  are zero, the synchronous machine takes continuously from the network a reactive power, the value of which is determined by the direct-axis reactance  $X_d$ : i.e.  $Q = -V^2/X_d$ . The supply of reactive power by the network is then just equal to the absorption capability of the synchronous machine. If no negative excitation current can be supplied and the capacitive network load increases further, self-excitation will occur, and the machine must be disconnected. Since, however, the synchronising torque  $M_e = dP/d\delta$  begins to decrease only with negative excitation beyond the value corresponding to  $E = -V[(X_d - X_q)/X_q]$ , negative excitation up to this value can be introduced with quick-acting, regulators, the reactive power absorption rising to  $Q = -V^2/X_q$ .

The ratio  $X_d/X_q$  for salient-pole hydrogenerators lies in the range 1.3–1.4, and the no-load excitation current  $I_{f0}$  corresponds to the generator terminal voltage. The maximum negative exciting current is therefore  $I_{f0}(X_d/X_q - 1)$ , which approximates to  $0.4I_{f0}$ . Thus the equipment for imposing negative excitation needs to be designed for only about 40% of the excitation on no-load; it does, however, ensure an increase of about 40% in the reactive power absorption at rated load and frequency. If the reactive load supplied by the connected network rises above  $Q_c = E^2/X_q$ , the synchronous machine will no longer be capable of holding the voltage, and the definitive self-excitation condition, which cannot

**Figure 40.29** Circuit diagram for excitation device: CT, current transformers; G, synchronous generator;  $I_t$ , field current of synchronous generator; PT, voltage transformer;  $T_1$ ,  $T_2$ , transformers; a, field suppression switch; b, control electronics;  $C_1$ ,  $C_2$ , firing-angle devices; d, crowbar; k, reactor;  $n_1$ , static converter for positive excitation current;  $n_2$ , static converter for negative excitation current; r, non-linear de-energising resistor

be controlled by any excitation current or regulator, will be initiated.

If the operating conditions now change specifically with regard to the frequency, the limitations on the use of negative excitation currents must be carefully investigated, since the design of the means for compensating the transmission system will be affected. For instance, with a synchronous machine operating on a long line, if a sudden drop occurs in the active load at the consumer end of the line then, in addition to the charging power for the network, a frequency rise also occurs. This leads both to a rise in the quadrature-axis reactance of the machine and to a fall in the capacitive network impedance. This implies, however, that maintaining the voltage is rendered more difficult by the square of the frequency change. The maximum negative excitation that can be used must in this case be reduced in inverse proportion to the frequency.

In order to decouple the two d.c. circuits (to absorb the different voltage-time areas) and to avoid short-circuit balancing currents, a reactor is incorporated in the d.c. intermediate circuit. The balancing current between the two bridges is regulated to a minimum, but it does provide a guarantee that the two converter sets always carry current; therefore changeover from negative to positive excitation current can be effected virtually without loss of time.

#### 40.5.10 Machine models for investigating stability

Generally, when investigating stability, one examines the consequences of the following disturbances.

- (1) Short circuit (one- to three-phase) in the network with subsequent complete (three-phase) or partial interruption of the load flow between generator and network (rapid reclosure).

- (2) Partial or complete interruption of load flow between generator and network (load rejection).
- (3) Small fluctuations in the load flow (static stability).

It is always assumed that the generators are connected to an infinite power system via a transformer and a network reactance  $X_n$  (single-machine problem).

The major parameters for studying stability are:

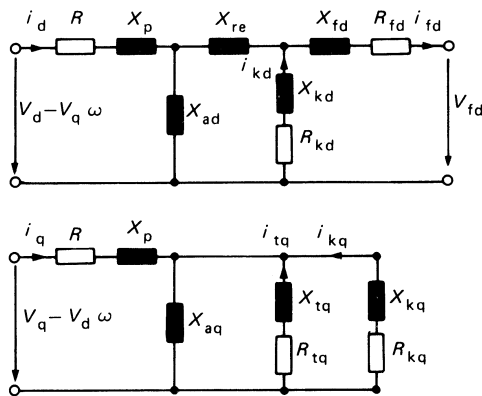

- (1) the generator parameters  $H$ ,  $X_d$ ,  $X'_d$ ,  $X''_d$ ,  $X'_q$ ,  $X''_q$ ,  $T'_d$ ,  $T''_d$ ,  $T'_q$ ,  $T''_q$ ,  $X_p$ ,  $X_{re}$ ,  $E = \mathcal{H}(J_F)$ ;
- (2) the transfer functions of the voltage regulator and turbine controller;
- (3) the unit-transformer reactance  $X_{tr}$  and the network;
- (4) the nature of the fault (one-phase, three-phase, short circuit, etc.), the fault location and fault time  $t_F$ .

The generator parameters are determined by the construction of the machine. Evaluation of the data for a variety of machines reveals the following trend: for a given frequency  $f$ , the inertia constant  $H$  diminishes with increase in rating  $S$  and a decreasing number  $p$  of pole pairs:

$$H = \frac{GD^2 \omega_s^2}{4 \cdot 2S}$$

where  $GD^2/4$  is the moment of inertia referred to diameter, and  $\omega_s = 2\pi f/p = 2\pi n_s$  is the synchronous angular velocity. Only a lower limit of  $H$  can be specified, because its magnitude depends considerably on the turbine inertia.

The reactances  $X_d$  and  $X'_d$ , the stator resistance  $R$  and the short-circuit time-constant  $T'_d$  show a tendency to become larger with increasing power rating. However, these relationships can be very strongly influenced by structural features and design layout.

**Figure 40.30** Equivalent circuit for model 1 of a synchronous machine (for symbols, see text)

Experience shows that the method of calculation and the machine model influence the results more strongly with high-speed transients than with slow ones.

#### 40.5.10.1 Synchronous machine models

Six different models of synchronous machine are generally used. Saturation is disregarded and the same equations of motion are used for all models.

**Model 1** This model has six windings (three damper windings). Its equivalent circuit diagram is shown in *Figure 40.30*. The corresponding equations are as follows.

The network equations are

$$\begin{aligned} V_d^G &= \cancel{4}d^N + \cancel{R_e}i_d + \cancel{L_e}(di_d/dt) - \cancel{L_e}i_q \\ V_q^G &= \cancel{4}q^N + \cancel{R_e}i_q + \cancel{L_e}(di_d/dt) + \cancel{L_e}i_d \end{aligned} \quad (40.1)$$

in which  $\omega L_e = X_{tr} + X_N$ .

The following equations are used for the synchronous machine:

### Flux–current relationships

$$\begin{aligned}
d &= (X_p + \mathcal{K}_{ad})i_d + \mathcal{K}_{ad}i_{kd} - \mathcal{K}_{ad}i_{ld} \\
kd &= \mathcal{K}_{ad}i_d + (X_{ad} + \mathcal{K}_{re} + \mathcal{K}_{kd})i_{kd} - (X_{ad} + \mathcal{K}_{re})i_{ld} \\
q &= (X_p + \mathcal{K}_{aq})i_q + \mathcal{K}_{aq}i_{tq} + \mathcal{K}_{aq}i_{kq} \\
q &= (X_p + \mathcal{K}_{aq})i_q + \mathcal{K}_{aq}i_{tq} + \mathcal{K}_{aq}i_{kq} \\
tq &= \mathcal{K}_{aq}i_q + (X_{aq} + \mathcal{K}_{tq})i_{tq} + \mathcal{K}_{aq}i_{kq} \\
kq &= \mathcal{K}_{aq}i_q + \mathcal{K}_{aq}i_{tq} + (X_{aq} + \mathcal{K}_{kq})i_{kq}
\end{aligned} \tag{40.2}$$

### Voltage equations

$$\begin{aligned}
d_d/dt &= -\cancel{K_d^G} + \cancel{\epsilon_q} \omega \cancel{\psi} - \cancel{R} i_d \\
d_q/dt &= -\cancel{K_q^G} - \cancel{\epsilon_d} \omega \cancel{\psi} - \cancel{R} i_q \\
d_{fd}/dt &= \cancel{A}_{fd} - \cancel{R}_{fd} i_{fd} \\
d_{iq}/dt &= -\cancel{R}_{iq} i_{iq} \\
d_{kd}/dt &= -\cancel{R}_{kd} i_{kd} \\
d_{kq}/dt &= -\cancel{R}_{kq} i_{kq}
\end{aligned} \tag{40.3}$$

### Mechanical equations

Torque:

$$M_B = \leftarrow_q i_d - \leftarrow_d i_q \quad (40.4)$$

Power:

$$P = \mathbb{K}_d^G i_d + \mathbb{K}_q^G i_q \quad (40.5)$$

$$Q = \mathbb{A}_q^G i_d - \mathbb{A}_d^G i_q \quad (40.6)$$

Equation of motion:

$$2H(ds/dt) = \cancel{M} - \cancel{M}_B \quad (40.7) \Leftarrow$$

$$d\theta/dt = \frac{1}{2} \frac{d\theta}{d\ln t} \quad (40.8)$$

$$\omega = 1 + \delta \quad (40.9) \Leftarrow$$

The quantities  $L$ ,  $X$ ,  $R$ ,  $i$ ,  $V$ ,  $M$  and  $\omega\phi$  are per-unit quantities.

From the input data

$$R, \psi X_p, \psi X_c, \psi X_d, \psi X_q, \psi X_d', \psi X_d'', \psi X_q', \psi T_d', \psi T_q', \psi T_d'', \psi T_q'', \psi S_N, V_N, \psi$$

$$f, I_{fd0}, \psi V_{fd0}, \psi p, H$$

of which  $T$ ,  $S_N$ ,  $V_N$ ,  $f$ ,  $I_{fd0}$ ,  $V_{fd0}$  and  $H$  are not per-unit, the constants  $X_{ad}$  and  $X_{aq}$  of the synchronous machine can be calculated in the following manner:

$$X_{\text{ad}} = X_{\text{d}} - X_{\text{p}} \quad (40.10) \Leftarrow$$

$$X_{\text{aq}} = \mathbb{A}_{\text{q}} - \mathbb{A}_{\text{p}} \quad (40.11) \Leftarrow$$

$$X_{re} = \frac{X_{ad}(X_{re} - \mathbb{A}_p)}{X_d - \mathbb{A}_{re}} \quad (40.12)$$

$$X_{td} = \left( \frac{X_d - X_p}{X_d - X_{re}} \right)^2 \frac{(X_d - X_e)(X'_d - X'_e)}{X_d - X'_d} \quad (40.13)$$

$$X_{kd} = \left( \frac{X_d - \mathcal{E}_p}{X_d - \mathcal{E}_{re}} \right)^2 \frac{(X'_d - \mathcal{E}_e)(X''_d - \mathcal{E}_e)}{X'_d - \mathcal{E}'_d} \Leftarrow \quad (40.14)$$

$$X_{tq} = \frac{(X_q - \mathbb{A}_p)(X'_q - \mathbb{A}_p)}{X_q - \mathbb{A}'_q} \Leftarrow \quad (40.15) \Leftarrow$$

$$X_{kq} = \frac{(X'_q - \mathbb{A}_p)(X''_q - \mathbb{A}_p)}{X'_q - \mathbb{A}_q} \quad (40.16)$$

$$R_{\text{fd}} = \left( \frac{X_{\text{d}} - X_{\text{p}}}{X_{\text{d}} - X_{\text{re}}} \right)^2 \frac{(X_{\text{d}} - X_{\text{e}})^2}{X_{\text{d}} - X_{\text{d}}'} \frac{1}{T_{\text{fd}} \omega_{\text{B}}} \quad (40.17) \Leftarrow$$

$$R_{\text{kd}} = \left( \frac{X_{\text{d}} - X_{\text{p}}}{X_{\text{d}} - X_{\text{re}}} \right)^2 \frac{(X'_{\text{d}} - X'_{\text{e}})^2}{X'_{\text{d}} - X''_{\text{d}}} \frac{X''_{\text{d}}}{T''_{\text{d}} X'_{\text{q}} \omega_{\text{B}}} \quad (40.18)$$

$$R_{kq} = \frac{(X'_q - X_p)^2}{X'_q - X_q} \frac{X''_q}{T''_q X_q \bar{\omega}_B} \quad (40.19)$$

$$R_{\text{tq}} = \frac{(X_{\text{q}} - X_{\text{p}})^2}{X_{\text{q}} - X_{\text{q}}'} \frac{1}{T_{\text{tq}} \omega_{\text{B}}} \quad (40.20) \Leftarrow$$

$$T_{\text{td}} = \mathbb{E}_d^{f \leftarrow X_d} \left( T_{\text{kd}} - \mathbb{E}_d^{f' \leftarrow \frac{X_d'}{X_d}} \right) \left( \quad \quad \quad \right) \quad (40.21)$$

where

$$T_{kd} = \frac{X'_d - X''_d}{X'_d - X''_d} \times \frac{(X_d - X_{re})(X'_d - X''_d) + (X'_d - X_{re})(X''_d - X_{re})}{(X'_d - X_{re})^2} \quad (40.22)$$

$$T_{kq} = \frac{X'_q - X''_q}{X'_q - X''_q} \left( T_{kq} - T'_q \frac{X'_q - X''_q}{X'_q - X''_q} \right) \quad (40.23)$$

$$T_{kq} = \frac{X'_q - X''_q}{X'_q - X''_q} \times \frac{(X_q - X_p)(X'_q - X''_q) + (X'_q - X_p)(X''_q - X_p)}{(X'_q - X_p)^2} \quad (40.24)$$

$$\omega_B = 2\pi f \quad (40.25)$$

The reference values are:

$V_N$  for voltages  $V_d^G$  and  $V_q^G$

$S_N$  for powers  $P$  and  $Q$

$$I_N = S_N / \sqrt{3} V_N \text{ for current } i_d \text{ and } i_q \quad (40.26)$$

$$M_N = S_N / \omega_B \text{ for torque } M \quad (40.27)$$

$I_{fd0}$  for excitation current  $i_{fd}$

$V_{fd0}$  for the excitation voltage

In Equations (40.1),  $R_e$  and  $L_e$  are respectively the resistance or the inductance of the positive-sequence system between generator and infinite network, i.e.  $\omega L_e = X_{tr} + X_N$ .

If the site of the short circuit is between the generator and the infinite network, there are ten first-order differential equations to integrate.

**Model 2** This model has only one damper winding in the quadrature axis, i.e.  $i_{kq} = 0$ . The relationships  $i_{kq} = \frac{X'_q - X''_q}{X'_q - X''_q} i_q$ ,  $i_{kq}$  in Equations (40.2) and  $d i_{kq}/dt = \frac{X'_q - X''_q}{X'_q - X''_q} di_q/dt$  in Equations (40.3) do not apply. Instead of Equations (40.16) and (40.19) we have

$$X_{kq} = \frac{(X_q - X_p)(X''_q - X'_q)}{X_q - X'_q} \quad (40.16a)$$

$$R_{kq} = \frac{(X_q - X_p)^2 X''_q}{(X_q - X'_q) T'_q X_q \omega_B} \quad (40.19a)$$

Equations (40.20), (40.23) and (40.24) do not apply.

Model 2 also takes account of the transformation terms, but has only two damper windings. In this case only nine differential equations have to be integrated.

**Model 3** This, like model 2, has one damper winding in each of the direct and quadrature axes. The transformation terms in the stator equations do not apply, i.e. Equations (40.3) become

$$V_d^G = \omega \psi_d - R i_d$$

$$V_q^G = -\omega \psi_q - R i_q$$

$$d i_{fd}/dt = \frac{V_{fd} - E_{fd}}{T'_{fd}} \quad (40.3a)$$

$$d i_{kd}/dt = -R_{kd} i_{kd}$$

$$d i_{kq}/dt = -R_{kq} i_{kq}$$

Model 3 also has two damper windings. The transformation terms are disregarded. There are only five differential equations to integrate. It is found from experience that with this configuration the time step can be much larger than with models 1 and 2.

The equations of motion (40.7)–(40.9) remain unchanged. In addition to  $M_B$  in Equation (40.4), however, the braking torque  $M_{Bs}$ , caused by the transformation terms when switching operations occur, must be introduced into Equation (40.7):

$$2H(ds/dt) = M - M_B - M_{Bs}$$

if the movement process is to be represented correctly.

**Model 4** This model has no damper windings. The basic equations therefore become

$$\begin{aligned} d &= (X_p + X_{ad}) i_d - X_{ad} i_{fd} \\ i_{fd} &= -X_{ad} i_d + (X_{ad} + X_{fd}) i_{fd} \\ q &= (X_p + X_{aq}) i_q \end{aligned} \quad (40.2b)$$

$$\begin{aligned} V_d^G &= \omega \psi_d - R i_d \\ V_q^G &= -\omega \psi_q - R i_q \\ d i_{fd}/dt &= \frac{V_{fd} - E_{fd}}{T'_{fd}} \end{aligned} \quad (40.3b)$$

In the absence of damper windings, the asynchronous damping torque ( $M_{B2}$ ) also must be included in the Equation of motion (40.7):

$$2H(ds/dt) = M - M_B - M_{Bs} - M_{B2}$$

Instead of Equations (40.10)–(40.24) we have the expressions

$$X_{ad} = X_d - X_p \quad (40.10^*)$$

$$X_{aq} = X_q - X_p \quad (40.11^*)$$

$$X_{fd} = \frac{(X_d - X_p)(X'_d - X''_d)}{X_d - X'_d} \quad (40.13a)$$

$$R_{fd} = \frac{X_d - X_p}{X_d - X'_d} \frac{X''_d}{T'_d X_d \omega_B} \quad (40.17a)$$

The transformation terms are disregarded. Thus only three differential equations need to be integrated.

**Model 5** This model has no field winding and no damper winding. The base equations for this model are:

$$d = X'_d i_d - E_f \quad (40.2b)$$

$$q = X'_q i_q$$

$$\begin{aligned} V_d^G &= \omega \psi_d - R i_d \\ V_q^G &= -\omega \psi_q - R i_q \end{aligned} \quad (40.3c)$$

The mechanical behaviour is described by Equations (40.4) and (40.7)–(40.9).  $E_f$  is calculated in terms of the initial values of  $i_d$ ,  $i_q$  and  $V_q^G$ :

$$E_f = X_q^G + R i_q + X'_d i_d$$

On the stator, conditions are represented by one winding each in the direct and quadrature axes, their reactances

being different. The effect of excitation appears as a current source in the equivalent circuit of the direct-axis winding. Only the two differential equations for the mechanical system have to be integrated.

**Model 6** This model, like model 5, has neither field winding nor damper windings. Equations (40.2b) contain  $X'_d$  instead of  $X_q$ . Thus Equation (40.4) becomes

$$M_B = \mathcal{E}_i i_q$$

Model 6 resembles model 5 except that it has identical reactance in the direct and quadrature axes.

#### 40.5.10.2 Comparison of the models

The essential difference between models 1 and 2 on the one hand, and models 3–6 on the other, is the allowance made for the transformation effect. Models 1–3 have damper windings, while models 4–6 do not. The stability of a synchronous machine after disconnection of the short circuit is determined chiefly by the accelerating torque  $M_A$ , or braking torque  $M_B$ , that was acting on the rotor during the short circuit. Accelerating torque  $M_A$  is composed of driving torque  $M$  and braking torque  $M_B$ : i.e.  $M_A = M - M_B$ . The braking torque  $M_B$  arising during the short circuit and oscillations must therefore be correctly represented in each model.

The braking torque  $M_B$  acting after the fault has occurred consists of the following component parts:

- (1) a braking torque  $M_{B1}$  corresponding to losses in the stator and network resistance  $R$ ;
- (2) an asynchronous braking torque  $M_{B2}$  corresponding to losses in the rotor field and damper windings; and
- (3) a decaying braking torque  $M_{B3}$  introduced by the transformation terms in the machine and network equations—this torque becomes effective at every change of state.

$M_{B3}$  is mainly responsible for the well-known ‘backswing’ effect. The synchronous machine is then braked initially in the first 20 ms after the short circuit. However, the extent of the backswing depends on the site of the short circuit, because torque  $M_{B2}$  incorporates the network reactances between the machine and short-circuit location. In some instances, therefore, a short circuit across the terminals may be less of a stability problem than a distant short circuit.

Direct account is taken of all the braking torques  $M_{B1}$  to  $M_{B3}$  only in the case of models 1 and 2.  $M_{B1}$  is present with all the models. With model 3 there is also torque  $M_{B2}$ .

The following conclusions can be drawn.

- (1) The transformation terms in the Park equations (models 1 and 2) and in the network equations must be taken into account (i) when power is low, (ii) when the short circuit is in the vicinity of the generator, and (iii) if the braking torque  $M_{B3}$  brought about by the transformation terms cannot be introduced into the mechanical equations.
- (2) The backswing effect occurs only when the site of the short circuit is close to the generator. From this it follows that under certain circumstances a short circuit remote from the generator can be more dangerous, as regards stability, than a short circuit nearby.
- (3) It is known that the individual synchronous machine models behave very differently.

In many instances, especially in the case of transient stability problems, the simpler models (4 and 5) exhibit the same behaviour as model 2 or 1 with transformation effect. Nevertheless, with the simple models it is particularly important to represent damping correctly. Models 4 and 5 are therefore particularly suitable for simulating synchronous machines with constant excitation voltage that are located far away from the short circuit. Investigation shows also that the widely recommended model 6 (constant voltage beyond transient reactance) yields results that are pessimistic.

If it is assumed that the constant  $H$  decreases, and reactances  $X_d$ ,  $X'_d$  and  $X_t$  increase, with rising generator capacity, then the critical short-circuit duration will be smaller as generator capacity rises. Studies show, however, that the behaviour of even large synchronous machines can be described with the known models of synchronous machines, and that there is usually no need to make allowance for the transformation terms.

## 40.6 Decentralised control: electronic turbine controllers

### 40.6.1 Introduction

The turbine equipped with a controller represents an important item of decentralised control as its controller governs the active power input to the power system. For many reasons, both historical and technical, this controller is kept separate from excitation control, although a computer would be able to fulfil the combined function.

Modern turbine controllers are electronic and have to meet a series of functions and requirements. Frequency control is just one of these; safety functions, monitoring, limit checking, etc., are equally important. The most important requirements are the following:

- (1) automatic start-up and shut-down of the turbine;
- (2) application of a load–frequency control system;
- (3) application of an external reference input;
- (4) adjustable droop of the speed controller;
- (5) good adaptability to the given operating condition;
- (6) high-response sensitivity;
- (7) Co-ordinated operation of the turbine–generator set and all other systems in the power-plant;
- (8) short reaction time between controller and control valves; and
- (9) short closing time of the control valves.

Nowadays turbine controllers are composed of electronic modules or functional groups. Most of these can be used in the control system of steam, gas or water turbines. However, the control schemes of such turbines vary widely. We therefore describe both a modern steam-turbine control system and a system for a Francis water turbine. First, however, we explain in simple terms the basic functions of frequency and load control. We derive the elementary block diagram of a frequency controller, explain set-point control, and set out the basic concept of droop. Our treatment concludes with a consideration of frequency control in a multi-machine system.

### 40.6.2 The environment

The turbine driven by water or steam is connected to a synchronous generator. The synchronous generator has the important property of being able to align itself with other

generators when the armatures are interconnected and the rotors are excited. When this alignment is achieved, i.e. when peaks and zero crossings of the induced voltages occur at the same instant, 'synchronous' operation is realised. In greater detail, there are small differences between the mechanical positions of the rotors due to the individual loadings, which may reach  $45^\circ$ . We do not consider different numbers of poles, but assume that all generators have the same number of poles.

In synchronous operation all generators have the same frequency or speed. When the frequency changes, all generators change their speed. Hence, frequency or speed control in synchronous or interconnected operation means control of one common frequency. Small deviations and transients with respect to this frequency are corrected by the inherent ability of the synchronous machines to maintain alignment.

A single generator can also be operated in a system. However, in this case there is no other generator to which it can be aligned. The operation is similar to that of a d.c. generator. Speed control and angular position are purely a matter of the balance between prime-mover torque and load torque acting on the inertia of the shaft. Following a load change, there will be a change in frequency. The speed governor, which is the frequency controller, has an important bearing on the frequency behaviour.

In contrast, a change in loading of a single generator in interconnected operation does not necessarily affect the frequency because it is maintained by the other generators. Hence it is important to know the environment in which a speed governor has to function. Modern governing systems are being designed to cope with a wide range of system conditions.

### 40.6.3 Role of the speed governor

The speed governor can best be understood by considering a steam engine with a generator serving a local load in isolation, the turbine being controlled by a fly-ball governor. The basic function is realised by a proportional control, whereby the valve position is the actuating signal. Speed or frequency is the input from the system, i.e. the controlled quantity which is compared with a reference signal (also called the 'set-point'). The difference between the measured signal and the set-point is converted to the valve position, which involves a gain. This gain has a two-fold meaning. First, it is a pure signal gain relating a deviation, based on nominal quantities, and a deviation of the valve position

which is also referred to as a nominal position. Second, the gain means also a power amplification, i.e. the conversion of a weak electrical signal to a strong mechanical torque. A schematic diagram of the basic arrangement is given in *Figure 40.31*, where the functional relations are shown.

Assuming that the stability of such a system is guaranteed, transient and steady-state conditions can easily be calculated. The basic functions can best be understood by considering steady-state or quasi-steady-state operating points. If the need arises to deliver more power to the generator, the valve of the turbine has to be opened. This is realised by forming a difference between the set-point and the measured speed signal either by raising the set-point or by a drop in frequency. Changes in the governing system will take place until a balance is reached. Steady-state conditions are found from the relations

$$\Delta f/K = M_e; \quad \Delta f = f_s - f$$

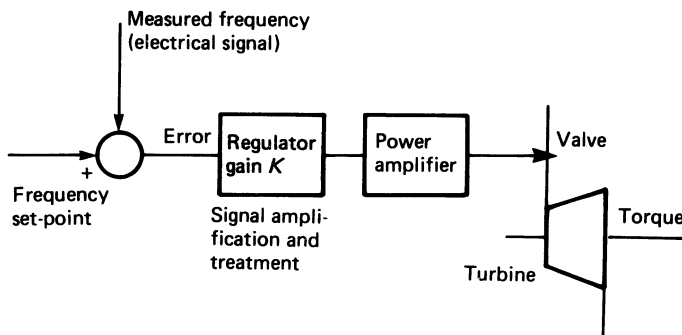

where  $f$  is the frequency,  $\Delta f$  is the frequency deviation,  $f_s$  is the set-point,  $M_e$  is the electrical or load torque, and  $K$  is the gain of the speed governor in units of torque per unit of frequency.

The gain determines the amount of frequency deviation. The higher  $K$  is, the smaller  $\Delta f$  will be. However, the gain cannot be chosen to be arbitrarily high. There are problems of stability and certain restrictions due to the allocation of changes of power. The relation  $\Delta f/K = M_e$  also shows that the speed governor has a double function. It carries out both load control, i.e. the matching of prime-mover torque to the load torque, and frequency control. The relation between these two functions is given by the gain  $K$ . Its dimensions in practice are megawatts per hertz; i.e. instead of torque, it is the power which is measured at the output.

Hence, in isolated operation, frequency changes follow a load change so long as the set-point is fixed. A change in set-point will cause a rise in frequency when the load remains constant.

In interconnected operation, the frequency remains practically unchanged. Therefore, a change in loading cannot be affected by the power system. The output of the generator changes without any variation of the frequency, only when the set-point is changed. In this case the speed governor is a pure load controller.

In practice the speed governor is always ready to take on either function. It is the boundary conditions that determine its momentary role, i.e. the governor controls the output power when the frequency is imposed and it controls the

**Figure 40.31** Basic arrangement of a speed governor (frequency controller: the basic functions of error detection, signal amplification and power amplification are shown)

frequency when the load is imposed. In a more complex situation, when load and frequency are dependent, the governor varies its output until an equilibrium is reached.

#### 40.6.4 Static characteristic

Modern speed governors have amplifiers that include an integrating property. This choice is made for both reasons of principle and technical reasons, the main one of which is the control of servomotors by valves or signal converters. The proportional behaviour is still maintained by adding the output power as a measured quantity. Such a governor acting on a turbine-generator is commonly represented by a block diagram as shown in Figure 40.32.

In this schematic, two signals measured at the output are compared with set-points, i.e. frequency and power. All deviations are combined in one summing junction, the frequency deviation being weighted by  $K$ . The summing junction produces an error which drives the regulator as an integrator. The regulator, which is at the same time a power amplifier, drives the valve.

The steady-state behaviour of the system is described by a characteristic graph with a few parameters. The starting point is the zero value of the error  $e$  when the system (Figure 40.32) has reached a stationary operating point. Then

$$e = P_s - P + K(f_s - f) = 0 \Leftrightarrow$$

where  $P$  is the measured power output and  $P_s$  is the power set-point; the other parameters have already been defined.  $P$  and  $f$  are variables, represented by the axes in Figure 40.33. The frequency  $f$  can be expressed by  $f = f_s + (P_s - P)/K$ , a linear relationship between  $f$  and  $P$ . The slope is

$$df/dP = -1/K = -D$$

where  $D$  is the *droop* of the system (in hertz per megawatt). Together with the intersection ( $f_s + P_s/K$ ), it determines the position of the straight-line characteristic of the speed-governing system. Discussion of the role of the parameters gives an insight into the operation of the system.

##### 40.6.4.1 No-load operation and $f_s$

On no load the output is zero and the speed is given by the intersection of the straight line with the ordinate. Thus  $f_s$  is used to set the no-load speed.  $P_s$  is set to zero.

**Figure 40.32** Schematic diagram of a power-frequency controlled generator: G, generator; T, turbine; R, regulator (integrating);  $P$ , measured power;  $P_s$ , set-point power;  $f$ , measured frequency;  $f_s$ , frequency set-point;  $K$ , gain

**Figure 40.33** Static characteristic: the operating point is confined to the sloping straight line

##### 40.6.4.2 Synchronous operation and $P_s$

When the no-load frequency has reached the system frequency and the synchronising conditions are met, the generator is first connected to the power system, then loaded by raising  $P_s$  to the desired value. The characteristic is thereby raised in parallel. The frequency remains unchanged. Should the generator breaker be opened inadvertently, the frequency will assume the value given by the intersection of the straight line with the ordinate. This involves a rise in frequency that is governed by  $K$ .

Consider a generator which has the following settings and parameters:

$$f_s = 50 \text{ Hz}; P_s = 200 \text{ MW}; K = 80 \text{ MW/Hz}$$

The generator is operating at  $f = 50 \text{ Hz}$ ,  $P = 200 \text{ MW}$ . After disconnection of the generator, the no-load frequency will become  $f = 52.5 \text{ Hz}$ . The droop is  $D = 1/K = 0.0125 \text{ Hz/MW}$ . It can, however, also be expressed as a percentage:

$$D = 100(\Delta f/f_0)(P_0/P) \Leftrightarrow$$

where  $f_0$  and  $P_0$  are nominal values. In this example, the droop is 5%. Thus the droop is a determining factor for the no-load frequency after load shedding.

##### 40.6.4.3 Isolated operation

Although the set-point  $f_s$  is maintained at 50 Hz, the frequency  $f$  will deviate from  $f_s$  because of load changes. The intersection of the characteristic with the load characteristic (e.g. vertical line) fixes the frequency.

Consider the situation given by Figure 40.34 (not drawn to scale). The set-points are  $f_s = 50 \text{ Hz}$ ,  $P_s = 160 \text{ MW}$  and  $K = 100 \text{ MW/Hz}$ . The load is 180 MW. Hence  $f = 49.75 \text{ Hz}$ . In order to adjust the frequency to its nominal value,  $P_s$  has to be raised by 20 MW. Load shedding would result in a frequency rise according to  $f_s + DP_s$ .

Frequency control in isolated operation means either letting the operating point vary along the characteristic or readjusting the set-point whenever a frequency deviation arises.

#### 40.6.5 Parallel operation of generators

Consider a two-machine system to serve a common variable load. Each set has a speed governor. The system schematic is given in Figure 40.35; it is assumed that the generators supply 200 MW shared in the ratio 80/120. The frequency is at the nominal value of 50 Hz.

**Figure 40.34** Isolated operation of one generator: load increase by 20 MW, and readjustment of characteristic in order to raise frequency to 50 Hz

**Figure 40.35** Two-machine system:  $G_1$ ,  $G_2$ , generators operating at the same frequency serving  $P$ .  $P_1 = 80$  MW,  $P_2 = 120$  MW

How will an increase of load by 40 MW be shared? The problem is readily solved by calculation or graph. The required data for the two generators,  $G_1$  and  $G_2$  are:

$$G_1 : f_{s1} = 50.0 \text{ Hz}; P_1 = 80 \text{ MW}; P_{s1} = 80 \text{ MW};$$

$$K_1 = 46 \text{ MW/Hz}$$

$$G_2 : f_{s2} = 50.0 \text{ Hz}; P_2 = 120 \text{ MW}; P_{s2} = 120 \text{ MW};$$

$$K_2 = 32 \text{ MW/Hz}$$

The new frequency  $f$  and the power increments  $\Delta P_1$  and  $\Delta P_2$  are to be determined, with  $\Delta P_1 + \Delta P_2 = 40$  MW. Then

$$P_{s1} - P_1 - \Delta P_1 + K_1(f_{s1} - f) = 0$$

$$P_{s2} - P_2 - \Delta P_2 + K_2(f_{s2} - f) = 0$$

But  $f_{s1} = f_{s2} = f_s$ , and  $f$  is the common frequency; hence these equations in combination give

$$(P_{s1} + P_{s2}) - (P_1 + P_2) - (\Delta P_1 + \Delta P_2) - (K_1 + K_2)(f_s - f) = 0$$

a resultant characteristic with a set-point of  $P_{s1} + P_{s2}$  and a gain  $K_1 + K_2$ , or a droop  $1/(K_1 + K_2)$  (Figure 40.36). The solution is  $\Delta P_1 = 13.3$  MW,  $\Delta P_2 = 26.7$  MW.

This principle of combining generators with equivalent generators, with a composite droop, is quite general and can be extended to multi-machine systems. Any generator can be taken as generator  $G_1$  and the rest as generator  $G_2$ . The combined system has a composite characteristic called a power-frequency characteristic. Thus in an interconnected system, control of power and frequency is realised by adjusting the set-points of the various generators either manually or by automatic means.

**Figure 40.36** Two-machine system, combined characteristic

The logical extension of frequency control at this level (primary control) to a regional level is load-frequency control or automatic generation control.

#### 40.6.6 Steam-turbine control system (Turbotrol)

The Turbotrol electrohydraulic control system has to fulfil the following objectives:

- (1) Automatic variation of the speed set-value for speed-controlled run-up of a turbo-set with respect to critical speed and temperature conditions.
- (2) Speed control during no-load operation.
- (3) Frequency control when feeding house load.
- (4) Accurate rapid load control in accordance with an adjustable linear frequency-load characteristic.
- (5) Automatic load set-value variation for loading or load shedding, taking into consideration all measures necessary to prevent the turbo-set from being overstressed.
- (6) Maintenance of the speed within admissible limits on load shedding.
- (7) Co-ordinated action of the steam generator controller and turbine controller during load operation.
- (8) Processing of the signals of an overriding control system, e.g. from the load dispatching system controller.

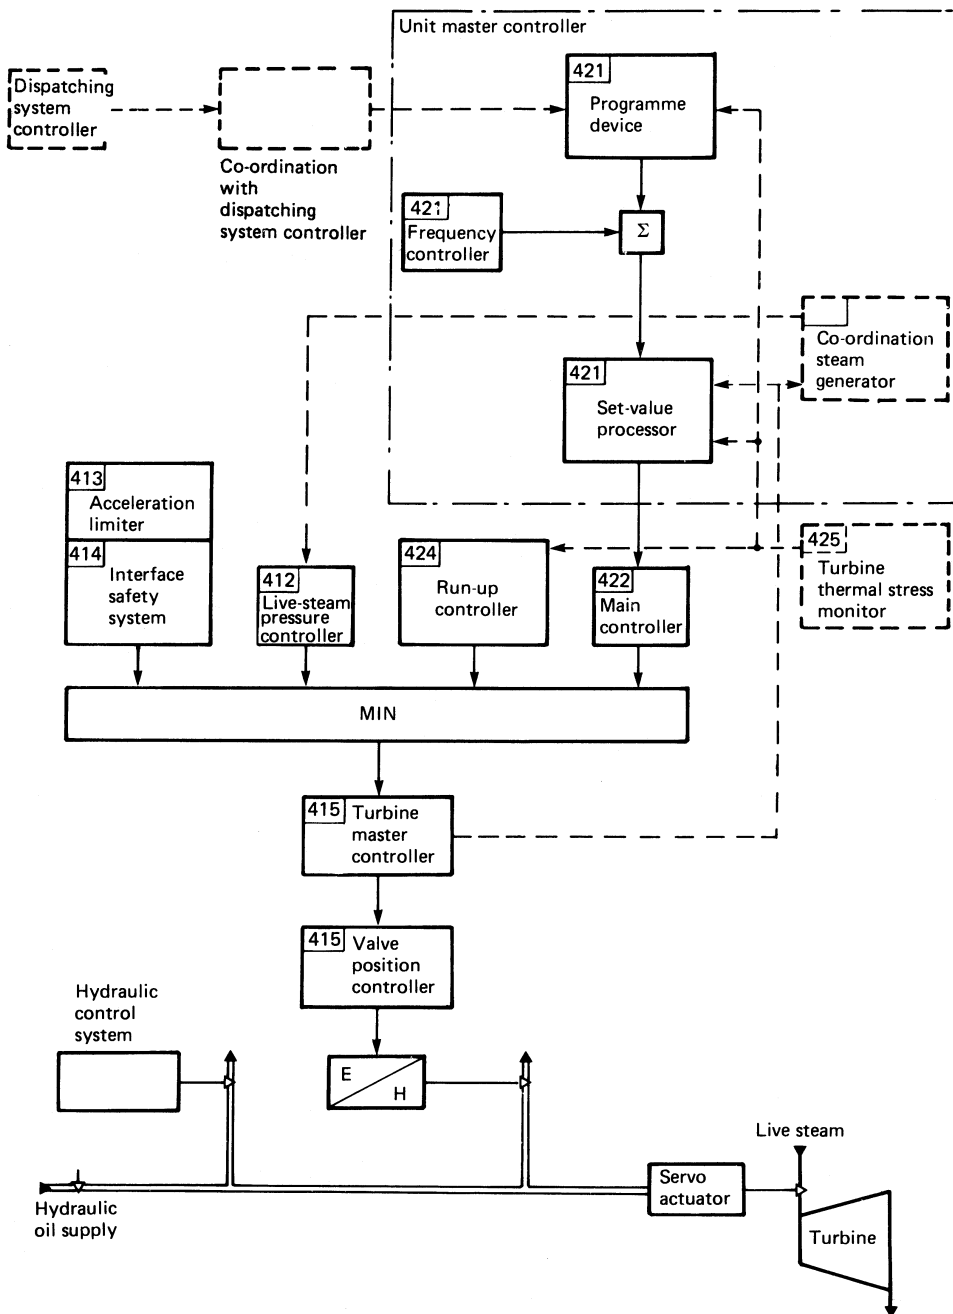

The Turbotrol system also must ensure (i) high operational safety and availability, (ii) high-response sensitivity when changing specific control variables, and (iii) ease of servicing and minimum maintenance.

##### 40.6.6.1 Structure of control system and types of operation

The arrangement of the individual function groups of a turbine controller is shown by the block diagram in Figure 40.37. For clarity the numbers assigned to these groups have been inserted in the text. The control system must be designed for the following types of operation.

- (1) *Normal conditions*—start-up, no load, synchronising, load operation.
- (2) *Special condition*—control of the live-steam pressure by the turbo-set.
- (3) *Fault conditions*—manual control with the turbine master station, turbine trips.
- (4) *Testing*—overspeed, simulation.

**Start-up** During this phase the run-up controller (424) is in action, the turbine master station is set to 'auto' and the

**Figure 40.37** The arrangement of the individual function groups of a turbine controller

valve-position controller (415) is switched on. The controller begins the run-up from any given starting speed to the nominal speed, full use being made of the admissible operating range of the turbo-set. On reaching nominal speed, the frequency controller, which is set to nominal frequency, takes over from the run-up controller. The operation arrived at is 'no load'.

**No load** During no-load operation the speed of the turbine is determined by the frequency set-point via the control unit

(421), the main controller (422), the turbine master station and the valve-position controller (415). No-load operation at nominal speed forms the basis for both the on-line synchronisation of the generator and the overspeed test.

**Synchronisation** This type of operation is authorised when a signal is received from the synchroniser. The turbine speed is determined by the frequency set-value, this being varied by pulses from the synchroniser until the frequency and

phase of the turbo-set coincide with those of the line, and the circuit-breaker closes.

**Load operation** After synchronising and closing of the generator breakers, loading can commence. The following function groups are then active: programme unit, frequency controller, set-value processor (421), main controller (422), turbine master station and valve-position controller (415).

The programme unit forms a reference variable from the predetermined target load set-value and the adjustable rate of change of load. This variable is added to the output signal of the frequency controller and then reprocessed in the set-value processor. The frequency controller compares the actual frequency value with the predetermined frequency set-value and delivers the amplified difference as an output signal. The set-value processor contains limit circuits which prevent the turbo-set from being overstressed by rapid changes of set-values. The output signal of the set-value processor is compared with the actual value of the active power in the main controller.

Thus, during load operation, continuous load–frequency control is accomplished under the direction of the load programme device, full use being made of the permissible operating range of the turbo-set.

**Turbo-set control of live-steam pressure** The Turbotrol system and the steam-generator control system here operate in conjunction. The live-steam pressure controller (412) intervenes when a fault occurs in the steam generation system, thereby taking over from the main controller (422). The system (412) overrides the load set-value and controls the live-steam pressure. The turbine output is then determined by the available live-steam flow.

**Manual control** The turbine master station is an auxiliary unit which is usually set to position ‘auto’, but which automatically changes over to ‘manual’ as soon as an appropriate monitor in the electronic control system has responded. The reference variable for the valve position existing prior to the fault is retained by the turbine master station, while faulty controllers that are not absolutely necessary for the safety of the turbo-set cease to intervene. Function groups 413 and 414 remain permanently on stand-by. Emergency operation may be carried out by manual control for as long as the fault is present.

During manual operation it is the responsibility of the operating staff to ensure that the admissible turbine limits are observed.

**Tripping of the turbine** Direct link-up of the turbine hydraulic safety system with the control system, and an electrohydraulic link between the Turbotrol and the safety system, ensures closure of the control valves each time the turbine is tripped. In addition, the Turbotrol is made ready for start-up, i.e. the turbine master station changes to ‘manual’ and the ‘zero’ correcting variable is dispatched to the control valves.

**Overspeed test** When standard tests have been completed and the necessary preparations made in the hydraulic safety circuit, the overspeed test should be carried out. This takes place semi-automatically with the aid of the run-up controller (424) and starts with the turbine in the no-load condition. Initiated manually, the run-up controller accelerates the turbo-set at a defined rate until the first overspeed monitor responds at 110% of nominal speed. A further command, likewise manually authorised, causes the run-up controller to accelerate the turbo-set up to 112% of nominal speed, at

which the second overspeed monitor responds. The turbine is then tripped. A fault in the system causing the set-point value to increase to 114% of nominal speed trips the turbine automatically, i.e. independently of the overspeed monitors.

#### 40.6.6.2 Principle of operation

**Run-up controller** Providing that the change-over unit is set to ‘auto’, a speed programme unit SFH (Figure 40.38) adjusts the speed set-value by a certain rate of change ( $dn/dt$ ). Change-over to ‘auto’ can only be authorised when the speed set-value and the actual value have been matched automatically. The correcting variable of the run-up controller with proportional–integral (PI) response passes to the electrohydraulic transducer over a smallest-value selector and the valve-position controller. It then influences, via the control oil system, the position of the turbine control valves. The critical-speed ranges are passed through with the maximum admissible acceleration.

Once nominal speed is reached, the frequency controller, set to nominal frequency, takes over from the run-up controller, which then ceases to intervene since the speed set-value  $n_s$  continues to increase up to 106%.

**Load controller with frequency response. Load-frequency set-value** The signal for the desired load is formed by the target-load set-value  $P_z$  and the adjustable loading rate of change ( $dP/dt$ ) or rate of change of load shedding ( $-dP/dt$ ). The load set-value  $P_s$  is varied accordingly, this taking place via a transfer unit actuated by push-button.

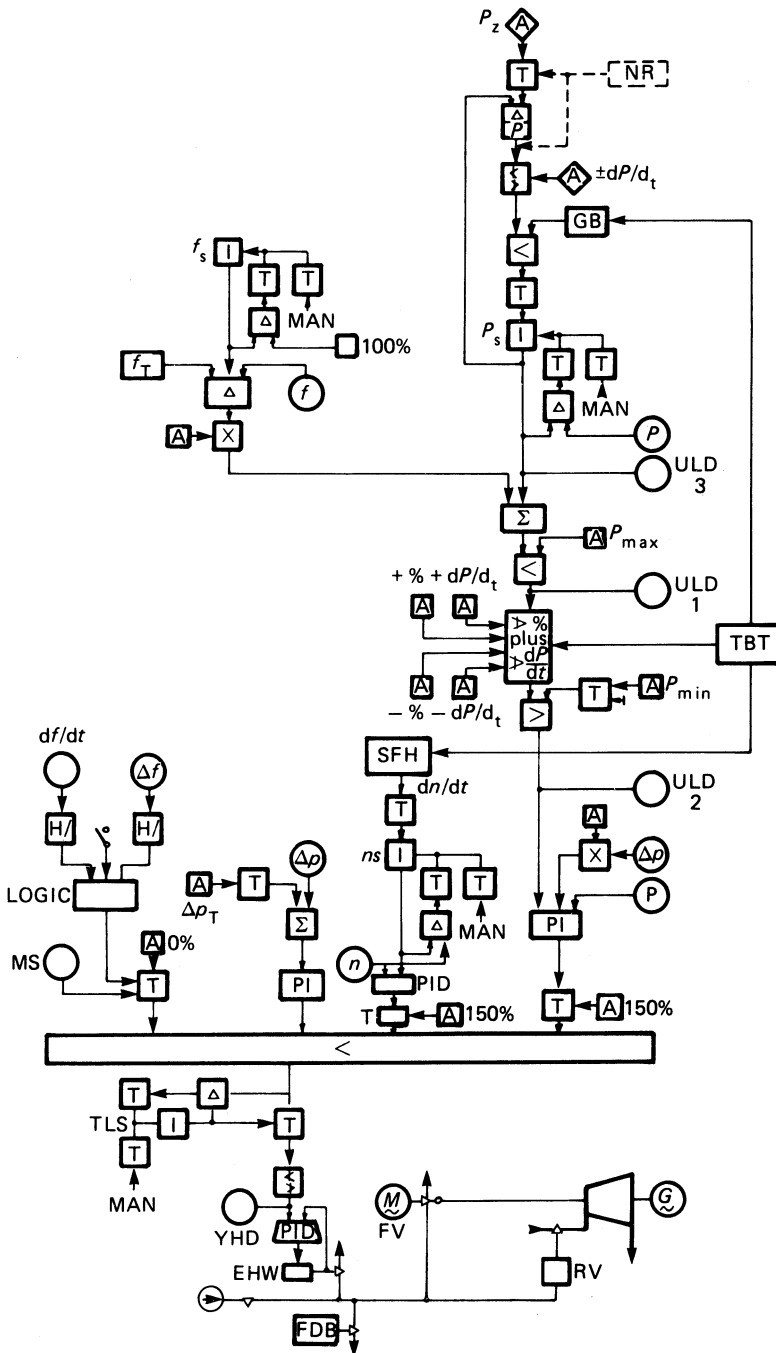

The load component dependent on frequency is formed by a comparison of the frequency set-value  $f_s$  and the actual value  $f$ ; the control deviation is gained by adjusting the frequency droop. If desired, the influence of the frequency controller can be suppressed within an adjustable range  $f_T$ .

The frequency-dependent load component and the load set-value are coupled via a summing junction. The output signal of this junction is thus representative of the load to be delivered by the turbine. All units connected beyond this output are either limiters or subsidiary controllers capable of temporary intervention. These are described individually below.

**Maximum-load limiter  $P_{max}$**  An analogue-value generator  $P_{max}$  transmits a value that, for the turbine or the steam generator, represents a load limit not to be exceeded under any circumstances.

**Load limiter, admissible rate of change of load** Neither the steam turbo-set nor the steam generator can contend with sudden large load changes. These occur particularly when control is according to a frequency–load characteristic and when large frequency fluctuations (e.g. line faults) occur. The step-change and rate-of-change limiter limits these load changes to a variable step change ( $\pm\%$ ) and the remainder to a likewise variable rate of change ( $\pm dP/dt$ ). This limiter can be influenced by a controller in relation to the thermal stresses of the turbine, thus overriding the load set-value.

**Minimum-load setting  $P_{min}$**  This prevents the turbine from being erroneously tripped by the reverse-power relay. This could take place after parallel connection of the generator and the line by the synchroniser. The setting is authorised as soon as the generator breaker closes, and causes the

**Figure 40.38** Block diagram of the overall arrangement of the turbine controller

generator to deliver a fixed minimum output. As soon as the load set-value exceeds the minimum-load setting, the latter automatically ceases to intervene. It remains, however, on stand-by until the preselected target-load set-value has been attained.

*'Unit load demand' signals (ULD 1, 2, 3)* These signals can be employed for operation in conjunction with the steam

generation control system. A signal relevant to the given application is used, e.g. as a reference variable or as a signal for corrective action.

*Load control with live-steam pressure influence* For the live-steam pressure controller, a load-controlled turbine represents a controlled object without inherent feedback. The pressure control can be additionally stabilised by

applying the control deviation  $\Delta p$ , within certain limits, to the load controller of the turbine. Thus for minor pressure control fluctuations a controlled object with inherent feedback is achieved.

*Valve-position controller, turbine control valves and turbine master station* The output signal of the lowest-value selector for all controllers represents the reference variable for the valve-position controller and is limited to fixed minimum and maximum values.

To ensure co-ordination of the various PI action controllers (run-up, main and live-steam pressure controllers) during normal operation, the integral part of each controller continually tracks the controller having the smallest registered proportional component.

The turbine master station TLS allotted to the valve-position controller is not used during normal operation but only in the event of faults in, for example, the main controller. In this event the correcting variable received from the main controller is suppressed and the turbine master set to 'manual'. The correcting variables received from the acceleration limiter and the safety-system co-ordinator always remain on stand-by. When the turbine master is set to 'manual', any desired valve position can be commanded. It should, however, be noted that with this type of operation the operating staff are responsible for ensuring that the admissible turbine limits are observed.

*Live-steam pressure controller* To prevent an excessive drop in the live-steam pressure when faults occur in the steam generator, or when there are rapid positive changes in load, the live-steam pressure controller intervenes on the adjustable limit  $p_T$  being attained. This reduces the turbine load in accordance with the available live-steam flow. The limit can, if desired, be set to zero, after which the Turbotrol acts as an initial pressure controller.

*Acceleration limiter* When load-shedding to house load, this limiter closes the turbine control valves immediately. Simultaneously, the load set-value  $P_s$  is brought to zero within less than 1 s. As soon as the acceleration of the turbine fades out, the limiter ceases to intervene. The frequency set-value alone now determines, via the main controller, the speed of the turbine by controlled opening of the valves (operation feeding only the house load).

*Safety system* When the turbine trips, the pressure switch MS responds. The signal is led via the evaluator logic to the turbine controller and causes all control valves to close immediately.

#### 40.6.6.3 Control room operation and display

Basically, the number and type of units required in a control room for the Turbotrol system vary according to the installation. The functions are actuated by means of non-arresting push-buttons. These may be adapted for use as illuminating buttons. Either solid-state output units or coupling relays should be provided for the alarm signals, depending on the type of warning system.

#### 40.6.6.4 Operating behaviour and maintenance

The philosophy applied to safety, availability and reliability is expounded here without details of the theories of system safety and reliability.

*Safety* A solid-state Turbotrol control system as described is a single-channel arrangement. In assessing the safety of the entire turbo-set, however, it should be borne in mind that, parallel to the electronic control system, a completely independent hydraulic safety system can be provided with redundant monitors (speed, pressure, vacuum, etc.) in a one-out-of-two arrangement and independent actuators (main and reheat stop valves).

The safety system is then coupled to the control valves both hydraulically via a relay, and electrohydraulically via function group 414. Loss of pressure in the hydraulic fail-safe circuit causes the control valves to receive closing commands over two independent channels.

The Turbotrol system itself is designed to ensure the highest possible degree of safety whilst, with regard to the signal paths, still upholding the principles of simplicity and transparency. The most important peripheral units and transducers are actively redundant.

Two separate d.c. power sources reduce the danger of a turbine trip as a result of failure of the supply voltage. Failure of internal power-supply units simply causes clearly defined subcircuits to be disconnected, fault indication taking place simultaneously. Generally, it is still possible to carry out restricted operation with the Turbotrol. When a fault occurs, some of the internal monitoring elements set the turbine master station immediately to 'manual', so that the turbo-set can at least still be operated manually. Even during such operation, the subcircuits important for the safety of the installation (413, 414) remain active. Response by either of these, or a fault in one of them, causes an immediate trip.

The subcircuits and functions can, to a large extent, be tested during operation.

*Availability* Regular checks, and the modular design of the equipment, permit faults that occur to be recognised early and eliminated by replacing the appropriate module before it causes operational failure. If a breakdown should nevertheless occur, the fault may be quickly located by means of the many indication, test and simulation devices, and promptly eliminated. The availability of the installation is thus ensured.

*Reliability* The individual parts of the control system, its components and, finally, the complete system unit should be subjected to rigorous testing. Combined with a simple logically designed system that has the minimum number of component parts, these measures contribute to the high degree of reliability of the entire control and safety system.

Final designs of various kinds, depending on the respective importance attached to the terms safety, availability and reliability, can be achieved.

*Operation with the hydraulic control system* This control system serves as back-up when the Turbotrol is in operation. If a fault occurs in either the turbine master station or the electro-hydraulic transducer (415), the respective hydraulic lines must be blocked manually. Renewed turbine start-up then takes place manually via the hydraulic control system. The variable readings required for this are displayed in the control room, provided that the d.c. power supply for the Turbotrol is intact.

#### 40.6.6.5 Fast valving

Power export is reduced by the loss of voltage in the event of short circuits in the transmission systems. Acceleration of

the turbine rotors occurs in the turbine-generator units involved by a change in the balance of the mechanical-drive and the electrical-load torques. In the turbine-generator unit closest to the short-circuit point, the rotor angle reaches a critical value that depends upon the generated load and the duration of the short circuit; this causes the unit to lose synchronisation.

By briefly closing the turbine control valves ('fast valving'), the drive torque of the turbine-generator unit is rapidly reduced to control a sustained short circuit without loss of synchronism. Depending upon the load in the transmission system, it may be necessary before reconnecting the load to set a load level lower than that before the short circuit.

The subassembly 'Fast valving' (functional group 470—see Figures 40.39 and 40.40), takes action in the turbine control system in the event of failures in the power transmission system by brief closure of the control valves in conjunction with a reduction in the load setting. This takes place if the load on the turbine-generator unit is greater than the adjustable maximum value (approximately 60% load). Failure detection in the power transmission system and the initiation of fast valving are performed by the grid supervision system.

Both the main control and the intercept valves take part in fast valving. While the intercept valves are briefly closed ( $T_{FV}$ ) via solenoid valves, the main control valves are actuated by the Turbotrol electronic control system.

The electrical position signal YHP for the main control valves is set to 0% by a minimum selection gate. The turbine master of the Turbotrol is switched to 'manual'. After the time  $T_{FV}$ , YHP is switched to a preselectable value  $X\%$ . Simultaneously, a 'lower' instruction for tracking the turbine master is issued. The integrators of the controllers also follow the tracking of the turbine master. The actual

load value then appears according to  $X\%$ . The load set-point is tracked in the unit master.

The load set-point drops until the controlled variable YR is smaller than YFV, i.e. until the main controller is ready to take over the control task. The turbine master then automatically switches back to 'auto'.

The load target set-point has remained stationary during the entire fast-valving process so that it is immediately possible to reconnect the load by switching on the automatic loading system.

It is only possible to test the subassembly with a load of less than an adjustable minimum value (about 30%).

#### 40.6.7 Water-turbine control system (Hydrotrol)

The Hydrotrol (Figure 40.41) performs, in conjunction with the electro-hydraulic transducers and the hydraulic servo-motors, the following tasks:

- (1) Automatic provision of an opening for run-up of the turbine until the speed controller takes over.
- (2) Speed control during no-load operation.
- (3) Frequency control during isolated grid operation and when station auxiliaries are being supplied.
- (4) Opening control according to an adjustable linear frequency-opening characteristic.
- (5) Arresting of overspeed after load shedding.
- (6) Connection and processing of signals of a higher-order control system with or without load feedback (e.g. from the water-level controller or dispatching system controller).
- (7) Position control of the guide-vane apparatus in Francis turbines.

Figure 40.39 Block diagram showing the action of the fast-valving function group (470)

Figure 40.40 The response of the signals YHP (421), YR (421) and YFV during fast valving

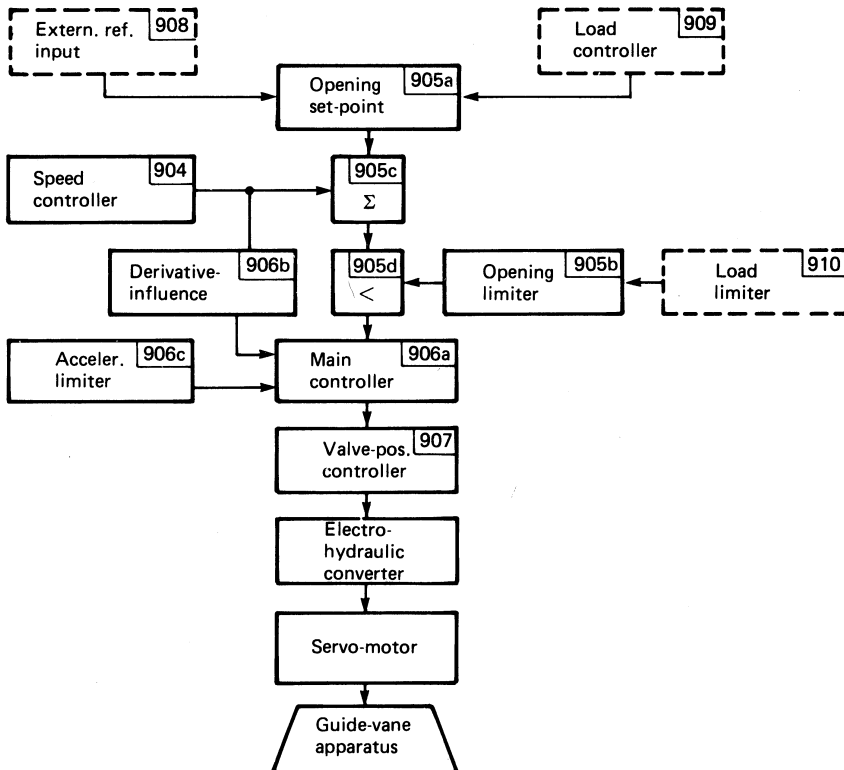

Figure 40.41 Function groups of the Hydrotrol with valve-position controller for Francis turbines

- (8) Position control of the guide vane and impeller blades (with a pre-set relationship between guide-vane and impeller-blade angles) in Kaplan turbines.
- (9) Position control of the needle and deflector (with co-ordination between jet diameter and deflector position) in Pelton turbines.
- (10) Redundant measurement of speed. The speed-measurement device is equipped with outputs for indicator devices, control and monitoring.

The Hydrotrol 4 ensures (i) high operating reliability and availability, (ii) high-response sensitivity in respect of changes in specific control variables, and (iii) easier servicing with low maintenance requirements.

#### 40.6.7.1 Design and operation of the controller

Figure 40.41 shows the basic design and the way in which the function groups of the Hydrotrol are interconnected. The numbers of the functional units are referred to in the text. The controller is designed for the following methods of operation:

##### Normal:

- start-up (with opening limiter);
- no-load operation;
- synchronising;
- load operation with opening feedback;
- load operation with opening limiter in action;
- load operation with dispatching system controller connected;
- load operation with external reference input; shut-down.

##### Disturbance:

- load shedding;
- turbine tripping.

##### Testing:

- overspeed;
- simulated operation.

**Start-up** As soon as the starting command is given, the opening limiter (905b) indicates the starting opening (Figure 40.41). In the smallest-value selector (905d) the control deviation of the speed controller (904) is limited by the start opening and is supplied to the main controller (906a). The servo-motor opens the guide-vane equipment via the valve-position controller (907) to the value specified by the opening limiter (905b). The machine accelerates until the speed controller (904) comes into action via the derivative action (906b) below the nominal frequency. Acceleration consequently ceases and the speed controller (904) controls the turbine at nominal frequency.

**No-load operation** The turbine speed can be set by the frequency set-point value. The control deviation of the speed controller is formed by comparing the set-point with the actual frequency, and passes via the smallest-value selector (905d) to the main controller (906a). In this method of operation the main controller is switched to proportional–integral–differential (PID) response for reasons of stability. No-load operation at nominal speed is the starting point for synchronising the generator with the network.

**Synchronising** The synchronising device acts on the frequency set-point. Its pulses adjust the set-point until the frequency and phase position of the unit coincide with the network, and the generator breaker then closes.

**Load operation with opening feedback** After synchronising, the plant changes to load operation with the generator

breaker closed. The following function units of the control system are now in operation: speed controller (904); opening set-point (905a); summing junction (905c); smallest-value selector (905d); main controller (906a); valve-position controller (907).

The turbine is loaded by run-up of the opening set-point. This is compared with the opening of the guide-vane equipment; the resultant deviation, after evaluation by the pre-set droop variable, is added to the control deviation of the speed controller. The acceleration influence (derivative action) on the main controller is blocked. In this mode of operation the main controller is switched to PI response.

**Load operation with opening limiter in action** As soon as the opening of the guide-vane device exceeds the value set on the opening limiter (905b), the latter begins to act via the smallest-value selector (905d) and limits the opening. The load limiter (910) automatically limits the maximum output of the turbine or generator via the opening limiter.

**Load operation with applied dispatching system controller** This is initiated by actuating a button on the control desk. The opening set-point is controlled by a superposed frequency–load controller (909). The load set-point can be pre-selected by a separate set-point generator or an external dispatching system controller.

**Load operation with external reference input** This method is pre-selected by a button on the control desk, which causes the opening set-point (905a) to approach the pre-selected reference input (908) from a water-level controller or dispatching system controller. As soon as the two signals agree, the external reference input is applied directly as an opening set-point. The opening set-point tracks the external reference input so that, when this mode of operation is switched off, the controller continues to retain the last-occurring reference input.

**Shut-down** After the load has been reduced by decreasing the opening set-point, the generator breaker is opened; the controller again operates in the no-load mode. The turbine can then be fully shut down by automatically switching the opening limiter to a closure command of about 10%.

**Load shedding** To arrest the speed rise of the turbine on load shedding as rapidly as possible, an acceleration limiter (906c) is incorporated. As soon as the acceleration exceeds a limiting value, this device, acting via the servo-motor, causes immediate closure of the guide vanes. When the overspeed vanishes, the speed controller again takes over control at nominal frequency.

**Turbine tripping** All the emergency-closure and rapid-closure criteria simultaneously have the effect of causing a switch-over to a closure command of –10%, as with the normal shut-down operation.

**Overspeed test** For this, the speed controller (904) is rendered ineffective. By increasing the speed with the opening limiter (905b), the function of the overspeed protection device can be tested.

**Simulated operation** This is initiated by inserting a plug in the Hydrotrol 4; it facilitates functional testing of the

electronic controller with the plant shut-down, by means of incorporated simulation equipment.

#### 40.6.7.2 Operation of the main controller

In order that the control deviation does not remain permanently in the stabilised state, the main controller is constructed with a PI circuit. With the circuit selected, the main controller governs for fairly small control deviations, and the servo-motor operates in its linear rapid-operating range. For large control deviations, the servo-motor can no longer follow the correcting variable (output of the main controller), since the maximum speed of the servo-motor is limited by hydraulic orifice plates. The main controller will disengage, resulting in pronounced overshoot of the servo-motor position (in the extreme case, event instability). However, electronic simulation of these hydraulic orifice plates limits the integral component of the main controller in such a way that, as soon as the servo-motor again reaches the linear range, the main controller immediately corrects itself and can take up optimised control.

Two types of stabilisation are possible in the main controller:

- (1) no-load stabilisation, initiated with the generator breaker open (no-load stabilisation corresponds to a reduced proportional component, a long integration time and effective derivative action); and
- (2) parallel stabilisation, initiated with the generator breaker closed (parallel stabilisation corresponds to a relatively large proportional component, a short integration time and ineffective derivative action).

If the generator is supplying an isolated network, the no-load stabilisation must be switched on. This occurs automatically when a specific frequency band is exceeded, and is signalled in the control room. It must also be possible to carry out this changeover manually.

#### 40.6.7.3 Operation of the valve-position controller

The output signal from the main controller (with PID response) acts upon the valve-position controller. The latter has the task of making the servo-motors of the control devices track the main-controller output (proportional response). It represents the actual connection device between controller and hydraulic system, and serves as a command device of the electrohydraulic transducer.

There are three types of valve-position controller.

- (1) For Francis turbines. In this variant, the position of the guide-vane servo-motor is regulated.
- (2) For Pelton turbines. In this variant, the positions of the needle and deflector servo-motors are regulated. By simulating a function, 'needle movement to water-jet diameter' in the 'deflector' control circuit, it is possible to ensure that the deflector is positioned above the water jet. The deflector then comes into action only if rapid control movements in the 'closed' direction occur.
- (3) For Kaplan turbines. Here the positions of the guide-vane and impeller servo-motors are regulated. Function transmitters ensure optimum tuning between the guide-vane angle and impeller-blade angle as a function of the head. The corresponding device is situated in the 'impeller' control circuit.

#### 40.6.7.4 Structure of the speed-measuring equipment

The Hydrotrol is equipped with a redundant speed-measuring device, with outputs for indicator devices, control and

**Figure 40.42** Block diagram of a speed-measuring device with speed-limiting values, overspeed protection and direction indicator: D/A, Digital/analogue

monitoring. The basic design of the device is shown in *Figure 40.42*. References to the units and outputs are given in the text in parentheses.

The speed is measured with three channels. The speed is picked up from a wheel (E) by ferrostat transmitters (A1, A2, A3). The generated frequency (proportional to speed) is transmitted via the pre-amplifier (B1, B2, B3) and the speed-measuring device (C1, C2, C3). The speed measurement generates an analogue voltage (N1, N2, N3) which is accurately proportional to the speed. The speed transmitters are monitored: a fault at speed transmitter A1 (such as a voltage failure, short circuit or line fault), is signalled via monitoring channel U1 and is announced by the alarm 'speed transmitter faulty' (output S). Simultaneously, the speed signal for the speed controller (I), the speed limiting-values (J) and the indicator (K) are switched over from speed transmitter A1 to transmitter A2.

The overspeed protection (P) consists of a double-channel 'two-out-of-three logic' (L). This triggers an emergency stop (output Q) and a quick shut-down (output R) as soon as two or three speed limiting values (D1, D2, D3) respond or faults occur at two or three speed transmitters. The direction indicator (T) serves for determining the direction of rotation in pump turbines.

The speed transmitters must be mounted at angular intervals  $\beta = 360(n + \frac{2}{3})/z$  (degrees), where  $z$  is the number of gearwheel teeth and  $n$  is an integer. The outputs V and W indicate the direction of rotation, and output X indicates when the shaft is stationary.

#### 40.6.7.5 Testing

**Component testing** Every component approved for use in electronic systems must be subjected to stringent tests, carried out in compliance with IEC publications.

**Testing of the controller** The controllers must be individually tested and adjusted in the laboratory on the basis of the particular turbine characteristics. Before delivery, every Hydrotrol must operate for a week in the closed-loop of an analogue turbine simulator, with all control variables and

the most important control parameters continuously recorded. In this way, changes in control behaviour and premature failure, for example of semiconductor components, can be detected.

#### 40.6.7.6 Operational reliability and availability

**Reliability** An electronic water-turbine Hydrotrol is, in general, of single-channel construction. The important peripheral devices and transmitters (e.g. for speed) are designed with redundancy. A failure in the supply voltage or internal supply equipment causes rapid closure and simultaneous signalling of the fault. Faults in internal monitoring devices such as those for the speed transmitters or valve-position controllers lead to an emergency closure.

**Availability** Regular testing and the modular construction of the equipment should permit any faults that occur to be detected at an early stage and to be rectified by replacement equipment before they cause operating faults.

## 40.7 Decentralised control: substation automation

### 40.7.1 Introduction

With the increasing complexity of power systems, the difficulties of manning substations and the requirement for shorter restoration times after power failures, more tasks are being automated in the substation. The conventional solution to automating these tasks has been by dedicated hardwired logic. Though effective, this is inflexible and difficult to test off-line. Hardwired logic is being superseded by systems based on mini- or microprocessors which have advantages over their hardwired counterparts with regard

to flexibility, space requirements, test and commissioning facilities. A further and important advantage is their ability to self-monitor and detect an internal fault almost immediately, and not only when operating. However, they have the disadvantage of intolerance to voltages in the connecting cables induced by switching of h.v. apparatus or thunderstorms. Special precautions must therefore be taken to decouple the plant connections from the electronic circuits.

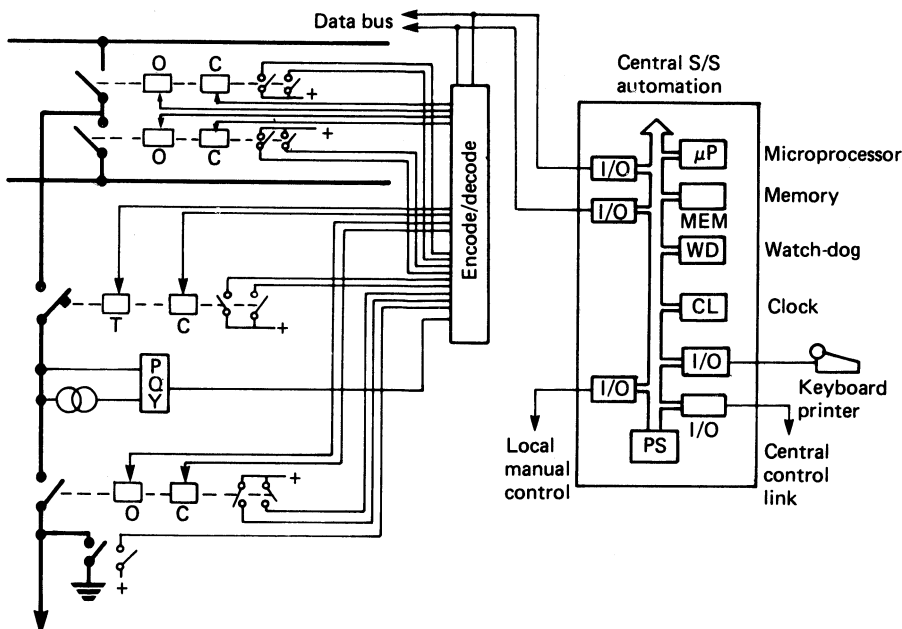

Several tasks can be assembled in one set of hardware, and thus a centralised system can be used. The speed of transmission and the availability of transmission channels are limiting factors in achieving reasonable response times for some substation tasks from a remote control centre; many of these tasks are therefore performed by substation equipment.

### 40.7.2 Hardware configuration

A simplified substation automation hardware configuration is illustrated in Figure 40.43, with its connections to one feeder circuit of an h.v. substation.

The central logic is a microprocessor with the automation routines stored in a non-volatile programmable read-only memory (EPROM) which can be erased and modified using special equipment. Thus, by triggering a power-failure restart routine held in the EPROM, the equipment can recover from power failures without reloading. The variable data are held in a random-access memory (RAM) which can be corrupted on power failure. It must be capable of replacement after a power failure either by local input or by down-loading from a higher level control system. Similarly, the variable data, such as limits tripping priorities, etc., must be capable of modification, e.g. from a keyboard.

The data acquisition and automation programs are executed by the microprocessor, which communicates with the input/output equipment via the system bus. The input

**Figure 40.43** An example of a decentralised automation system: O, open; C, closed; T, trip; P, active power; Q, reactive power; V, voltage; PS, power supply; S/S, substation

and output modules are similar to those already described for the telecontrol remote terminal unit (TRU). The connection to the higher level control system can be via a direct link or a telecontrol TRU.

An important decision to be made in the layout of an automation system in substations is the location of the transducers and the method of transmitting the h.v.-circuit data to the central processor unit. Economically, the transducers are better located near to the measurement point to avoid long instrument-transformer connections. However, this means that light-current connections are long and vulnerable to interference and high induced voltages. A solution is to install encoding equipment at the data source and serial transmission equipment to send the messages to the central logic over a serial data bus which can be common to a number of h.v. circuits, as in the telecontrol system transmission already described. As the technique develops, this transmission can be over a fibre-optic line.

### 40.7.3 Software configuration

The software is modular to allow the system to be easily extended and developed. The individual application programs run independently of each other, but share data and input/output routines. For small systems the programs can run cyclically; however, for larger systems a system of priorities must be established and the resources allocated by an executive program. The program structure is illustrated in Figure 40.44.

### 40.7.4 Applications

#### 40.7.4.1 Sequence control (switching programs)

In closing circuit-breakers on to live circuits, several criteria have to be met to ensure a successful operation; for example, in energising a feeder, the breaker must first be connected to the required bus-bar, the line isolator closed, the line-earth switch open, and the synchronising criteria satisfied. It must be ensured that no sanctions are valid that would inhibit the operation. Similarly, when energising a transformer circuit, manually or automatically, it is normal to make similar checks and circuit preselections before

closing the l.v. breaker and then the h.v. breaker. In changing a circuit from one bus-bar to another, a switching sequence involving the bus coupler and perhaps the bus section switches must be performed.

These sequences can be programmed and performed by local automation equipment, provided that all switches are motorised. The sequences can be initiated by one command (e.g. 'close line 123 on to bus 3'). The responsibility from there on is taken from the operator and the instruction is performed by the local automation equipment which, in carrying it out, will respect all the interlocking requirements and inhibits.

#### 40.7.4.2 Switching interlock supervision

Manual switch operation in a substation is required either as the normal mode of operation or as a back-up to the automatic mode. For these operations, interlocking is required to prevent incorrect switching that might endanger equipment or the stability of the power network. The conventional solution for interlocking is a device with auxiliary contacts and inter-device wiring forming a hardwired supervision logic. Interlocking can also be achieved by the local automation equipment using programmed logic accessing the shared data base. This latter solution considerably reduces the inter-device cabling as well as the number of device auxiliary switches or repeater relays used and their discrepancy supervision.

#### 40.7.4.3 Load shedding and restoration

With a falling frequency, at certain levels of frequency it may be necessary to reduce load without waiting for remote intervention or relying on transmission channels. The load shedding can be performed automatically by local automation equipment in progressive steps, starting with the tripping of storage heating or cooling loads via ripple control signals, and progressing to more drastic action by tripping feeder circuits at the substation.

These tasks can be performed by substation equipment that scans the frequency measurand and, at various pre-set frequency thresholds, instigates load-shedding action in pre-arranged steps and programs. The programs can be arranged to cycle the load shedding so that each consumer

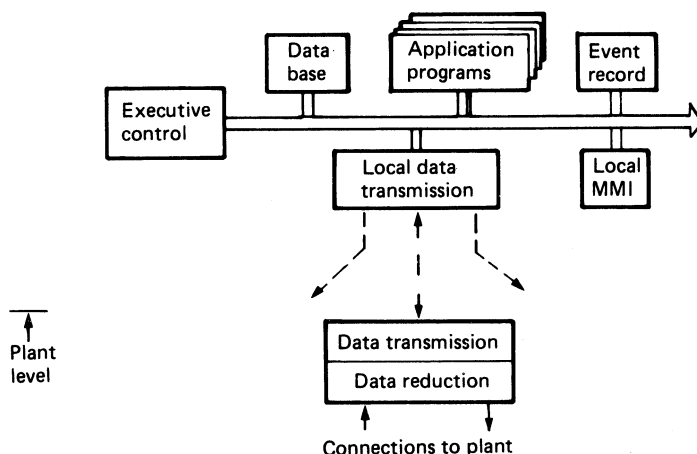

Figure 40.44 Software configuration. MMI

is tripped in turn and no particular load is singled out to be always first on the tripping list.

Once the frequency has returned to predetermined levels, supplies to loads can be progressively restored in a predetermined order until the situation is normal.

Similar actions can be initiated on a feeder overload when the current exceeds the thermal limit of the cable.

#### 40.7.4.4 Automatic reclosing

The majority of overhead line faults are transient, caused by falling trees, birds, lightning, etc., and they clear after the breaker interrupts the fault current. To reduce the duration of the outage, the breaker can be automatically reclosed, after a time delay to allow for deionisation of the fault path. If after the first interruption the fault has not cleared, either the breaker is locked open or further reclosing attempts are made before locking the breaker open. Tripping and reclosing can be either one-phase or three-phase, depending on the selectivity of the protection and the construction of the breaker.

Conventionally, these reclosing sequences are performed by timing relays and hardwired logic requiring dedicated breaker auxiliary switches. Settings of the number of reclosures, the dead time between reclosures, and the reclaim time are adjustable. Equally, these functions can be performed by common logic using a shared database to reduce wiring and auxiliary contacts on the breaker. An additional advantage appears with microprocessor-based logic in that parameters such as dead times and one-phase or three-phase reclosing can be selected and down-loaded from the control centre, depending on the network conditions.

#### 40.7.4.5 Event recording

Event recording in a substation can be divided into two basic categories: one that records alarms, contact closures or device operations, and another that records waveforms of currents and voltages prior to, during and immediately after a fault on the power system.

The first category detects changes of state of contacts with a time resolution of 10 ms and records the operation on a printer. Thus, in post-event analysis, the maintenance engineer has a record of the times at which the events occurred and their chronological sequence.

The second category is an 'oscillo-perturbo-graph', which continuously records, temporarily memorises and then erases the waveforms of the currents and voltages in a circuit. After the detection of a fault, the memorised pre-fault, fault and post-fault data (which can include contact operation) are permanently recorded for subsequent analysis. The conventional equipment for faulting recording is an electro-mechanical device that has a galvanometer logger writing the waveforms on to a rotating inked cylinder. At the end of the cylinder rotation, the marks made by the recording pen are erased and replaced with a later value. When a fault is detected, paper is brought into contact with the rotating cylinder to print the recorded parameters. This device requires periodic maintenance, but it has been effective for many years. It can be superseded by a microprocessor-based digital system but, as the scanning speed required to record the fault parameters is of the order of 1000 Hz, it is unlikely that this function can be incorporated in a central substation logic. One advantage of digital recording is that the data can be transmitted to a remote control centre for subsequent post-fault analysis.

#### 40.7.4.6 Protection

Protection is a vast subject, the principles of which have been covered elsewhere. It suffices here to mention it as a part of substation automation. Because of the high scanning speeds required, it is unlikely that primary protection can be integrated into a central substation automation system. Thus, even though microprocessor-based protection will be available, it will be dedicated to a particular task or circuit as with the present solutions.

### 40.8 Decentralised control: pulse controllers for voltage control with tap-changing transformers

As a result of ever-increasing automation and rationalisation, electronic pulse controllers are becoming widely used in the field of tap-changer controls. In interconnected operation, maintenance of frequency characterises the equilibrium between generation and consumption of active power, while voltage control determines the control of reactive power in the system. The essential difference between the frequency/active-power and the voltage/reactive-power characteristics is that the frequency has the same value throughout the system while the voltage forms a system of ever-varying peaks and valleys (assuming a constant rated voltage) which in turn decides the direction and magnitude of reactive power flow.

Tap-changing transformers are the variable step functions in this range of peaks and valleys, and this introduces additional freedom at certain points in the interconnected system. Depending on their place of application, tap-changing transformers can be generator or interconnecting or consumer-load units.

The task of the pulse control unit is automatically to maintain the voltage in the system or to direct the reactive power flow. *Figure 40.45* illustrates an example of application—the control of a consumer network.

The voltage to be regulated is compared in the regulator with an adjustable reference value. Depending on the polarity and magnitude of the difference between these values, 'higher' or 'lower' impulses are given, resulting in the necessary adjustment of the tap-changer. The impulse sequence is inversely proportional to the difference signal. The integration time  $t_1$  and the pulse duration  $t_2$  are adjustable. As long as the difference signal is smaller than the set sensitivity, the impulses are blocked. A further adaptation of the impulse sequence is possible owing to a time factor so that a stable and quasi-steady regulation may always be obtained. *Figure 40.46* shows a typical characteristic of a final control element with a stepwise mode of operation.

**Figure 40.45** Consumer network regulated by a tapped transformer: I, tap-changer; II, reactive-power flow; III, consumer network; IV, supply network; V, line reactance

**Figure 40.46** Typical characteristic of a final control element with steps of 1%.  $\Delta V=5\%$ ,  $\alpha=0.25$ ,  $\epsilon=0.8\%$ ,  $t_1=50$  s,  $t_2=0.2$  s,  $t_3=0.5$  s

It is important that the controller does not cause the tap-changer to carry out unnecessary switching operations. If, for example, a short-time fault were to occur on the system, no purpose would be served by the tap-changer responding. The fault would be rectified before the switching operation could be completed and the controller would then immediately issue commands for the tap-changer to return to the original position. Adequate damping is therefore essential for preserving the life of the tap-changer.

If the control deviation tends to exceed the set sensitivity, an integrator comes into operation. No control command is issued before the pre-set integration time expires.

## 40.9 Centralised control

### 40.9.1 Hardware and software systems

In a control centre, the basic requirement of the operator is information about the power system, presented to him/her

in a clear and unambiguous manner. He/she needs an overview of the network, usually in the form of a large wall diagram or overhead projection giving the network configuration and perhaps coarse line load levels. He/she also needs detailed diagrams of individual parts of the network showing the load of each HV circuit plus its switching configuration by isolator, circuit-breaker and earth-switch positions. These circuit diagrams are selectable on to colour visual display units (VDUs). Figure 40.47 gives an overview of a typical control room.

In addition to the basic requirements, the operator requires other information to be calculated and automatic controls to be performed, as discussed later. These requirements can be realistically met only by an on-line, real-time computer system interfacing with the telecontrol system to provide up to date network data and to accept commands.

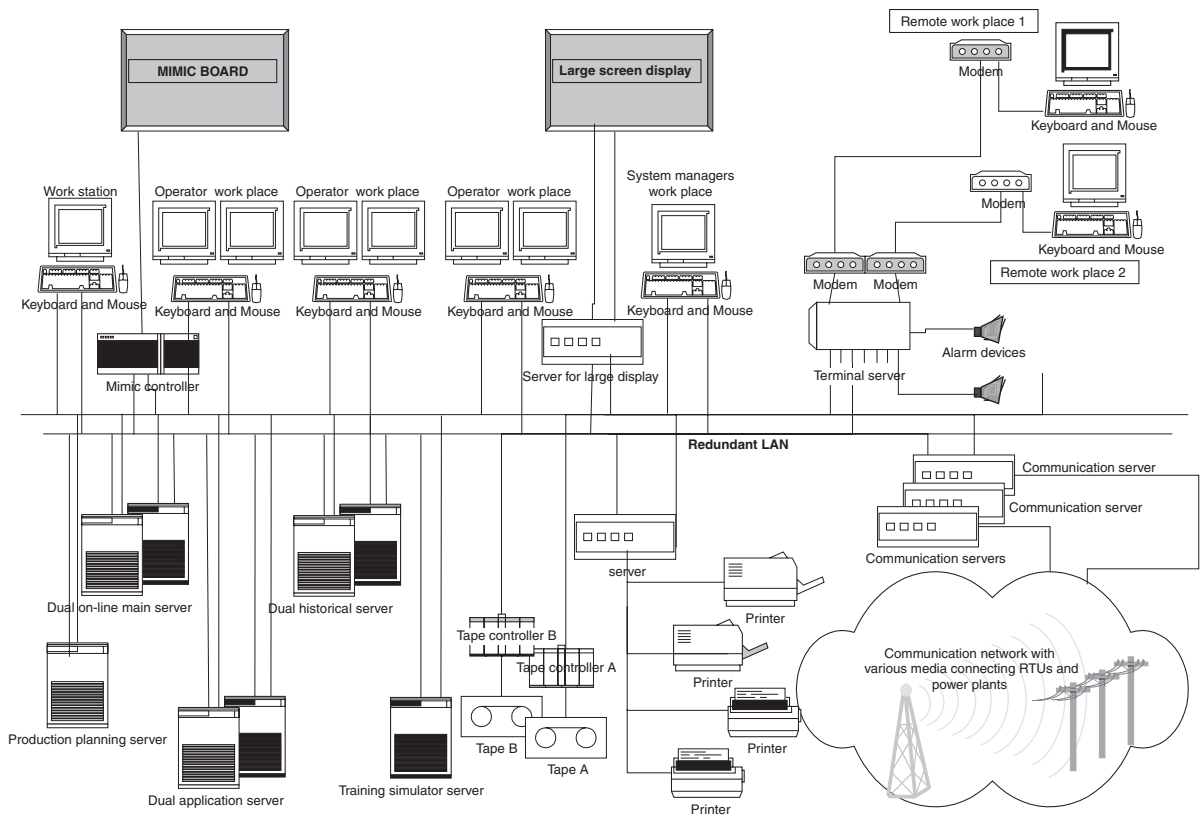

The availability of such a system must be of a very high order (99.5%plus); a single processor system would not be adequate. Distributed processing with dedicated multi-processor systems must therefore be considered. The classic configuration of the dual main computer system with front-end processors for the telecontrol system, and an independent wall-diagram control has given way to a distributed system. In a distributed system any of the processors may be duplicated to increase the availability of the individual critical components.

### 40.9.2 Hardware configuration

A typical computer hardware is shown as in Figure 40.48, which allows various groups of applications to be distributed on different processes. The backbone of this configuration is a Local Area Network compliant to the IEEE 802.3. The typical speed of this network is from 10 to 100 Mb/sec. The most common network protocol used on the LAN is TCP/IP corresponding to transport and IP layer of the seven-layer ISO open system model. The LAN itself could be in few segments and redundant to make it failure tolerant.

**Figure 40.47** Overview of a typical control room

**Figure 40.48** Distributed control centre configuration

Individual processors can operate in on-line or redundant backup mode. The peripheral devices such as printers, loggers, hardcopy devices, acoustic alarms, Human Machine Interface devices are also connected to the Local Area Network. In case of failure of the main device the backup or standby device takes over without loss of functionality. Such a configuration can be tailored to suit individual reliability and availability requirements.

The communication servers are also used in multiple configurations for load sharing and redundancy purposes. The communication lines from the RTUs, or other control centres bring the data to these communication servers. The basic object of the communication servers is to collect data from the field devices, pre-process the data for change, limit violation, convert them to engineering units and make them available for all the users. A device supervision function keeps watch on all the devices configured in the system and in the event of the failure of the on-line or main device the watchdog may switch the function to the designated backup or standby machine. The main processor communicates with the remote terminals via the communication server systems and with the man machine interface equipment connected to the LAN or WAN.

### 40.9.3 Man-machine interface

The operation peripherals forming the man-machine interface equipment are connected over the LAN to various processors. These can be configured and switched either individually or as a group to main, standby or backup

servers. Normally, these are switched to the main server. The main human machine interfaces devices are the keyboards and the graphic or semi-graphic VDUs, mouse or track ball type pointing device, acoustic device for alarms, wall diagram, printers, loggers, hardcopy as shown in the hardware configuration diagram (Figure 40.48).

The VDUs with the mouse and keyboard are the main tools of interaction. Each operator's place may have several VDUs driven by one HMI processor. Each of these VDUs may be configured to display several windows of different types of information. All windows may continuously display updated information from the network but at a time only one of the windows is active for the operator interaction. These display windows may be used to display geographic or schematic network diagrams, alphanumeric information such as reports and lists, trend curves and other type of pictures. The selection or navigation through these diagrams is done via a fixed or dynamic menu, which may popup or be pulled down depending on the context of the cursor or pointer location. The operator may pan in a large picture to locate himself in the area of interest for monitoring and control. He may zoom in to display more detailed information. A certain zoom level may be associated with the level of information to be displayed. These panning, zooming and de-cluttering techniques may be very effectively used to display or condense information on the level of information required by the user.

The displays on the VDU Windows may consist of both static and dynamic data, the later being updated as often as necessary. For example, when a station diagram is displayed,

the switch-position indications are automatically updated after the information of the change of state has been received from the substation. Measurand values are also updated on the screen at the same rate as the telecontrol cycle. For trend curves, the screen is used rather like a multi-pen chart recorder, using colours to identify the curves.

The keyboards contain both functional keys for operations that are repeated frequently, and alphanumeric keys for inputting numerical data and text. The keyboards are interactive with the displays on the VDUs, which allows parameter changes and device control by identification of the object to be addressed by device or position reference input, or via the function and alphanumeric keys, or by the positioning of a cursor. The cursor movement is controlled by a mouse, trackball, joystick or direction keys. Thus a dialogue is possible between the operator and the computer system to select displays, to give commands, and to input data for limits, set-points, calculation parameters, etc. Text, for tagging or recording or sanctions, can be temporarily added to the displays, entered via the alphanumeric keyboard.

#### 40.9.4 Wall diagram

The large wall diagram also called Mimic board is used to give the operator an overview of the power system network. The large screen displays using LCD or projection technology serves the similar purpose. On the mimic board however, few details need to be given, as these are available on the VDU screens, whereas large screen or projectors can display the same level of information as on the VDUs with

all the full-graphic functions. A typical wall diagram can be used as a backup to the VDU system and, in addition to showing the network topology, it can also display the loading of the network with line load indicators. In their simplest form, the line load indicators give direction of power flow and load level in quartiles, by lamps or light emitting diodes. The wall diagram can also be used to display some alarms if, for example, a substation has an alarm state current or if it has been blocked from the telecontrol scan.

The drive unit for the wall diagram can be the main computer or a separate unit deriving the data direct from the communication servers. In the latter case, the wall-diagram system can serve as a back-up control system in the event of the main computer being unavailable. If a separate console is added, commands can be sent and a limited number of measurands can be displayed under emergency conditions. The large screen can be used as a full-fledged human machine interface. Wall maps or large screens are very useful when more than one operator are interested in monitoring a larger area of the network.

#### 40.9.5 Hard copy

Events and alarms are recorded for subsequent analysis on event and alarm printers. Printers and hard copying devices connected to the LAN may also be primary and backup devices. If any of the printer fails, the print message will be automatically directed to the alternative unit. The printers which operate at a lower speed are suitable for small amounts of data; however, output from a study program producing large quantities of data would be sent

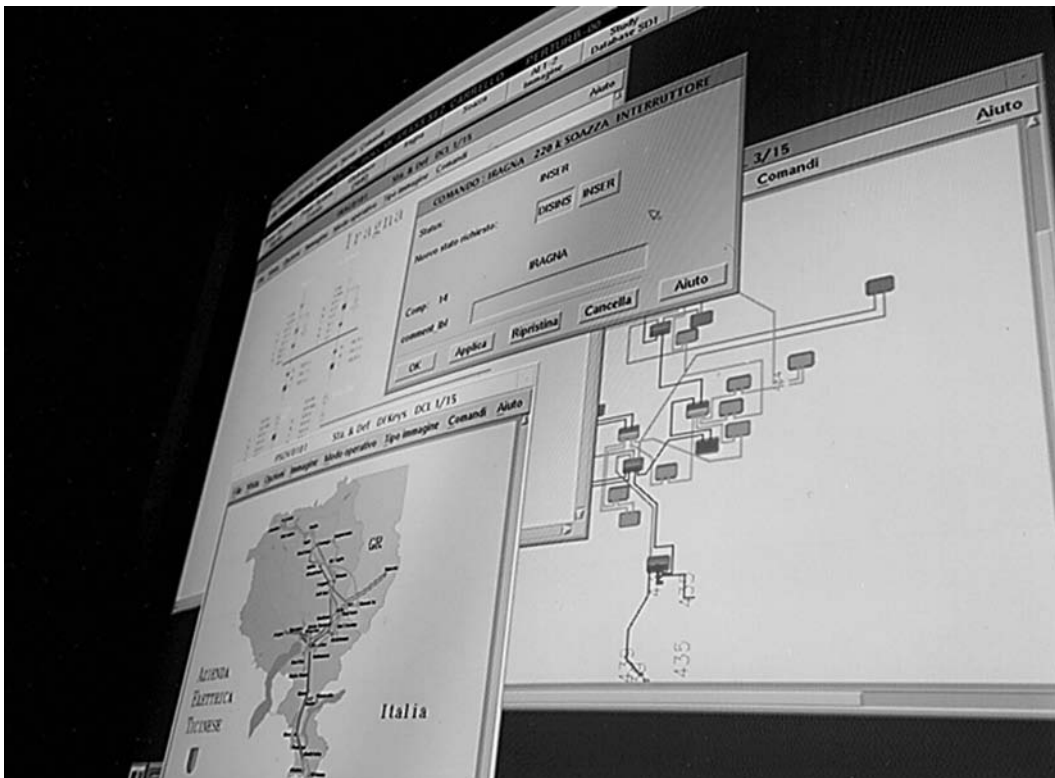

Figure 40.49 Layered and zoomed full graphic display windows

to high-speed printers. Modern laser printers, which can print graphics in addition to the alphanumeric characters, are used as printers in the control room. Typically event and alarm logs are printed on the slower printer on endless paper.

Other hardcopy devices are available that can copy either alphanumeric or graphic data displayed on the VDU screen, in colour to make a permanent record of a display existing at a particular moment. Such devices temporarily freeze the VDU picture and take a snapshot of the screen and then come back to continuous update mode. It is typical to have a VDU hardcopy in A4 or A3 format. For distribution networks hardcopies up to size A0 are plotted on large plotters.

#### 40.9.6 Software configuration

The software system of a computer based control system consists of many individual tasks which fall into three basic categories of real-time, extended real-time and batch or background processing. The programs of the real-time group, such as data acquisition, human machine interface, automatic generator control, etc., have to respond to external events within a given time. The response time of extended real-time programs, such as state estimation or economic dispatch control, is not so critical, though these programs work with real-time data. Extended real-time programs, and batch programs, have no stringent response time definition.

In a centralised network control system, there may be several hundred programs and subroutines all competing for the limited hardware resources; they must therefore share the computer time and store. Consequently, an overall co-ordination system is required to allocate the processor time and the memory space and access. A real-time multi-programming operating system and a database management system ensure that all programs can share the computer system *resources* and all data, without mutual exclusions and inter-program or data corruption.

The heart of an operating system is the real-time executive, which allocates the computer *resources*, in order of priority, to the programs requiring them at a particular moment. When *real-time* or extended real-time programs are required to run, they need high priority on the system *resources* including main memory space and processor time. The *executive* allocates the *resource* in order of priority by assigning partitions of main memory to a program and the appropriate input/output handler routines. When the higher priority programs do not require the *resources*, the batch (off-line) programs can run in turn. Programs can be interrupted at checkpoints in their sequence and be delayed while a program of higher priority is executed.

The priority control is *triggered* by hardware and software interrupts which can be externally or internally generated. The interrupts are assigned *levels* of priority. Several interrupts can be assigned to the same *level*, in which case they are *queued* to run when the resources are available to that priority level.

#### 40.9.7 Memory management

The main memory must be shared *between many* programs which cannot all reside simultaneously in the main memory. Thus they must be loaded into a partition of the main memory, from the mass memory (usually disc) when they are required to run. Once a program has been *executed*, the partition can be liberated for another program. The memory

management system governs the allocation of the main memory, which may also *require rearrangement* of the space already allocated to obtain a contiguous area for a partition large enough for a program that has been called to run. The operating systems of modern computers take over the memory management tasks and the memory allocation is done dynamically for multi-user and multi-process computing environment.

Programs that run frequently and need fast *response times* are normally resident in the main memory, as this avoids loading time from disc, which may be of the order of hundred milliseconds. It is obviously desirable to *keep the* disc access to a minimum, but it *becomes an* unavoidable overhead for programs that overflow their partition allocation.

#### 40.9.8 Input/output control

The operating system incorporates *peripheral device drive* routines, which are available for all application programs and can be called to read data from, or write data to, the *peripheral devices*. The driver conducts the communication with the device and reports malfunction or non-availability of the device. The operating system temporarily allocates the driver to an application program requesting it.

#### 40.9.9 Scheduling

Some programs (e.g. automatic generation control (AGC)) must run periodically, others must run at certain times of the day (e.g. daily log), and yet others after a certain delay (e.g. time outs). All timers for this program scheduling are available in the operating system, which also keeps track of the date. The computer time can be periodically *corrected by reference* to a 'standard' time unit external to the computer system. Typically this could be an input signal from a global positioning system (GPS) or a radio. The GPS provides a cost effective and accurate measurement of time. Using such a signal the time may be synchronised within a few microseconds of each other.

#### 40.9.10 Error recovery

An important part of the operating system lies in the *detection* of errors in hardware and software, and in taking subsequent action to *ensure the* security of the system. The errors may be *device errors* which, if the device is redundant, do not jeopardise the satisfactory running of the system. In the case of serious errors from which the system cannot *recover* (e.g. disc drive or a *recurrent parity* failure), the errors must initiate a switch-over to the standby machine.

At the detection of a power failure, the *executive* *arranges* that the contents of the volatile registers are stored in the non-volatile memory before the system halts. When the power supply is restored, the system can restart automatically under control of the executive, which restores the system to its former state. However, where program operation (e.g. data acquisition or AGC) is affected by an extended power failure, reinitialising is necessary.

#### 40.9.11 Program development

Throughout the life of the control system, power network extensions will have to be added to the database, and program development will be required without interference with the on-line systems. The operating system must permit and assist this work; hence it must include language

compilers (for languages such as FORTRAN, Coral, Pascal and Assembler, C, C++ as well as editing and debugging facilities. The present trend is to provide application-programming interfaces, which can be used by the programs in higher language, and the program developer does not have to take care of the physical layout of memory or location of the programs.

#### 40.9.12 Inter processor communication

If the control centre is a part of a hierarchical network control system and must be capable of exchanging data with its neighbour, a method of processor to processor communication is necessary. The communication system should have minimal effect on the computer system; thus it should have direct memory access to perform cyclic redundancy encoding and checking (CRC) with separate hardware logic and buffers. The security of the code should have a minimum hamming distance of 4 and automatic repetition of messages if errors are detected. Such types of mechanism are used by master station to RTU communication. In a hierarchical control centre the communication may also be based on protocols developed for such communication. Inter centre communication protocol (ICCP) developed by EPRI and adopted by IEC are a step in standardising this communication, irrespective of the supplier of the control centre.

#### 40.9.13 Database

The many programs and subroutines that make up the control centre software require access to data that, in many cases, are common to several programs. For example, the display update routines and the state estimation program both require the same measurands supplied by the data acquisition program. To avoid the necessity of passing data, created or acquired by one program, to many different programs that may require them, is more convenient, secure and economical to have the data stored once only. If the central data storage is organised and manipulated by a data management system, the data storage becomes independent of any application program. Data reorganisation then necessitates no modifications to the programs using the data, an essential requirement if developments and extensions are to take place economically and with the minimum interference to the working system.

The data base management system (DBMS) organises and keeps track of all system data and makes them available to any authorised program, through standard access routines. Thus, in a multi-programming environment, a certain discipline is imposed on the data users, which prevents accidental corruption of the system data. The management system also guarantees consistency of the data: for example, when an interdependent set of data are being modified, access by other programs must be prevented until modification is complete. To access the data, the user program holds the data access references and, when calling for the data, presents these references to the access routines. The access routines refer to a 'schema' that contains a unique definition of each data item in the database. Thus, as long as the references do not change, even though the data have changed their physical position, the user program is unaffected by database extensions or reorganisation.

In present day control centres the core functionality, which is time critical, is handled by a fast and robust database, which is in most cases a proprietary database. The slower information and large amount of data is stored

and managed by a commercially available Data Base Management system, which may be relational or object oriented in their approach. The advantage of commercial DBMS is their openness and ease of access for all the authorised users. Such databases may be physically distributed over several processors and can be accessed over local or wide area network. All the redundancy, security levels are configurable and the application layers are published and well established. Each developer may use these application-programming interfaces to the data.

#### 40.9.14 System software structure

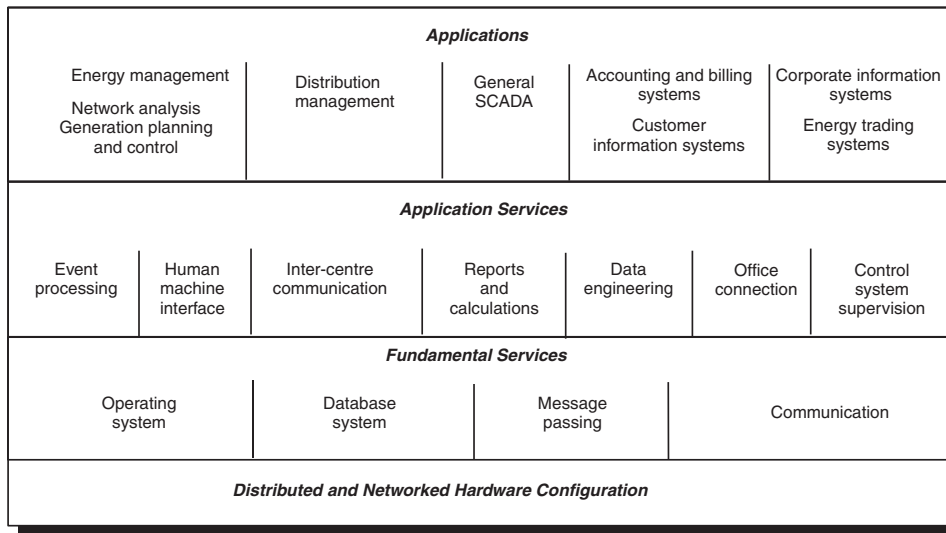

The power system network is continuously expanding as new lines and substations are commissioned. The software structure must allow the control system to expand in step with the network to include not only additional data but also the new network control facilities demanded as the complexity of the network increases. The software structure must therefore be flexible so that modifications or additions have minimal effect on the rest of the system.

The ideal method of achieving this goal lies in the modularity of all application programs, whose execution is organised by the operating system and by co-operating with other programs via the database (see *Figure 40.50*). However, with well established co-operating programs, in the interest of response time this is not always necessary or even desirable, thus, in certain cases, it is advantageous to exchange data directly between programs.

### 40.10 System operation

The various controls and the incidence of a vast number of disturbances make the operation of a system a very complex task. It is manageable only by the allocation of appropriate subtasks to different hierarchical levels; this breaks down the problems, which can then be handled effectively by man or machine.

So long as changes in load and topology, and fault incidence, appear as foreseen in the planning stage, the power system is able to maintain stable conditions through the action of decentralised control. This is true for protective devices and voltage, load and frequency control. However, whenever topological changes take place or become necessary, limits are reached or potential risks appear, control actions that cannot be handled at the decentralised level are imminent. This is where centralised control has to take on its important role. To what degree these control actions can be executed by automatic means is still an open question. The only centralised automatic control system is that for load frequency control (automatic generator control) together with economic dispatching. Switching operations, and start-up and disconnection of generators, are still subject to manual intervention. However, extensive support for the human operation is provided by the computer based control system. Primarily, it provides the real time information about incidents in the power system; next, it forecasts load development and the effects of possible faults, facilitating efficient decision making. Beyond that there is a host of control functions, which can be conceived as a black box, having a set of inputs and a set of outputs. They can be called upon by manual intervention or by another function. The output is available after the lapse of a certain response time. The mode of using these functions is either repetitive or event driven.

**Figure 40.50** Software configuration for control centre

As seen, most of these system control functions are implemented in terms of digital programs, i.e. by software. However, some functions are realised by hardware.

In order to illustrate typical software necessary for the control of a power system, the structure of the framework of functions is given in *Figure 40.51*. It comprises centralised control only, and is typical for the control centre of a utility. It shows distinct categories of functions that are characterised by: data acquisition (level A); dynamic control (e.g. frequency) (B); security assessment and optimisation (C); and adaptation (D). A common link is established by the databases (real-time, operation planning). Commands generated by the functions or originating from the human operator are executed via the telecontrol system).

### 40.11 System control in liberalised electricity markets

In most countries the electrical industry has been undergoing through drastic and dramatic changes. The institution of state-owned, protected, privileged infrastructure electrical industry has been abolished in almost all the industrialised countries. The electrical utilities have been structured in separate generation, transmission and distribution segments bringing in a transparency in the utility business. Depending on the market structure, the individual segments have also to compete in liberalised markets. The third party access gives equal rights of transmission system to each market participant. The control of transmission network becomes more complex due to third party access. In most of the countries the transmission system control is entrusted to a transmission system operator (TSO) or independent system operator (ISO). TSO/ISO may or may not own the transmission network but are responsible for system security and reliability. In addition to the system integrity the TSO has the main activity of enabling power transfer among various participants in the liberalised electricity market.

Such an operational scenario treats all the other services as auxiliary services. These services are to be organised, supervised and provided by TSO/ISO. The TSO has to control the

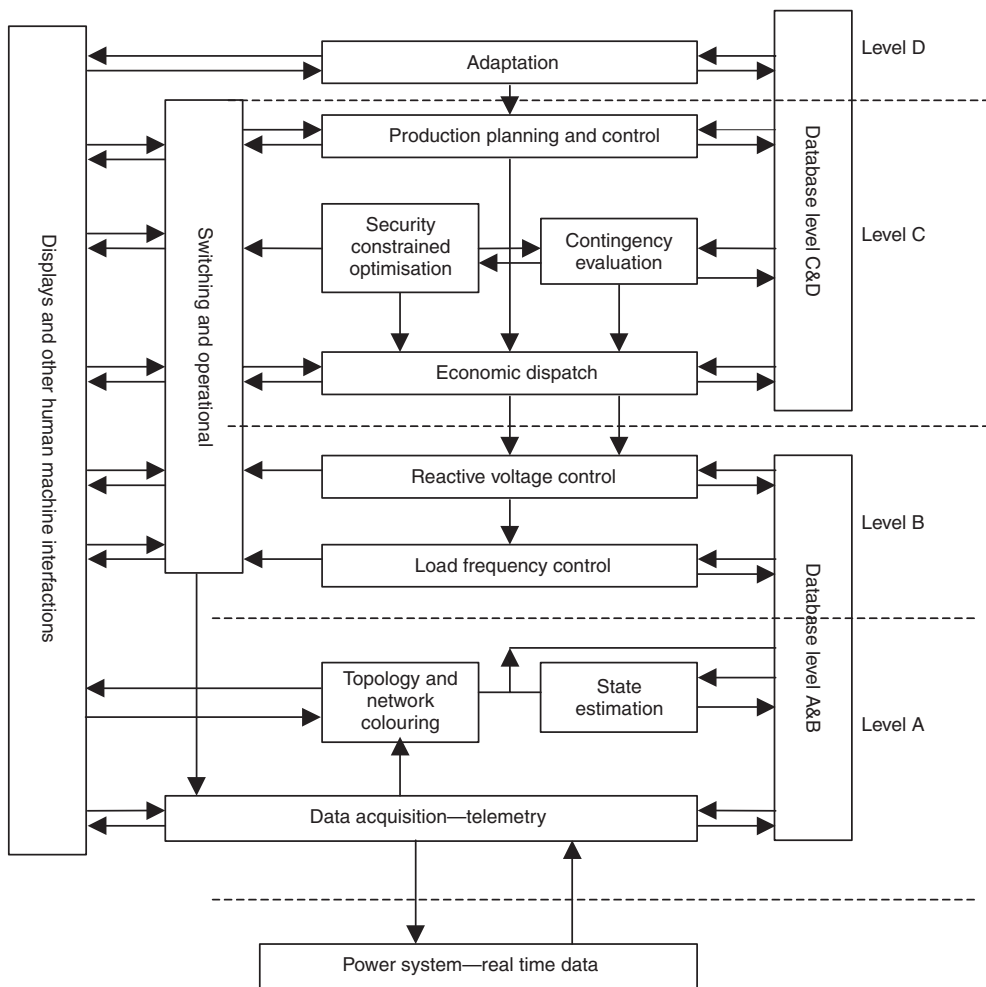

frequency, voltage, stability and loading of the transmission network. Under certain circumstances the TSO might have the job of system restoration or start-up. In order to fulfil these responsibilities the TSO must procure services such as automatic generation control, governor control, reactive power, operating and standing reserves, black-start capabilities, emergency control actions, and adjustment of inadvertent tie-line exchanges. In some markets the TSO may be responsible for compensation of grid losses and providing means to solve the transmission constraints.

In a vertically integrated utility the cost of generation, transmission and distribution was lumped together and passed on to end-user. In the liberalised energy markets each of these segments must have their own transparent cost structure. Depending on the market model in the country the transmission tariffs may vary. The transmission costing may vary from a simple postage stamp type model over MW-Mile method to full fledged load-flow based models. In most of the cases the TSO is responsible for setting up a fair and transparent tariff structure.

The congestion management, in classical vertically integrated electrical utility, was done by doing adjustment in generation or load. The increase of costs was absorbed in the overall cost of the operations. In the open access and liberalised market such a method is no more acceptable. There are organisational and analytical factors associated with the congestion management problem. The transmission constraints or congestion management problem becomes more complex when the wheeling of power is over the national boundaries. In such a case several TSOs in different countries may have to co-ordinate the transactions. *Figure. 40.52* shows interaction of TSO applications in a liberalised energy market.

### 40.12 Distribution automation and demand side management

The field of distribution systems, where the customer base is very heterogeneous and scattered over a wide area, open competition is forcing new ways to search for improved

**Figure 40.51** Framework of functions: software structure for a control centre

efficiency and better customer service, while rethinking the network operation. Distribution automation and demand side management (DA/DSM) provide solution to the efficient, reliable operation of the distribution utilities.

Distribution automation and demand side management has to be seen as a part of a holistic picture where the solution starts from network planning/refurbishment. The medium voltage breakers, substations, switchgears and along with the feeder automation, SCADA, automatic meter reading systems and load management systems are the other system components in the solution scenario. These are communicating with each other via communication systems specifically designed with requirements of distribution systems.

A distribution utility faces various challenges in this new liberalised energy market: The end-customer is free to choose its supplier in a non-franchised market. A combination of satisfactory services and competitive pricing is a must to survive. In open competition, efficiency and cost savings are critical for survival. Only well managed companies will have a chance in market driven scenario. Mandatory requirements imposed by the market regulator on energy distributor may make it obligatory to monitor power and prove

the quality of the electrical energy delivered. The political guidelines of the region or country for energy delivery must be adhered to.

For distribution systems planning and engineering are performed to optimise the refurbishment of the network or extension of the medium voltage networks. These studies and consulting services are necessary to optimise the investment, which is required for these activities without deterioration in the customer service. Substations, transformers and power lines to reach a desired level of power quality must be designed to make the best use of the existing resources. An integrated planning, design, installation, commissioning and maintenance of these vital components in a medium voltage system must be undertaken to get full benefit of DA-DSM activities. Distribution switchgears are to be designed for integrated communication and control and fulfil the needs of flexible control and operation.

Automatic meter reading (AMR) provides systems to collect meter values read over different communication medium and different generations of meters. AMR improves flexibility in meter reading periods and selective services to the end customer. Load profile provided by the AMR systems helps to plan energy consumption and distribution. Feeder

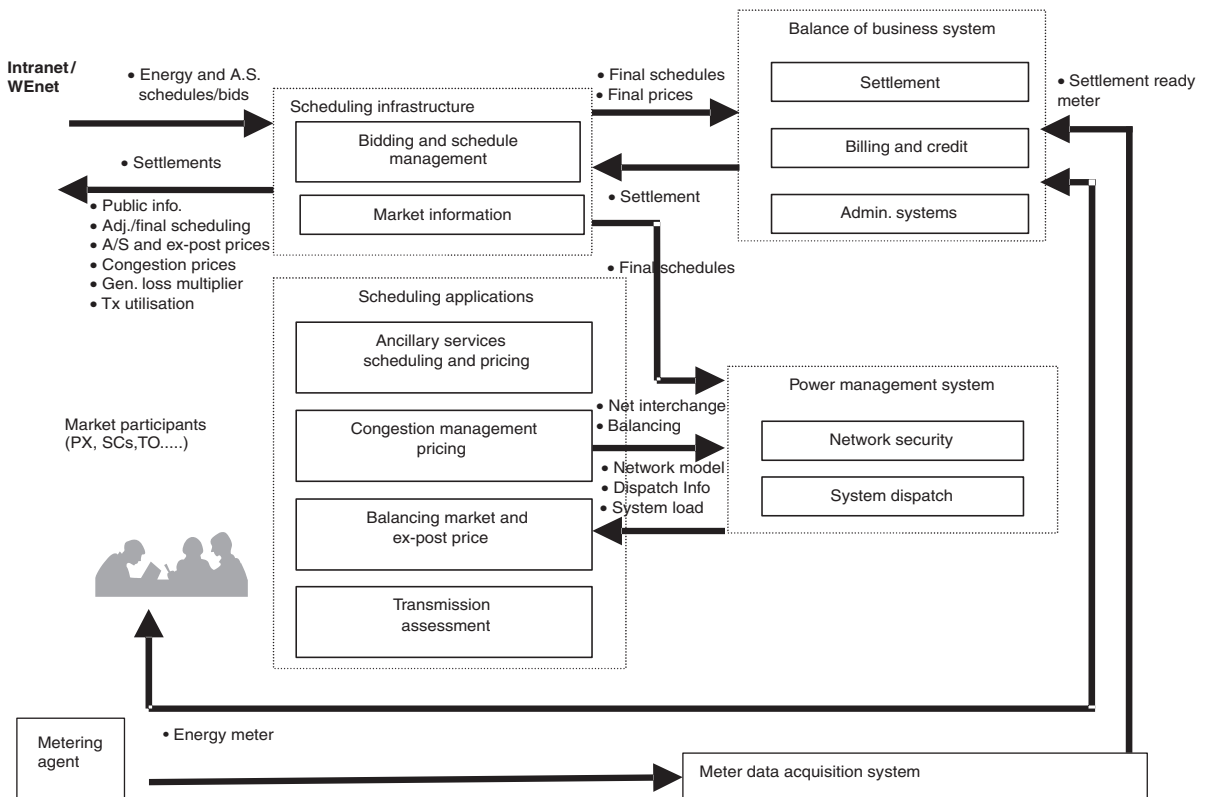

Figure 40.52 TSO applications in liberalised energy markets

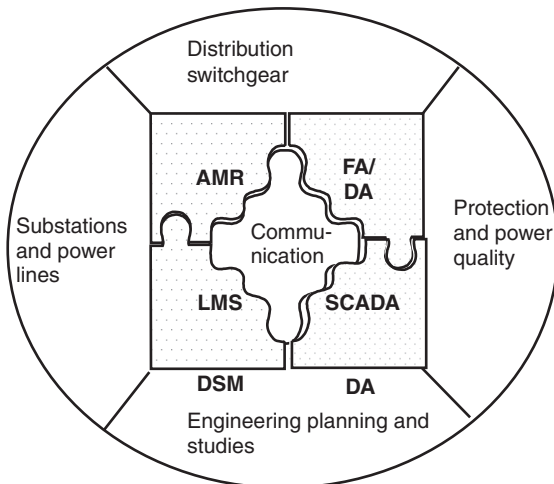

Figure 40.53 DA/DSM for distribution utilities

automation/distribution automation gives the possibility to integrate local automation with the co-ordinated customer services. The fault detection, location, isolation and restoration keeps the customer minutes lost to minimum. Automation further reduces the cost of operation by reducing the manpower required for system operation.

Load management systems actively support in the reduction of peak demand and improving the utilisation of available assets. Classical ripple control systems are now augmented by two-way demand side management systems to tailor each customer load as and when required. Supervisory control and data acquisition (SCADA) as used in the transmission system control centres must be extended to monitor and supervise distribution network. SCADA for distribution system is typically based on fewer measured values and gives possibility to keep an overview of the system in order to achieve a high level of reliability and safety. The advanced distribution management applications, on this platform empower distribution utilities to simulate, plan and optimise their operation.

Power quality is a major issue for a significant number of end-customers who need a very high level of availability and distortion free voltage supply. Various solutions based on powerful static components, advanced relaying and reclosure schemes, which help in maintaining a purer waveform by reducing dips and flicker and interruptible power supply.

Communication systems and gateways for distribution system are crucial for any DA/DSM system. The DA/DSM systems should have possibility to mix and match different physical mediums for data communication up to the customer premises. Depending on topography and performance requirement communication systems can be designed using heterogeneous media mixing DLC, radio, microwave, GSM, PSTN, PLC giving an optimum cost effective coverage.

The individual solutions for the distribution utilities must consider the requirements from each of these components to

achieve the best results for distribution systems in an open energy market.

## 40.13 Reliability considerations for system control

### 40.13.1 Introduction

The overall objective of power system operation, namely the provision of power to the customer at all times (i.e. with a high availability), places certain obvious requirements on the reliability and performance of power system components and their controls. Accidental events in the outside world (e.g. the atmosphere) that influence the system, failures of system components and imperfections of the control system including the operator can all affect the performance of the overall system and the final objective, and must therefore be taken account of. The positive or negative contributions of the generation, transmission and distribution systems should also be distinguished. For these subsystems, statistics on the failure rates, unavailabilities, etc., are given, and the question arises as to what degree system control in the widest sense can improve the performance of the system, i.e. the availability of power and energy.

In a more detailed analysis of an overall system with the objective as outlined above, a closer look has to be taken at the following:

- (1) the meaning of availability in a power system, particularly at the consumer's end;
- (2) the availability of components and subsystems;
- (3) the specification of reliability characteristics for the control functions;
- (4) the method of reliability analysis and of availability evaluation; and
- (5) availability optimisation considering certain cost constraints.

It should be implicitly understood that improvements in system performance can be achieved via both the heavy equipment and the control system. Since certain similarities exist in the procedures for both domains, the emphasis here is placed on the control side, where hardware and software have to be considered. In addition to hardware considerations, which are very often put in the foreground, we consider the treatment of data and manual interventions.

The main line of the given approach is the establishment of a functional relationship between the supply of power at the consumer's end and the characteristics of the control functions. Bearing this in mind, one can evaluate controls at all levels from protection to the system control centre.

### 40.13.2 Availability and reliability in the power system

Before working out various details, we discuss the meaning of the terms 'availability' and 'reliability' as applied to a power system. How these concepts are understood depends largely on the object, the location, etc., to which they are applied.

Here three points of view are considered; namely those of (i) the consumer, (ii) the utility, and (iii) the system specialist. Quite different considerations and requirements apply to the three domains.

#### 40.13.2.1 The consumer

At the consumer's end, i.e. at a single load point or at a supply point to a l.v. system, an availability in terms of up times and down times can be defined:

$$A = \frac{MUT}{MUT + MDT} = 1 - \frac{MDT}{MUT + MDT} = 1 - \bar{A}$$

where MUT is the mean up-time, MDT is the mean down-time,  $A$  is the availability, and  $\bar{A}$  is the unavailability.  $A$  represents an average fraction (per unit) of the time during which power and energy could have been delivered to the load point. In developed systems this figure reaches values of up to 0.9995–0.9997, so that the average down-time per year is as low as 2–4 h. This applies to single supply points and customers. The figure may vary from point to point and cannot be transferred to a complete voltage level or to the transmission system.

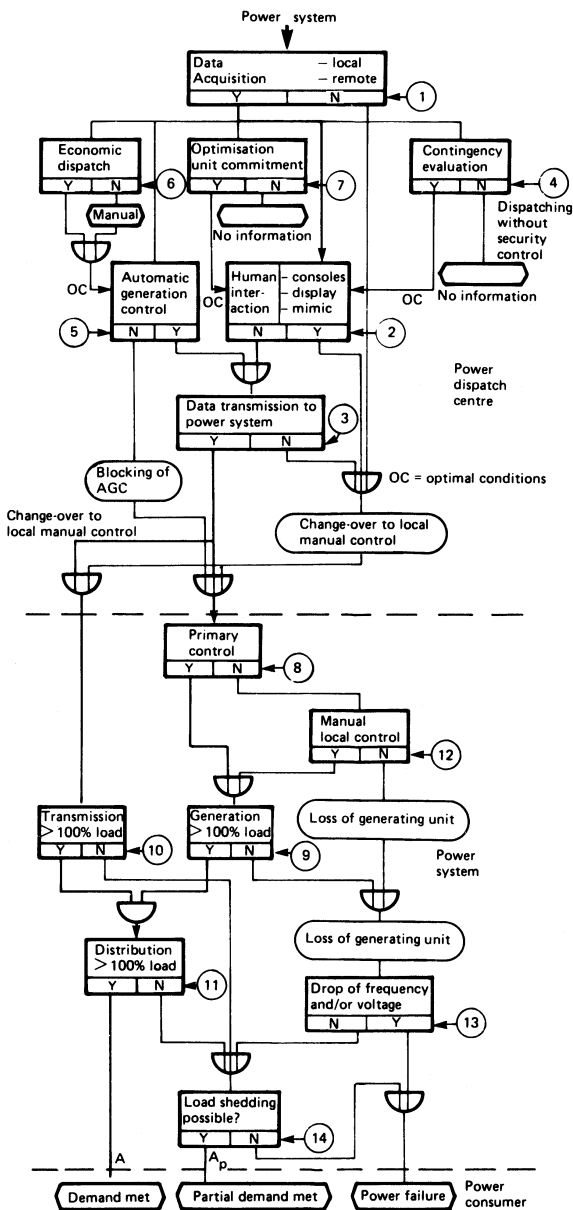

#### 40.13.2.2 The utility

Single outages at supply points and unavailabilities at the consumer's end are undesirable and should be kept to a minimum that is determined by economic considerations. Technically, however, the disconnection of single consumers has no detrimental effects on the overall system. There is simply a certain reduction of the load, which is balanced by the various control mechanisms. The utility must be interested to reduce these outages in accordance with its legal obligations, but its real concern lies in the continuous operation of the transmission and generating system. There, any disturbance that might endanger the overall system is to be avoided. There are concepts that measure the amount of non-served energy accumulated over a given period, e.g. 1 year, in terms of the maximum load multiplied by 'system minutes', where the system minutes constitute a measure of the unavailability of the system. However, this figure in minutes is of secondary importance to the utility as long as no complete breakdowns of the transmission system occur. This consideration is further supported by the fact that many utilities employ load shedding in order to avoid emergency situations. Load shedding also causes outages, so that consumers are not served, but it is done for the benefit of the integrity of the overall system.

So, what finally counts for the utility is the availability of the transmission system measured in terms of up and down times. Many utilities have remarkable records, i.e. availabilities of 100% over tens of years. However, there have also been catastrophic black-outs lasting for hours in utilities all over the world; these have received considerable attention and have motivated significant research efforts.

#### 40.13.2.3 The control specialist

Here, we consider the reliability aspects of control levels in a power system from a technical point of view. These aspects include protection and decentralised and centralised control. Clearly, improving the availability of control functions will improve the availability of the supply of power and of the system itself. However, the control specialist differentiates between flat improvement of a characteristic of control functions and augmentation of a parameter which might have significant effects on the system. Detailed investigation reveals that the power system is quite tolerant, as it can maintain its function in the absence of certain control functions, at least over a certain period. Hence, the control

**Figure 40.54** A CCC for the power system, its primary control and its system control centre

specialist is interested in identifying those elements and controls that contribute most significantly to the goal of system availability. There are, however, other elements which tolerate a lower availability or a reduced performance, and the control specialist must certainly take a broad view, i.e. he must also consider events and failures with low probability. In the end, it is the concerted effort of all types of control over a long period which constitutes success, i.e. the high performance of the power system under acceptable economic conditions.

To illustrate the interaction between disturbances and control actions on various levels, a cause-and-consequence

**Table 40.1** Details of the CCC in Figure 40.54

Circle	Cause	Consequences
1	Loss of transducers, telemetry system, front-end equipment	Loss of information on system state
2	Failure of computer or peripherals	Loss of information on status of substations, line loading, alarms
3	As for 2	No updating of set-points in power-stations
4	As for 2, loss of application program	No contingency evaluation, no security check
5	As for 4	No automatic generation control
6	As for 4	No economic dispatch control
7	As for 4	No operating planning unit commitment
8	Loss of auxiliary equipment in speed governor	No telemetered change in set-point
9	Loss of generation	Not sufficient reserve
10	Loss of transmission	Not sufficient transmission capacity
11	Loss of distribution	Not sufficient distribution capacity
12	Loss of generation	Reduction of reserve
13	Load demand not met	Load shedding
14	Load shedding not possible	Power failure

chart (CCC) for a power system with its primary controls and its system control centre is shown in Figure 40.54, and explained in Table 40.1. The CCC is the basis for any reliability analysis of a controlled power system. It reveals the causal relations between events and faults on the one hand and effects on the system on the other.

### 40.13.3 System security

The concept of system security is often discussed together with reliability considerations. It is primarily a deterministic concept which gives an answer as to whether the system can survive a given set of contingencies. It uses the model of system states as explained in Section 40.2 and load-flow techniques to check contingencies. In the basic concept, nothing is said about the duration of the various states (probabilities). However, the concept is amenable to extension to include this, and various approaches to the reliability analysis of the transmission and generation system have followed this direction.

Basically, a secure system is understood to be one that can withstand a number of outages, mostly single outages. This leads to the idea of  $n-1$  security, in which, out of

$n$  components, the disconnection of any component alone does not endanger the operation of the system

#### 40.13.4 Functions

To assess the various control functions and their contributions to the availability of the power system, it is necessary to know their structure and framework as given in Figure 40.51, though with much additional detail and an allocation to the various hardware components. On the basis of such a structure and its functional relations, the possible contribution of the control system could be assessed by a simulation. In principle the following relations must hold.

The contribution of a *perfect* control system to the availability  $A$  is given by

$$A = A' + \Delta A_0$$

where  $A'$  is the availability of the uncontrolled power system and  $\Delta A_0$  the possible contribution of the control system. A *real* control system, however, has itself got a finite availability  $A_c$ ; hence

$$A = A' + A_c \Delta A_0$$

The availability  $A_c$  of the control system can be derived from the various functions  $f_j$  and their individual functional availabilities  $A_{cj}$  under the assumption that certain stationary probabilities  $g_j$  are known which give a rate at which the function  $f_j$  are called upon. The probabilities  $g_j$  must add up to unity:

$$\sum_j g_j = 1$$

then

$$A_c = \sum_j g_j A_{cj}$$

$A_{cj}$  is a functional availability that applies directly to a so-called 'real-time' (RT) function. Its contribution comes from its on-line operation. It is called upon whenever an event bearing some risk for the power system arises. In contrast, so-called 'preventive' (PR) functions condition the system for the event in advance. Their operation does not coincide with the appearance of the event, and the control function is not needed in the event. Thus, there are less stringent requirements for the actual availability  $A_{aj}$  of such a function. For a more detailed discussion of this subject, see references 1 and 2.

#### 40.13.5 Impact of system control

At this point, the question arises as to the possible contribution of system control to the availability of the power system. The answer would be of great value for the design of control systems, telecontrol equipment, regulators and control centres. However, a complete assessment for a real system seems impossible. With the help of a mathematical model, though, a limited answer can be given, at least in terms of the relative merits of the various functions. The treatment of such a model requires a Monte-Carlo simulation of the system behaviour over sufficiently long time periods.

**Figure 40.55** Effectiveness of different functions. +, Mean value (five simulation runs); [ , range of results assuming small uncertainty within the failure data; ], range of results assuming large uncertainty in the failure data

Such simulations prove that the performance of the power system can actually be improved, although the degree of improvement will depend upon the inherent performance, the loading, redundancy, etc. (for details see reference 3). It can also be shown that the distinction between RT functions and PR functions is well justified. It turns out that repair plays an important role for the PR functions, which is further supported by the fact that the requirements for control change with the daily load cycle. Stress situations appear two or three times per day. In between, the system can be conditioned for a possible event. A PR function need not be available at a specified time but can be delayed. Thus, repair is possible.

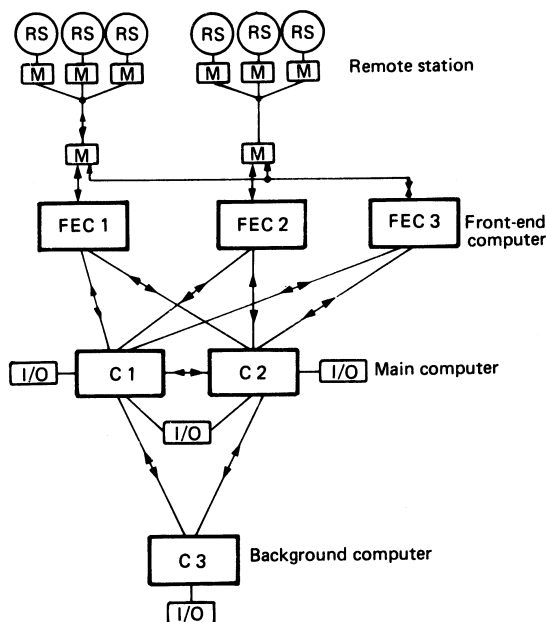

In order to give an idea of such a result, an example from reference 3 is presented in Figure 40.55. The figure and its enlarged section show the increase in the availability of energy as a function of the categories of control functions. Clearly, the most significant improvement can be achieved by the basic functions of system control like SCADA. Further improvements are harder to realise, but some gain is still possible. The remaining unavailability is due to the particular structure of the test system. It is an isolated system with a peak load of about 4000 MW. The system was assumed to be heavily loaded. Thus, control had a limited effect because of the lack of reserves in the system.

#### 40.13.6 Conclusions

As far as the performance of a power system as expressed by its availability is concerned, three domains have to be considered: (i) the generation system and its reserves; (ii) the transmission system; and (iii) the control system. Assuming that the first two systems are fixed, it has been shown that system control will improve the performance. Quite detailed studies are necessary in order to evaluate the contributions of the various control functions. In such a treatment the final question concerns the configuration of the computer system.

Over the years one basic set-up has evolved which has not changed very much and seems to prove its validity as time goes on. It is the multi-computer concept on three levels having several front-end computers, a double system on

**Figure 40.56** Hierarchical and redundant multi-computer system with three levels: I/O, input/output; FEC, front-end computer; C, main processor; M, modem; RS, remote station

the main level and a background computer. The configuration is shown in Figure 40.56.

## 41.1 Introduction

When designing a transmission or distribution system or studying its operation, the engineer must take into account not only the power requirement of the loads, but also the fact that they consume reactive power and, equally important, that the networks include inductive and capacitive elements which themselves absorb or generate reactive power. In contrast to power, which is generated and consumed in a controlled manner only at specific points in the networks (ignoring losses), reactive power is generated and absorbed throughout the network in significant quantities which vary with the system loading and configuration.

Growth in the demand for energy, the development of competition for the production and supply of this energy, together with increasing opposition to the construction of new overhead power lines, make it increasingly important to improve the utilisation of existing assets. However, there are constraints on the operation of power systems that often result in under-utilisation of their assets.

For a power system to operate efficiently and securely, the importance of the correct and co-ordinated provision and control of reactive power cannot be overemphasised. It is necessary to examine reactive power requirements under both steady-state and dynamic conditions. Although it has been normal in the past to consider these requirements separately, it is preferable that they should be dealt with in a well-co-ordinated way.

'FACTS' is an acronym for 'Flexible AC Transmission Systems', which is defined as 'alternating current transmission systems incorporating power electronic-based and other static controllers to enhance controllability and increase power transfer capability'. Many of the reactive

power plant items described in this chapter are covered by this definition. FACTS equipment that provides control of one or more of the parameters of an electrical network is often referred to as a FACTS controller.

The International Electrotechnical Commission, IEC, has defined the unit for reactive power as the 'var' (volt-ampere reactive) and uses the name 'vars' for reactive power. For brevity, the IEC terminology will generally be used within this chapter.

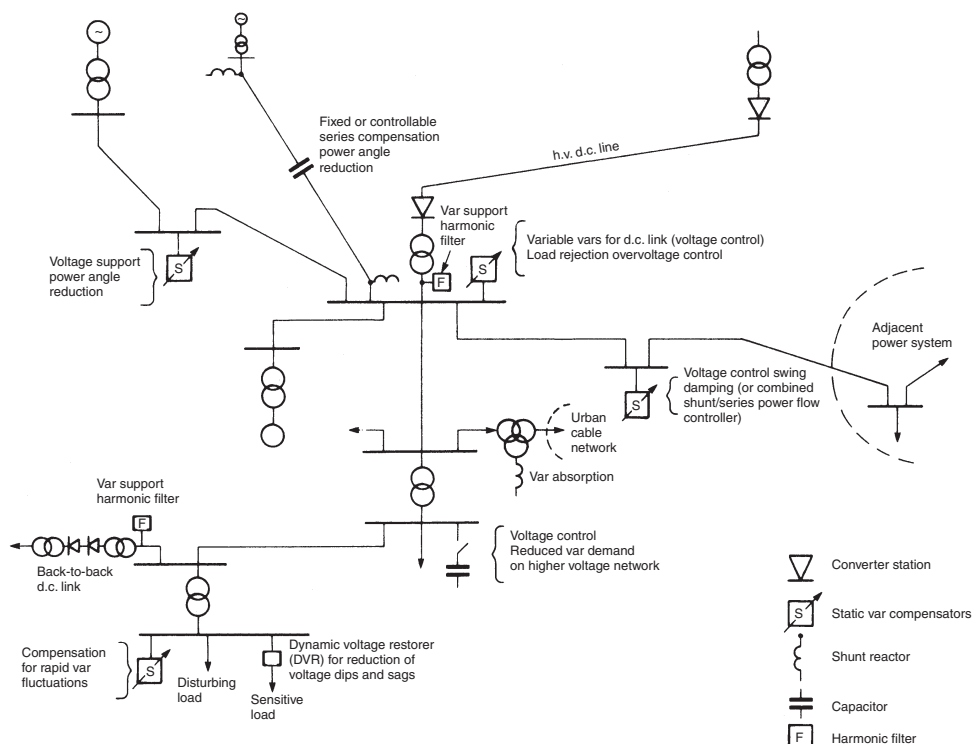

## 41.2 Basic concepts

In electrical power systems, electrical energy is produced by generators, transferred by means of transformers into a transmission system by which it is conveyed to distribution systems and supplied, again via transformers, to the users of the energy. *Figure 41.1* shows a system where different components and reactive power devices have been combined to illustrate the main features of var supply and demand in such a power system. The characteristics of individual components and the methods of network analysis are covered in other chapters. The following sections outline the characteristics and parameters relevant to the management and supply of vars, network voltage control and reactive compensation.

### 41.2.1 Characteristics of system components

#### 41.2.1.1 Generators

The main generator parameters relevant to the var balance in a system are the transient reactance and the short-circuit

**Figure 41.1** Applications of FACTS controllers in a flexible transmission system

ratio (SCR, which is approximately the reciprocal of the synchronous reactance). Where transient stability is to be examined, or where var control is required to be used for the damping of system oscillations, the inertia of the turbine-generator combination also needs to be known.

To obtain economies from standardisation, many manufacturers of turbogenerators will offer a machine from a standard range of frame sizes; different combinations of megawatts, rated power factor and short-circuit ratio are possible with each design of the range. The characteristics and capabilities of each generator must be allowed for in considering the overall var balance for a particular system.

The frame size of a generator depends upon its megavolt-ampere (MVA) rating; hence, the cheapest design for a given megawatt output would be one rated to operate at unity power factor (pf). However, unity pf operation may not be acceptable for stability and optimum operation of the network. Operation of a generator at a lagging power factor, i.e. when generating vars, requires a higher level of field excitation than at unity pf; this reduces the generator load angle for a given power output. To prevent a generator losing synchronism during angular swings following a system disturbance, it is desirable to operate it in steady state with an adequate margin of load angle from its stability limit. A typical cylindrical-rotor turbogenerator will have an SCR in the range 0.45–0.6; this would require operation at around 0.9–0.95 lagging pf, as shown in the capability chart in Figure 41.2, if the generator is feeding into a reasonably strong system. Under these conditions the generator will be supplying a significant amount of vars to the system, amounting to 0.48–0.33 Mvar/MW of output.

When it is necessary for a generator to absorb vars (i.e. to operate at a leading pf), as occurs during light load conditions for generating stations supplying remote load centres through long high-voltage lines, the field excitation must be lower than that at unity pf. The generator must then be designed to maintain stability, which requires that positive excitation is needed under all conditions. This gives a design with an SCR of, say, 1.0–1.5. Such high values are common in salient-pole low-speed generators in hydroelectric stations, which account for most such applications. Such a high value is unusual in round-rotor turbogenerators and would require an unusually large machine for the MW output. It may be more appropriate to provide var absorption equipment within the transmission network in these circumstances.

The proportion of the system var requirements supplied by generators varies from system to system. In many systems,

the high-voltage transmission network has a surplus of vars, i.e. its shunt capacitance generates more vars than are absorbed by the  $I^2X$  losses in its series reactance—even under maximum-demand conditions. This allows the generators to operate at high power factors, even if the system loads themselves have low power factors. The operating pf may, in practice, be dictated more by stability than load requirements and it is quite usual for generators to be operated at a lagging pf higher than their rated value.

#### 41.2.1.2 Transformers

Although generators are now becoming available which are suitable for connection directly to system voltages of 145 kV and higher, in most cases it is necessary to couple the generator to the transmission system by means of a transformer. Similarly, transformers are used to reduce the voltage level at the points of connection of the distribution companies and again for the supply of individual customers or groups of customers. They are also used between the different voltage levels used by the transmission company, or companies.

The transformer leakage reactances have great significance for the operation of the transmission system. Although the power loss and magnetising current of a transformer can be neglected when considering var flows, the var absorption in its leakage reactance (given by  $I^2X$ ) is important. During temporary network overvoltages, transformer cores may become saturated, resulting in abnormally high magnetising currents. Although the increased var consumption will assist in reducing the overvoltages, harmonic currents will be generated. In flowing through the network, these currents may excite undesired resonances which themselves can cause overvoltages.

On-load tap-changing of transformers is a useful function in the co-ordination of var control between various voltage levels within a system and for balancing var flows within a single voltage level. Two distinct practices occur with transformers used to interconnect different transmission voltage levels in a single system; a number of authorities, with a view to using transformers having the highest reliability, install fixed ratio transformers, whereas others use on-load tap-changers having a typical total range of 20–30%. For the interconnection of transmission networks to sub-transmission or distribution networks, the use of tap-changing transformers is almost universal.

#### 41.2.1.3 Transmission lines and cables

Transmission lines and cables absorb vars in their series inductance. They also have an inherent capability to generate vars by their shunt capacitance, which causes a reactive 'charging current' to flow into the line. Both the series inductance and the shunt capacitance are distributed along the length of the line.

From the analytical point of view, cables are indistinguishable from overhead lines except that the ratio between shunt capacitance and series reactance is considerably higher. The use of cables in high-voltage networks is increasing because of the difficulties of building new overhead lines for electrical power transmission into urban areas and, to a more limited extent, for a.c. underwater links; the use of cables is still very small compared with overhead lines because of the cost disadvantages. Where cables are used in any quantity, their high shunt capacitance reduces the need for additional var generation at peak demand periods but

Figure 41.2 Generator capability chart

increases the need for var absorption during low loading conditions.

When there is no load current flowing through a line or cable, it is found that the voltage at the receiving end of the line is higher than that at the sending end; this is caused by the flow of the capacitive charging current through the series inductance and is known as the Ferranti Effect. The magnitude of the voltage rise increases very rapidly with increasing length of the line, from only about 3% for 200 km to about 50% for 800 km. The magnitude of such a voltage rise within a transmission system must be limited (generally to either 5 or 10% above rated voltage), in order to avoid exceeding the safe limits of operation for the insulation of the line or cable itself as well as the safe limits for the various equipment connected to the transmission system. Very long lines are normally split into sections 200 to 300 km long; voltage or var control measures can then be applied at the intervening substations, if required.

As the power flowing through the line is increased, the var absorption in the series reactance also increases. There is a critical current at which the magnitude of 'series vars' absorbed in the line is just enough to balance the 'shunt vars' generated by the shunt capacitance of the line. With this level of power flow, the line voltage will have the same value all along the line (neglecting resistive losses). When there is a further increase in power flowing through the line, the vars absorbed will outweigh the vars generated and the voltage at the receiving end of the line will start to fall very rapidly with increasing load and may reach the point of complete collapse.

The surge impedance of a transmission line having series inductance  $L$  and shunt capacitance  $C$ , is a resistance equal to  $\sqrt{(L/C)}$ . If a load that has this value of resistance is connected to the end of the line, the power that flows into the load is called the surge-impedance load or SIL. This is the load, mentioned above, at which the var absorption in the series reactance equals the var generation in the shunt capacitance, and for which the voltage along the line is constant. For a given surge impedance, the SIL increases in proportion to the square of the line voltage.

The value of surge impedance for a 132 kV line is about 400  $\Omega$ . For higher voltage systems, multiple conductors are normally used, in part to reduce corona effects, and the series inductance is also somewhat lower, giving a surge impedance of about 250 to 300  $\Omega$  for a 400 kV line. One effect of choosing an increased transmission voltage is to reduce transmission losses at a given power flow, but another effect is to enable an improved power transmission capability per right of way. In selecting a transmission voltage, therefore, a balance must be struck between equipment costs, operating costs and future capacity.

The SIL of typical cables usually exceeds their rating, so that cables generate more vars than they absorb and compensation is often required. This imposes a limit to the uninterrupted length of cable that can be used; for example, for submarine cables the limit is typically 50–75 km before the capacitive charging current reaches the current rating of the cable.

Cables that use cross-linked polyethylene (XLPE) insulation are now available for transmission voltages of 400–500 kV; for a 400 kV, 1100 MVA XLPE cable design, the SIL is about 2500 MW, which is still much higher than the rating. Nevertheless, these cables generate rather less charging current than the earlier types and allow uninterrupted lengths of up to about 100 km. Where longer distances are required, another solution becomes necessary, for example, h.v.d.c. or a gas-insulated transmission line (GIL).

Most countries have two or three transmission voltage levels within their systems, the highest normally being in the 400–500 kV range, with a few countries in North and South America and the USSR operating or installing networks in the 750 kV range. Although the use of u.h.v. at 1000–1500 kV is technically feasible, the expense is high and its commercial application seems likely to be limited for the foreseeable future.

#### 41.2.1.4 Loads

In general, loads are inductive and their power factor can vary widely, dependent on *type*, from industrial through commercial to domestic loads, and on *location* (for example, commercial and domestic loads in hot climates have an increasing proportion of motors for air conditioning). For most studies, load representation as constant impedances (or constant  $P$  and  $Q$ ) is adequate but, when studying dynamic conditions involving wide variations in voltage, a more detailed representation that allows for changing power factors will be required. Power-factor-correction (pfc) capacitor banks located in load and distribution networks should also be taken into account in any studies.

Air-conditioning and many industrial loads use induction motors; when these comprise a substantial proportion of the total load on a network they display a typical voltage stability challenge. A short interruption due to a fault causes each motor to slow down. When the fault is removed and the voltage re-established the motor tries to regain full speed but, because of the increased slip, there is an increased var demand. The effect of many such loads is to depress the system voltage so much that recovery from a fault is slow and, in extreme cases, voltage collapse stability may be threatened and all load motors may stall.

Loads that can produce network disturbances or distortions require special attention. These are, in the main, found in the metal and mining industries and in a.c. traction systems; the large and rapid fluctuations in the load currents of arc furnaces and large thyristor drives, particularly their fluctuating var demands, can cause annoyance to other customers. These loads often also cause problems due to the generation of harmonics.

### 41.3 Variations of voltage with load

For each part of a power system it is necessary to define a nominal operating voltage and also a maximum operating voltage, which is usually 5% or 10% higher than the nominal voltage; these voltages are used in establishing the rated voltages of circuits and components. The rated MVA capacity of each circuit or component is then determined on the basis of its rated current and rated voltage. When an item is required to operate at its rated capacity but at less than its rated voltage, the current will exceed its rated value; this overload condition may only be acceptable for limited periods when the ambient temperature is less than the defined maximum value.

It is therefore usual to try to operate a system in steady state so that the voltage is constrained, throughout the system, to be within a very few per cent above or below its nominal value. Wider deviations of voltage are inevitable during and following faults and other disturbances. The most severe transient and switching overvoltages are usually limited by means of surge arresters; slower, dynamic or long-term, overvoltages and undervoltages may require var compensation equipment to reduce their magnitudes and durations to acceptable levels.

### 41.3.1 The flow of power and vars

Electricity supply networks have predominantly inductive series impedances. *Figure 41.3(a)* shows an elementary circuit in which a load is supplied from a generator via inductance,  $X$ . The generator output voltage,  $V_S$ , is constant; the voltage at the load is  $V_R$ . When there is no load, the voltages  $V_S$  and  $V_R$  are equal in magnitude and phase. When a load is connected it will draw a current,  $I$ , through  $X$ .

*Figure 41.3(b)* shows the vector diagram for a resistive load;  $I$  is in phase with  $V_R$  and  $\phi = 0^\circ$ . If the value of the load resistance is  $R$ , the power is  $P = I^2 R = V_R^2 / R$ . The voltage drop through the reactance  $X$ , is  $\Delta V = I X$  and is in quadrature with  $V_R$ . It causes a phase angle difference,  $\delta$ , between  $V_S$  and  $V_R$ . Also,  $V_R$  is smaller than  $V_S$  because of the vars ( $Q = I^2 X$ ) consumed in  $X$ .

*Figure 41.3(c)* shows the vector diagram for a purely inductive load, with  $I$  lagging by  $\phi = 90^\circ$  behind  $V_R$ . The voltage drop through  $X$  is now in phase with  $V_R$ , which therefore remains in phase with  $V_S$  but is appreciably smaller. *Figure 41.3(d)* is the general case, with a lagging power factor load that causes differences both of phase angle and magnitude between  $V_S$  and  $V_R$ .

These examples illustrate that, when power flows through inductive impedance from one point to another, it is accompanied by a difference in the phase angles of the voltage at those points. Var flow between two points is accompanied by a difference in the voltage magnitudes at those points. It is important to bear in mind that these features may be expressed in the converse way. Thus, when a difference in phase angle is enforced between the voltage vectors at two points in a network, power will be transmitted from one point to the other; by enforcing a difference between the voltage magnitudes at the two points; var flow will take place. Put simply, differences in phase angle control the flow of power and differences in voltage magnitude control the flow of vars. This is a highly simplified, but crucial, description of the principles of a.c. power transmission; reference should be made to Chapters 3 and 35 for the theoretical background.

### 41.3.2 Voltage instability

*Figure 41.3(e)* plots the relationships between power, vars and current supplied by the generator, together with the load voltage,  $V_R$  for the purely resistive load illustrated by *Figure 41.3(b)*. As the magnitude of load resistance,  $R$ , is reduced, the current, power and vars each increase at different rates, but  $V_R$  decreases. When  $R$  is equal to  $X$ ,  $P = Q$ ,  $V_R = V_S / \sqrt{2}$  and  $\delta = 45^\circ$ . For this load resistance, the power has its maximum value, given by  $P_{\max} = V_S^2 / 4X$ . Any further reduction of resistance will cause a further reduction of  $V_R$  and also of  $P$  whereas  $Q$  continues to increase. *Figure 41.3(f)* plots the relationship between voltage  $V_R$  and power  $P$  and shows how important it is, for the stable operation of a system, that voltages at load points should not be allowed to drop below certain limits. If the load voltage falls too far, the condition can become progressively worse, leading to a complete collapse of voltage. Such voltage instability is more prone to occur in systems with large inductive impedances and can be exacerbated by loads that tend to consume constant power and vars irrespective of the magnitude of their supply voltage. Loads of this kind include those that are supplied by transformers with on-load tap-changers, when the tap-changers have an automatic control which attempts to maintain a constant secondary voltage.

*Figure 41.3(g)* shows a family of voltage-load curves for different power factor loads, including the unity pf case of *Figure 41.3(f)*. When the load current has a lagging component, i.e. is at less than unity pf, the maximum power capability will be smaller and the voltage for a given load will be reduced compared with *Figure 41.3(f)*. For a particular power factor curve and for any power less than the maximum there are two operating points; points  $A$ ,  $A_1$ , etc., are stable (i.e.  $dV_R/dP$  is negative) and points  $D$ ,  $D_1$ , etc., are unstable. The upper, stable, values represent possible system operating conditions; however, if the load is increased, or the load pf is decreased, the operating point moves towards the 'nose' of the curve, accompanied by a progressive reduction in voltage, which tends towards a complete collapse of the system.

*Figure 41.3(g)* includes the interesting result for a load with a leading pf. This increases both the load voltage and the maximum load that may be transferred.

The phenomenon of voltage instability has been the cause of, or a contributory factor in, a number of major system failures. The adequate provision and the correct control of the network var resources can play a vital role in preventing voltage instability.

### 41.3.3 Var balancing for steady state conditions

It is clear from the previous sections that there are significant benefits in local balancing of load vars by power factor correction. In addition to the improvement in load voltage conditions, the magnitude of the load current is reduced, which reduces transmission losses and releases circuit capacity for increased power transfer. Capacitors draw a reactive current that leads the voltage across their terminals and shunt capacitor banks provide a relatively economic means of improving the power factors of loads connected to a power supply system especially if the load is constant, or almost constant. When there is a slow variation of the load, shunt capacitors may be switched into or out of service to provide an approximate balance of the load vars. When the load varies quickly, it can no longer be regarded as 'steady state' and a compensating system that can be quickly controlled to counteract the load fluctuations must be used, as will be described later.

It is also clear that, if the vars absorbed in the supply inductance were to be reduced by series var balancing, the effective inductance of the supply would be reduced. The adverse effects of both active and reactive currents would then be lessened and the stability margin could be increased.

### 41.3.4 Power transmission over long distances

The use of reactive compensation to improve transient stability and so increase the amount of power that can be transmitted over given transmission lines is discussed next. In contrast to the example of a simple load discussed above, it is usual for machines to be present and to provide voltage sources within the systems at each end of the line.

### 41.3.5 Transmission characteristics

A number of performance features are associated with long distance transmission.

At light loads which are only a small fraction of SIL, or at energisation of the line from one end only, the distributed inductance and capacitance of the line can cause a large over-voltage due to the Ferranti effect; this must be countered by either (a) reducing the vars from the line capacitance

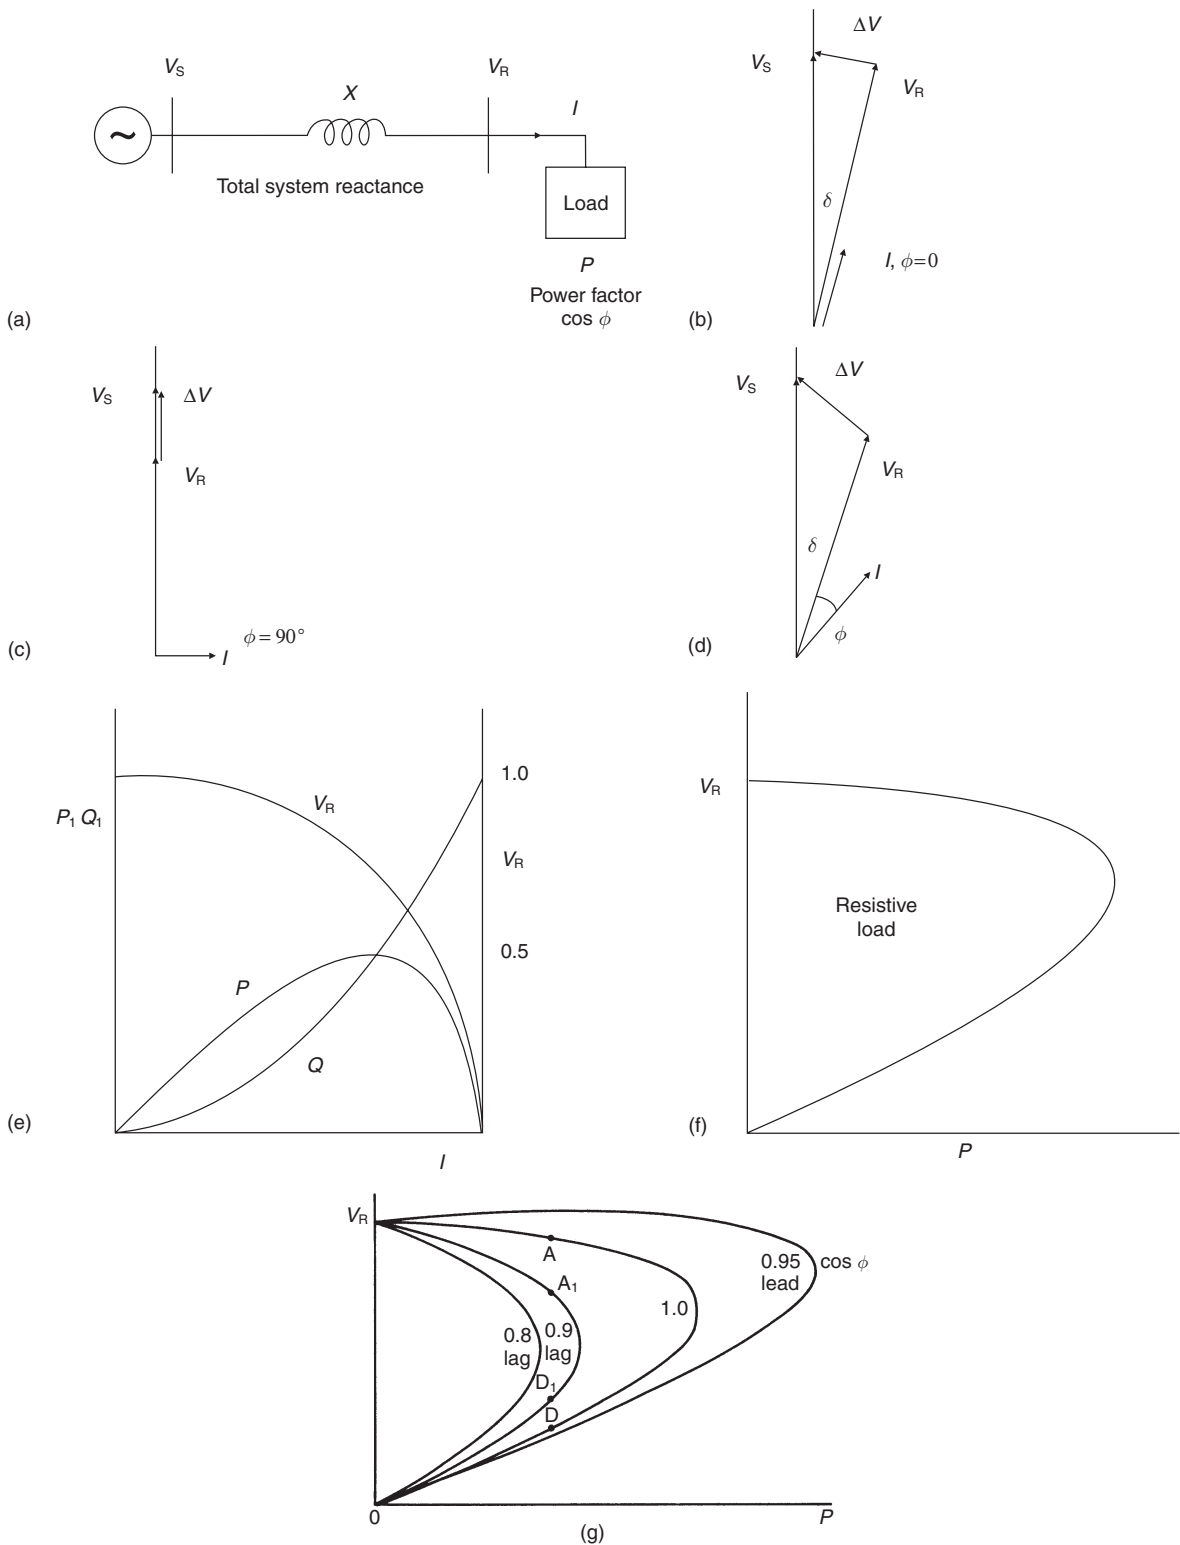

Figure 41.3 Transmission line voltage/load characteristics

by shunt reactive compensation, or (b) cancelling part of the line inductance by series reactive compensation.

The maximum power that can be transmitted down a long uncompensated line is limited by its series inductance and by the line surge impedance. Increase in transmitted power can be achieved by series or shunt reactive compensation.

Figure 41.4(a) represents a long transmission line, with a total series inductive impedance  $X$ ; to simplify this illustration, the effect of the line shunt capacitance is ignored. In Figure 41.4(b) the voltages  $V_S$  and  $V_R$  at the two ends of the line are assumed to be maintained constant and equal for all values of current,  $I$ . As the current increases, so does the angle,  $\delta$ , between the voltages. The voltage at the mid-point of the line will be

$$V_M = V_S \cos \delta/2$$

and, with  $V_S = V_R$ , will be in phase with the line current.

The power flowing through the line will be

$$P = V_M \cdot I = (V_S V_R / X) \cdot \sin \delta = (V_S^2 / X) \cdot \sin \delta$$

As shown in Figure 41.4(c) the transferred power rises to a maximum (given by  $P_{\max} = V_S^2 / X$ ) as the angle  $\delta$  reaches  $90^\circ$ . The power decreases as  $\delta$  increases beyond  $90^\circ$ . It may be noted that control of the load voltage has doubled the power obtainable in the simple case illustrated in Section 41.3.2 where  $V_R$  is not controlled.

The shunt capacitance of a practical line will have the effect of increasing the voltage at all intermediate points along the line, including the mid-point, and consequently will give a corresponding increase in the maximum power.

However, the voltage rise must not be allowed to exceed the maximum operating voltage of the system under no load or light load conditions.

Owing to the inertia of the rotating machines connected within the networks at either end of transmission lines, any system operating near its steady-state stability limit (corresponding to the phase angle of  $90^\circ$ ) is bound to become unstable following a major disturbance, due to the ensuing increase of phase angles. It is therefore necessary to design a line to be able to transmit more than pre-fault power up to the point of maximum angular swing. Consequently, sufficient var generation must be available to compensate for the increased var consumption by the line current at increased phase angles. Thus, for transient stability to be secured, some excess var generation must be available. This can be achieved either by operating the line sufficiently below its surge impedance power before the fault or by adding var generation transiently for the period in which the line phase angle will be abnormally increased. However, without adequately fast voltage control along the line, either solution can lead to dangerous overvoltages, particularly under the condition of a severe 'back-swing' (i.e. a transient phase condition when the power transmitted is much less than the pre-fault level) or during a load rejection situation consequent to loss of stability.

Then the total vars  $Q$  to be absorbed from the line when operating at a voltage  $V$  and power  $P$  approximates to  $Q = Q_0 [V^2 - (P/V)^2]$  where  $Q_0$  is the vars generated by the line shunt capacitance,  $C$ , at rated voltage  $V_1$ . Here  $P$ ,  $Q$ , and  $Q_0$  are expressed in per-unit of the SIL,  $P_S$ , and  $V$  is expressed in per-unit of  $V_1$ .

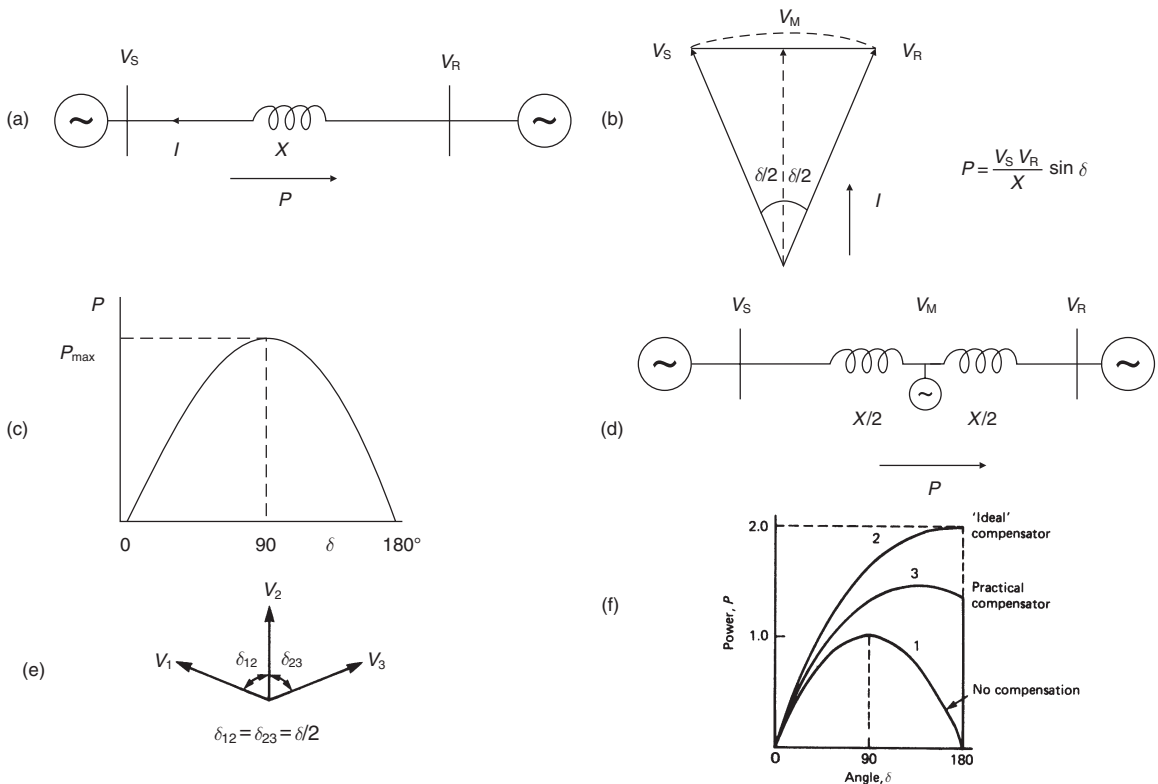

Figure 41.4 Power-angle features of a transmission line with and without shunt var compensation

For  $V = 1$  p.u.,  $Q$  is equal to  $Q_0$  at  $P = 0$ , and falls to zero for  $P = 1$ , i.e. for a power equal to  $P_S$ . Power can be increased above  $P_S$ , if  $Q$  can be made negative, i.e. if var generation is added.

### 41.3.6 Transient instability

There has been a tendency to increase the distance over which power is transmitted for the following typical requirements:

- the supply of large amounts of power to conurbations and industrial centres from economic, but distant, energy sources—e.g. hydroelectric or mine-mouth thermal stations;
- the supply of moderate amounts of power to areas remote from the power grid of the central region—i.e. by radial sub-transmission lines, having loads tapped at one or several locations along each line.

Transient instability can occur in a transmission system following a sudden disturbance such as a short-circuit. The power output of a generator located near a fault may be greatly reduced, thereby allowing its speed to increase, while the output of a remote generator may be hardly affected by the event. As the acceleration of the two generators will differ, the phase angle between their internal emfs will change. In a simple system the two generators will drop out of synchronism if the fault persists long enough to allow the phase angle between their emfs to swing too far above  $90^\circ$ . The loss of synchronism takes place usually within 1 s of the disturbance. It is clear that the larger the series inductive reactance of the transmission lines and system transformers in the network interconnecting the generators, the greater attention must be paid to the possibility of phase-angle instability. In a well-interconnected system that does not have long distances between generators, transient and dynamic instability is rarely a difficult problem because fast clearance times can be obtained by using modern relays and circuit breakers.

On the other hand, slow swings or oscillations may develop between two parts of the system (or perhaps between one remote generator and the rest of the system), possibly initiated by minor disturbances, and these may build up to unacceptable levels after perhaps 20 or 30 seconds. Modern automatic controllers for generator excitation, with auxiliary stabilising signals, can exert some damping on such oscillations. Shunt or series dynamic compensation may be used alternatively or in addition to generator excitation control.

### 41.3.7 Var balancing for dynamic conditions

Figure 41.4(d) represents the same transmission line as Figure 41.4(a) but with the assumption that the mid-point is connected to a virtual infinite bus-bar, which will always keep the magnitude of  $V_M$  constant and equal to the voltages at the ends of the line. In this context, the 'infinite bus-bar' is not required to supply active power, (i.e. it will not control the phase angle of  $V_M$ ) but must behave as an 'ideal' FACTS controller to supply the vars required to control the voltage at the mid-point.

Figure 41.4(e) shows that this additional voltage support effectively divides the line into two equal sections, each with a reactance of  $X/2$  and operating at an angle,  $\delta/2$ . Each line section now has an independent stability limit which is reached when  $\delta/2 = 90^\circ$ . Thus the theoretical total angle between  $V_S$  and  $V_R$  can now be  $180^\circ$ , i.e. double the

conventional critical value of  $90^\circ$ , with a resultant increase in power transfer capability.

Without any voltage support at the mid-point the power will be as in curve 1 of Figure 41.4(f) (repeated from Figure 41.4(c)).

With voltage support at the mid-point, the condition will be as in curves 2 and 3. If the vars were to be supplied instantaneously, the power transfer would be doubled (curve 2),

$$\text{i.e. } P_{\max} = (V_S^2)/(X/2) \Leftarrow$$

In practice it is not possible for the theoretical maximum to be achieved, owing to losses and the response delay of a practical controller (curve 3). However, it is possible to provide voltage support at several places along the line and so make up, to some extent, for the lack of the 'ideal controller'.

Figure 41.5 illustrates an example of conditions to be expected on a very long high-voltage transmission line with voltage support, provided for example by SVCs (static var compensators) at two intermediate substations, Figure 41.5(a).

For each of the three sections there are two conditions that can be responsible for limiting the maximum power that is reached.

Assume that the controllers can hold the voltage rigidly constant irrespective of load. In this case the stability limit will theoretically be reached if the phase angle between two adjacent voltage controlled bus-bars reaches  $90^\circ$ . In practice, even with controllers, the resistance of the line and the controller response delays limit the total angle at maximum power to less than the theoretical maximum of  $3 \times 90^\circ$ , e.g. to  $175^\circ$  in Figure 41.5(b). Figure 41.5(c) illustrates the phase angles of the line at this steady-state power limit.

The second limiting condition might be that any one of the controllers reaches the limit of its var generation

Figure 41.5 Long transmission line with multiple static var compensators

capacity; the required vars from the controller are illustrated in *Figure 41.5(b)* by the curve  $Q$  (generation or absorption). When the power  $P$  and angle  $\delta$  reach the condition of this limit, as for point 'a' in *Figure 41.5(b)*, the controller ceases to be effective in controlling the line voltage at its point of connection and the stability limit is reached even if the total angle has not reached the expected limit (e.g.  $175^\circ$ ).

The action of a shunt controller in improving the transmission capacity of a line can be thought of in terms of its effect on the natural surge impedance of the line; the shunt  $C$  is controlled so that the effective surge impedance matches the load being transferred. For heavy loads the shunt  $C$  is increased and the surge impedance is decreased, thereby increasing the value of SIL.

An alternative way of reducing the surge impedance in order to provide extra margin for a long transmission line is to reduce the series inductive reactance; this can be done by inserting a controller with a negative inductive reactance (usually in the form of capacitive reactance). Series compensation inserted in one or two locations along a transmission line has the following important characteristics.

- (1) By reducing the effective series inductive reactance of a transmission line, series compensation allows a higher power transfer capability. This enhancement may provide a higher power over a given distance or enable a given power to be transmitted over a greater distance; alternatively, series compensation may be used to reduce the steady-state phase angle for a given power and distance.
- (2) By increasing the (capacitive) vars generated as the load current increases, the series compensation improves the var balance in a line and hence reduces its voltage regulation, thereby reducing shunt var generation requirements at the line terminals.

Even when a long h.v. or e.h.v. line is series compensated, shunt reactors are normally needed to absorb part of the shunt vars of the line. Typically between 40% and 100% of line shunt capacitive power may be compensated at light load to prevent overvoltages on the line. To restrict insulation stresses caused by overvoltages following sudden load rejection, a substantial part of the shunt reactive compensation is usually left permanently connected; clearly, this reduces the maximum power limit of the line.

*Figure 41.6(a)* shows an illustrative theoretical example of the power-angle characteristic of a line including its terminal impedances; the line is represented as three  $\pi$ -sections of about 200 km length each, with shunt reactors ( $R$ ) at each line section terminal and series capacitors ( $C$ ) at two intermediate locations. The curves in *Figure 41.6(b)* were calculated neglecting power losses, and the values are given in per-unit terms on the base of the surge impedance load ( $P_s$ ).

As the degree of shunt compensation is increased, the line requires a greater amount of series compensation to maintain the power-angle characteristics of the line. A comparison of curves 1 and 6 and the table in *Figure 41.6(c)* shows that with 100% shunt-reactor compensation the line requires almost 50% series compensation to reach the same maximum stable power limit as for the case without any shunt or series compensation. The maximum allowable limit of series capacitor compensation and choice of its location are governed not only by economic considerations, but also by various practical aspects, such as subsynchronous resonance (SSR, described later) and by the series capacitor short-circuit overcurrent protection needs. The latter requires spark gaps or non-linear resistors. The line distance protection relaying must be co-ordinated with these features.

Figure 41.6 Transmission line with series and shunt compensation

## 41.4 The management of vars

### 41.4.1 Objectives

Traditionally, a single organisation was responsible for all aspects of generation, transmission and distribution but, increasingly, these functions are being separated and allocated to organisations that are independent of each other. This subdivision of responsibilities usually results in competition between generating companies to supply power to the transmission network and often between distribution companies to supply power to customers, but the responsibility for transmission sometimes rests with a single organisation. The transmission company must then ensure that an adequate supply of energy is called up from the generators and that satisfactory levels of voltage exist throughout the transmission system in order to satisfy the moment by moment demands of the distribution companies; this requires the effective management of vars at the points where the energy is received and delivered, as well as within the transmission system itself. Adequate provision of vars at all times can be crucial for the security of a system.

It is necessary to balance various factors to arrive at an optimum solution for the management of vars. The objectives in such management must be both economic and technical.

- (1) to optimise the capital investment in, and location of, plant for the generation and absorption of vars;
- (2) to minimise system losses;

- (3) to optimise plant utilisation, so postponing the need for system reinforcement;
- (4) to obtain adequate system security;
- (5) to maintain adequate quality of supply; and
- (6) to control system overvoltages.

#### 41.4.2 Tools for var management

To attain the above objectives of efficient var management, system designers, operators and consumers can use some or all of the following types of plant or procedures: generators; on-load tap-changing transformers; switching of transmission circuits; various types of FACTS controller. Later sections provide information on the development and application of these controllers, which include shunt reactors and capacitor banks, switched or unswitched; series compensation; synchronous compensators; static var compensators; STATCOM; other FACTS controllers.

#### 41.4.3 Var management by the supply authorities

The benefit of good var management by the supply authority can be significant. Three areas of management can be identified.

The first is in the system planning and design stage, where a choice must be made on the rating and type of any reactive compensation equipment to be used, where it should be connected in the network, and when is the optimum time for installation. The characteristics of any power system, particularly the proportion of generation connected at the different transmission voltage levels and the ratio between the system maximum and minimum loading, greatly influence the decisions to be made.

Most transmission networks, even at peak demand, operate below their surge impedance load and hence generate more vars than they absorb, i.e. they have a positive var balance. However, under emergency conditions following a loss of one or more lines, the positive balance may turn into a deficit which under extreme conditions can give problems of voltage instability as well as possible loss of synchronism due to the network's low power-transfer capability.

A var planning study involves the balancing of the vars in the complete network. Then, after allocating an amount of var production to generating plant, it is necessary to decide on the best method to deal with the resultant surplus or deficit. For a large system this can require a protracted and major design exercise, and over the last two decades much effort has gone into the development of mathematical and computational techniques to aid system designers in this task.

The second area of var management is in system operation, where the facilities provided must be used in the most efficient manner to maximise system operational security and minimise system losses. Again much work has been done on the development of both off-line and on-line computer programs. Various studies have shown that, in general, minimising network losses also gives maximum security and minimum unnecessary circulation of vars in the network.

The third area is the commercial one of tariff policy, in which financial incentives are adopted to persuade consumers to maintain a power factor close to unity.

#### 41.4.4 Var management by consumers

The induction motor is by far the most common driving machine and, in consequence, the natural power factor of

most industrial loads is in the 0.7–0.8 lagging region in the absence of reactive compensation. Such a load requires a var supply of between 75 and 100% of its power, increasing the loading on the plant (e.g. transformers and cables) and causing significant losses and voltage drops. By generating the required vars close to the loads, these disadvantages can be largely overcome and for this reason supply authorities impose tariffs on industrial consumers to encourage them to install power-factor correction plant within their systems. This can often be achieved in a relatively inexpensive way by shunt capacitors, either direct on the motor terminals or as larger banks on supply voltage bus-bars. Often a combination is the optimum solution.

Fixed capacitors or switched banks may not always be adequate where the var requirements fluctuate widely and rapidly and cause greater voltage variations at a point of common coupling with other consumers than the supply authority allows. Such loads are found, for example, in the steel industry where, with thyristor driven rolling mills, the sudden impact of the billet meeting the rolls produces a rapid increase in low-power-factor current; and with electric arc furnaces, where frequent and random short-circuits occur between electrodes, producing short bursts of high current, again at a very low power factor.

Most supply authorities have regulations covering allowable limits for voltage fluctuations, particularly in respect of lamp flicker; as the human eye is most sensitive to fluctuation frequencies in the region of 8–10 Hz, these limits vary with frequency. Typically they might allow only 0.25% voltage dips at 10 Hz but 1–2% at 1 Hz. To compensate for such conditions requires a fast and continuously variable reactive source such as some types of static var compensator.

Thyristor power conversion equipment (which is increasingly being used in large ratings) and electric arc furnaces generate harmonic currents that flow into the supply network. These can affect other plants, causing losses, possible overheating or interference with electronic and telecommunication circuits. Supply authorities must therefore limit the harmonic distortion on their networks and many authorities stipulate maximum permissible values. To avoid exceeding these, it may be necessary to prevent a proportion of the harmonic currents generated by the consumer from penetrating the supply system. It is common to bypass these currents into harmonic filters. It is often possible to convert capacitor banks for power-factor correction into harmonic filters, giving significant cost savings. In any case the harmonic filters will generate vars at the power supply frequency and these must be accounted for in the system var balance.

### 41.5 The development of FACTS controllers

Earlier sections have pointed to the important part that reactors and capacitors play in improving the steady state characteristics and capacity of a.c. power systems. Although the application of reactors and capacitors can often be enhanced for slowly varying conditions by means of mechanical switching, faster changes of compensating vars are needed to provide dynamic improvements. At one time, the synchronous compensator was the only tool available for dynamic compensation; it acted as the benchmark for the early development of static FACTS controllers, which now provide a wide range of functions and characteristics for both shunt and series application. The following sections provide a simple outline of the components that have been developed to provide variable var output for FACTS controllers.

### 41.5.1 Synchronous compensators

All synchronous machines can give continuously variable var compensation and, in industrial systems where large synchronous motors are installed, they are frequently used in this way to provide power factor correction of the local load in addition to their main driving duty. Self-driven synchronous machines not connected to any mechanical load (synchronous compensators) can be used anywhere in a system either to generate or to absorb vars on a balanced three-phase basis. The synchronous compensator directly generates a voltage at its terminals. The magnitude of this voltage is controlled by a high-speed excitation system, which is often arranged to provide control of the voltage at another point, usually at the high voltage side of the compensator transformer. When overexcited, the machine generates vars and operates in a stable condition; when underexcited, it absorbs vars but its stability decreases as the excitation falls towards zero. Because of this tendency towards unstable operation, the var absorption rating of a synchronous compensator is typically only 50% of its var generation rating. Most machines operate with an automatic excitation control that needs to have a rapid response to assist the machine in maintaining stability through system disturbances or to follow rapid reactive load changes. The control time constant is normally in the range from 5–10 cycles.

Figure 41.7(a) illustrates the voltage–current characteristics of a synchronous compensator. The rated excitation voltage corresponds to the rated voltage of the system. If the system voltage falls below its rated value to  $V_d$  and the field current remains unchanged, the var generation will initially follow the sub-transient characteristic to point B but it will finally settle to point A on the synchronous reactance characteristic. In practical applications of synchronous compensators, the machine excitation will usually be controlled either to maintain a nominally constant Mvar output or to maintain a nominally constant ‘target voltage’ on the system, subject to a defined ‘droop’, or slope characteristic. Thus, for 5% droop, and starting from the float condition with zero output, a reduction of 5% of terminal voltage will provoke an increase in excitation sufficient to generate rated leading current. Conversely, a voltage rise of about 2.5% will cause the synchronous compensator to absorb its rated lagging current. When there is a sudden disturbance, the output will initially follow the sub-transient characteristic as before, but after a few cycles the fast excitation control will cause the output to settle at the appropriate point C on the controlled characteristic. As shown in

Figure 41.7(b) the slope of this characteristic is equivalent to a reactive impedance,  $X_m$ , such that a voltage change,  $\Delta V_m$ , at the controlled bus-bar will cause a reactive current change  $\Delta I_m$  in the synchronous compensator, i.e.

$$\Delta I_m = \Delta V_m / X_m$$

Synchronous compensators have several limiting or disadvantageous features; costs are relatively high and losses significant; they need good foundations, buildings, complex auxiliary systems and regular maintenance and refurbishment that detracts from availability. These drawbacks prompted the development of alternative types of equipment, using static components, with the synchronous compensator acting as the initial benchmark for dynamic response.

### 41.5.2 Sign convention for vars and reactive current

There are standard sign conventions for power and vars when current flows from a system bus-bar into a load. Power is positive for the component of current that is in phase with the voltage; vars are positive for a load operating at lagging power factor, i.e. when the current flowing into the load lags the voltage on the bus-bar. By this convention, when treated as loads as in Figure 41.7, shunt reactors will draw positive vars from the system, shunt capacitors will draw negative vars and generators will draw negative power. However, a reversed sign convention has been adopted to define the ratings of var compensation equipment for the following reason.

Generators supply both the power and the vars to satisfy the demands of the system and its loads. The sign convention for generators is that both power and vars are positive when current is flowing from the generator into the system bus-bar to supply a lagging power factor load. A synchronous compensator behaves in the same way as a generator operating at zero power and therefore it uses the same sign convention for vars. Thus, vars are positive when the synchronous compensator is over-excited, acting as a shunt capacitor and supplying an inductive (positive var) load and negative when it is under-excited, supplying a capacitive (negative var) load.

The same sign convention has become the norm for defining and specifying the var duties and output ratings of shunt static var plant and is thus consistent with that for rotating plant, i.e. shunt capacitive vars are designated as positive and shunt inductive vars are designated as negative. Note, however, that as shown in Figure 41.7, which treats the

Figure 41.7 Voltage–current characteristics of a synchronous compensator

compensating plant as a load, the corresponding currents have opposite signs to those for vars.

### 41.5.3 Basic features of static compensation

The main elements of the traditional type of static var compensator (SVC) are a capacitor to generate vars and an inductor to absorb vars. To provide operation in both the generation and absorption modes, both elements must be used; at least one of them must be rapidly variable, *Figure 41.8(a)*, in order to replicate the dynamic characteristic of a synchronous compensator shown in *Figure 41.7(b)*. A capacitor element cannot give a stepless variation: therefore, if a smooth continuous variation is needed over the whole range  $A-A'$  in *Figure 41.8(b)*, a capacitor bank having a rating to give at least the current  $I_C$  must be connected and the variable element must be inductive, with a rating to give a current at least equal to  $I_C + I_L$ .

Although a SVC does not generate a real voltage, its dynamic voltage–current ( $V$ – $I$ ) characteristic enables it to be represented in studies of the system behaviour as if it were a synchronous compensator. The reference parameters for the SVC's characteristic are a target voltage,  $V_{\text{ref}}$ , equivalent to the excitation voltage of a synchronous compensator, and an equivalent slope reactance,  $X$ . The SVC inductive current,  $I$ , (or capacitive current if  $I$  is negative) at an actual system voltage,  $V$ , is given by the function

$$I = (V - V_{\text{ref}})/X$$

The equivalent machine can be controlled to generate and absorb vars over a defined range of system voltage variation, but has no inertia. At the limits of the linear range, the SVC representation is changed to that of a simple shunt capacitor or reactor, as appropriate.

In some system applications the SVC must be capable of operating under different system conditions at the extremes of its range (i.e. at  $A$  and  $A'$ ), but it need not be capable of swinging in a continuous manner from one extreme to the other. Its 'dynamic' or 'swing' range, which is the range over which it can give a very fast response, may be only a

Figure 41.8 Basic static var compensator (SVC)

Figure 41.9 SVC installed capacity (data approximate only)

proportion of its total range. In such a design the size of the variable element, which is the most expensive item in per unit of rating, can be reduced to deal only with the required swing; mechanically switchable L and/or C elements, *Figure 41.8(c)*, can then be controlled automatically to adjust the position of the dynamic range within the total range. The overall cost of the SVC is then reduced. Sometimes the total range of a SVC is extended by using its control system to control the switching of shunt capacitors or reactors connected elsewhere in the substation.

The first commercial application of a SVC was in 1964. It used a self-saturated reactor to reduce the lamp flicker caused by an electric arc furnace. The first static var compensator for a transmission system was installed in 1967, followed by another in 1969: both used saturated reactors (SRs) as the continuously variable inductive component, the first was a d.c.-controlled transductor and the second a self-saturated reactor with harmonic-compensation and slope correction.

During the next decade many SVCs were commissioned, particularly on industrial systems where SVCs were installed to reduce voltage disturbances and to suppress disturbing lamp flicker caused by the var fluctuations of loads such as arc furnaces, large converter-fed drives in rolling mills and, in some cases, particle accelerators. The first thyristor-controlled reactor (TCR) for a transmission system entered service in 1978 and this coincided with a rapid growth in such applications of both thyristor and SR types of compensator, *Figure 41.9*. This growth resulted mainly from two factors. First, the rapid increase in the cost of power made utilities more conscious of the need to minimise transmission losses. Second, the growing opposition in industrialised countries to the construction of new transmission lines encouraged the maximisation of power transfer down existing rights of way. The 1990s saw the advent of a completely new type of static controller, the 'STATCOM', which uses voltage sourced converter technology.

### 41.5.4 Harmonic-compensated self-saturated reactor

The saturated reactor (SR) is the original type of SVC; it gives an inherent variation of reactive current with voltage and its response does not depend on an imposed control system. The variable element comprises an iron-cored inductor whose core becomes saturated during each half cycle of the supply voltage and this core saturation results in a r.m.s. voltage–current characteristic as shown in *Figure 41.10*. This voltage–current characteristic resembles the controlled characteristic of a synchronous compensator. A saturated reactor can only absorb vars from the system

Figure 41.10 Saturated reactor characteristic

but not generate vars; its saturation voltage is the 'excitation voltage' of an equivalent machine and its slope reactance is the 'droop'. The operating current of the saturated reactor automatically adjusts itself to the point at which its characteristic intersects the system load line. If the terminal voltage falls below the saturation voltage, the SR current becomes negligibly small. Shunt capacitor banks are used to enable a SR type of SVC to generate vars.

An iron-cored inductor with a simple winding is rarely used on a power network, as it generates large magnitudes of odd harmonic currents. However, by interconnecting sections of all three-phase windings it is possible to cancel out most of these harmonics in normal operation. The twin-tripler and treble-tripler harmonic compensated SRs (invented and developed by Dr E. Friedlander of the former General Electric Company, England) use this principle and have, respectively, six and nine active iron-cored limbs with inter-star connected windings and ratings up to 170 MVA for a treble-tripler saturated reactor, *Figure 41.11*. In addition to reducing the harmonic content of the reactor current to negligible proportions the designs give a voltage-current characteristic with a sharp knee point and a slope that remains linear to within about 1%, for currents from about 10% to more than 300% of rated load. The slope reactance is normally within the range 8–15% on the basis of nominal full-load rating.

#### 41.5.5 Thyristor switches

In the 1960s, the demand for thyristors in industrial applications led to the very rapid development of devices with high withstand voltages and also capable of operating at high currents. Thyristor pairs with inverse-parallel connection

Figure 41.11 Circuit of the treble-tripler reactor

*Figure 41.12(a)* are suitable for use as static switches, capable of extremely fast and frequent switching operation without the time delays, wear and tear and maintenance requirements of mechanical switchgear. A.c. thyristor switches were at the heart of most of the SVCs supplied during the 1980s and 1990s.

For a practical application, thyristors are assembled in a modular way into an 'a.c. thyristor valve'. An a.c. valve is made up of inverse-parallel connected thyristors, which are themselves connected in series (and occasionally in parallel) to obtain the necessary rating, with voltages up to 40 kV and currents up to about 6 kA. The cost of a thyristor valve is influenced not only by the ratings of the thyristors, but also by the number of voltage levels in series. Thyristors are available with voltage ratings up to about 8 kV (peak), although derating factors of 2 or more need to be applied in a series string of thyristors to determine the actual rms operating voltage of each thyristor.

Differences in the thyristor leakage currents, stray capacitances and stored charge all tend to cause an uneven voltage distribution between series-connected thyristors. A resistor-capacitor a.c. grading network is used in parallel with a d.c. grading resistor across each thyristor level, *Figure 41.12(b)*. These grading networks reduce the voltage unbalance, and the R-C network also serves to damp the transient overshoots in the reverse voltage that occur when thyristors come out of conduction (twice per cycle per valve). Individual thyristor levels within a module are protected against overvoltage by breakover diodes or similar devices, which provide a gate pulse for forward firing of the thyristors above a pre-set overvoltage level. Special care must be taken in the design of the gating electronics and the signal transmission circuits to ensure coherent (simultaneous) firing of all the series-connected thyristors.

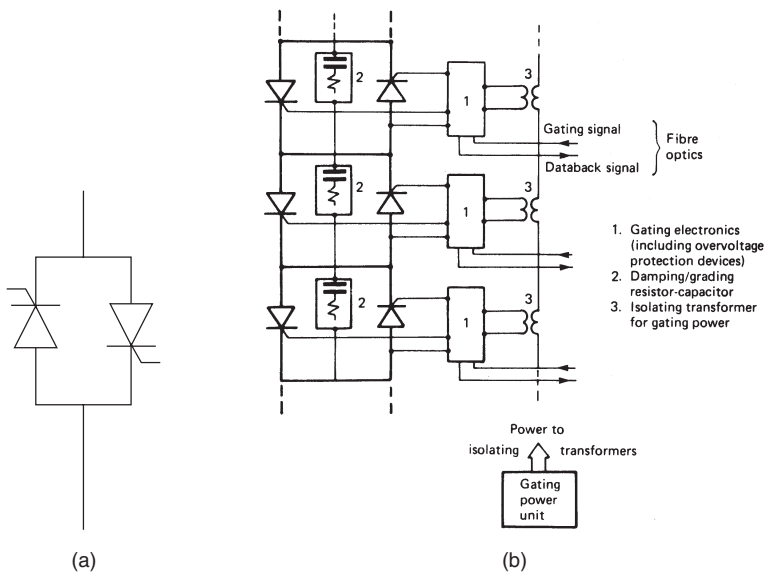

Most thyristor valves are indoor installations, with air insulation and water cooling. Only pure demineralised water having very high resistivity is allowed to flow through the thyristor heat sinks, which are at high voltage with respect to ground. The water cooling plant is mounted separately at ground potential and the pipework from ground to the thyristor stacks includes some sections made of insulating material. Air cooling is much simpler than water cooling, but it limits utilisation of the current capability of the thyristors and is rarely used for SVC applications. *Figure 41.13* shows one type of thyristor valve used in a SVC installation in a transmission network.

The thyristor-controlled reactor (TCR) comprises an a.c. thyristor valve connected in series with a linear reactor. One phase of a TCR is shown in *Figure 41.14*. Variation of the current in the TCR is obtained by control of the thyristor conduction duration in each half-cycle, from a 90° firing angle delay (as measured from the applied voltage zero) for full conduction to 180° delay for no conduction.

A.c. thyristor valves consisting of inverse-parallel connected thyristors, very similar to those used for the TCR, are used to enable rapid and frequent switching of blocks of capacitors, *Figure 41.15*. The thyristor-switched capacitor (TSC) gives directly the effect of a variable capacitance, although for reasons given below the variation is in steps.

Once gated, the thyristor valve will conduct for a half-period and unless again gated the current will then cease. A TSC, therefore, can only give a variation of capacitance between two states, on and off, for a discrete period of an integral number of half-periods. The kind of point-on-wave control used to give variable output with a TCR is not a practicable option for a TSC.

At the end of each half cycle of conduction, the capacitor current through the thyristor reaches zero; unless re-gating

**Figure 41.12** (a) Basic thyristor switch; (b) typical thyristor valve circuit

occurs the capacitor will remain charged at peak voltage while the supply voltage peaks in the opposite polarity after a half-period. This imposes a doubled voltage stress on the non-conducting thyristor, so that a TSC valve usually needs approximately twice the number of thyristors in series compared with a TCR valve of equivalent voltage. Ideally, gating is arranged to take place when the voltage across the thyristor is zero and the supply voltage is at its peak (i.e.  $dv/dt = 0$ ); this results in a transient-free energisation. Except when continuous conduction is achieved by repetitive re-gating, such ideal switching conditions are rarely achieved, owing to mismatch between the capacitor voltage (which normally slowly loses its charge from its previous energisation) and the system voltage (which may have changed its value during the same interval).

The TSC control system is normally arranged to choose the gating instant that gives the minimum transient. Nevertheless, quite large transients occur during initial energisation of an uncharged capacitor and current limiting reactors must normally be installed to reduce the magnitude of the inrush current to a value within the thyristor capability. With the exception of these switching transients the TSC does not produce harmonics.

It is possible to arrange for a very rapid discharge of the capacitors after each period of conduction; this can reduce the voltage stress on the non-conducting thyristor and provide more consistent conditions for the next energisation. With a delta-connected three-phase TSC, current zero is reached sequentially in the three phases. By connecting a suitably designed three-phase transformer across the capacitors, most of the energy stored in the capacitors can be commutated back into the system, and into discharge resistors, by transformer action. Core saturation effects supplement this transformer action.

## 41.5.6 Converter-based FACTS controllers

### 41.5.6.1 Basic concepts

As described in Section 41.5.3, the behaviour of conventional SVCs is often represented by a model of an equivalent, but

inertialess, machine incorporating an equivalent 'excitation voltage' and an equivalent 'slope reactance'. However, there is a type of circuit, sometimes called a 'synchronous voltage source', in which a real alternating voltage,  $V_e$ , is produced from a d.c. source  $C_s$  by the process of inversion in a solid-state d.c. to a.c. converter; the a.c. voltage source is connected to a system bus-bar through a coupling reactance,  $X_e$ , *Figure 41.16*. The converter and its coupling reactance behave as an idealised rotating machine with an extremely fast response and, again, no physical inertia although there may be significant stored energy in some cases. The class of SVCs which uses this principle has been assigned the name STATCOM (a shortened form of STATic COMPensator).

The basic behaviour of a STATCOM is very similar to that of a synchronous compensator. If the voltage generated by the converter is less than the voltage of the system bus-bar to which it is connected, the STATCOM will act as an inductive load, drawing Mvar from the supply system. Conversely, a STATCOM will act as a shunt capacitor, generating Mvar into the supply system, when its generated voltage is higher than the system voltage. The rated inductive current and the rated capacitive current are usually equal, giving the STATCOM an almost symmetrical lagging and leading Mvar rating. This is very advantageous for some applications, but for those that require an asymmetrical Mvar rating, it is usually economical to reduce the total STATCOM rating and to bias its output using conventional fixed or thyristor switched reactive elements.

The losses of the converter are normally supplied from the system, in the same way as for a machine, and not from the source of direct voltage or current. Nevertheless a STATCOM can exchange real power with the a.c. system if the d.c. source is arranged to supply or absorb the power that it is desired to exchange on the a.c. side.

### 41.5.6.2 Voltage-sourced converters

Various types of inverter circuit and source have been suggested and examined. D.c. voltage-sourced converters (VSCs) have received the most attention in the practical

**Figure 41.13** Thyristor valve for an SVC

**Figure 41.14** Basic TCR operation

realisation of the STATCOM principle and can also be used in FACTS controllers connected in series with a transmission line or load.

The inverter may use either conventional thyristors with forced commutation, or devices that have been designed to be turned off as well as turned on, such as gate turn-off (GTO) thyristors; these devices have been used for many years in drives for traction and industrial applications. Other devices, for example the Integrated Gate

**Figure 41.15** One phase of a thyristor-switched capacitor compensator

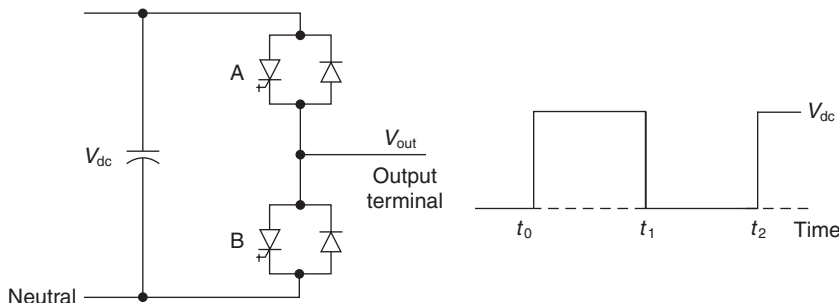

**Figure 41.16** Synchronous voltage source

Commutated Thyristor (IGCT) or the Insulated Gate Bipolar Transistor (IGBT), require less energy for the switching process and are available with ratings that can readily be used in some FACTS controllers.

Figure 41.17 illustrates a basic single-phase inverter employing diodes and GTOs connected in inverse-parallel; the converter produces a square voltage waveform at the output terminal as it switches the direct voltage source on and off. This basic two level converter can be developed to produce various multi-level converters, such as the five level converter of Figure 41.18, for which the harmonic content is reduced and the voltage approximates more closely to a sine wave.

The direct voltage source can be a battery, whose output voltage is effectively constant and which has the capability to supply or absorb energy. For FACTS controllers a simple d.c. capacitor is usually used as the source; the d.c.

**Figure 41.17** Basic single-phase voltage-sourced converter

terminal voltage can be raised or lowered by controlling the inverter in such a way as to increase or decrease the capacitor's stored energy.

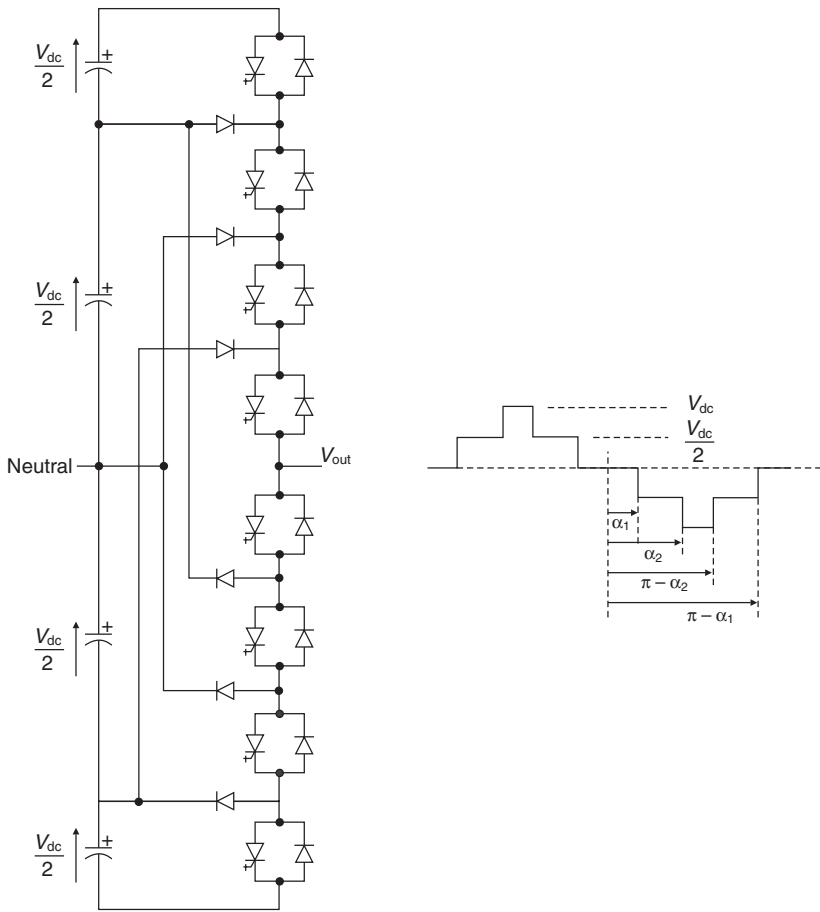

#### 41.5.6.3 Three-phase converters

Three single-phase converters, for example of the type illustrated in Figure 41.17, can be connected, one per phase, to form a three-phase converter. The three single-phase converters can be controlled in a co-ordinated way to generate a balanced three-phase set of voltages. There is also freedom, under system fault conditions—or for compensating unbalanced loads—to control each phase independently, in order to assist in balancing the system while avoiding converter overload. When using independent capacitors for the d.c. voltage sources, the voltage in each phase can easily be changed independently of the other two phases if necessary.

When the primary objective of the STATCOM is to respond to balanced load conditions, it is convenient to use the same d.c. source voltage for all three phases; the three converters can take the form of a Graetz bridge as shown in Figure 41.19(a). The three phase voltages are shown in Figure 41.19(b), with respect to the apparent neutral of the three-phase system. It will also be seen that the line-to-line voltages reach twice the peak magnitude of the phase voltages but for a shorter duration ( $120^\circ$  conduction angle rather than  $180^\circ$  due to the commutating action of the individual phases). This inherently eliminates third harmonic components from the line-to-line voltages under balanced system conditions, but during fault and unbalanced conditions, particular care is needed in the control and protection of the converters because of the use of a common d.c. source voltage.

#### 41.5.6.4 Improving the voltage waveform

Clearly the basic square waveform is too distorted with low order harmonic components to be of practical application but can be improved by means of multi-pulse operation similar to that used for large rectifiers. Identical three-phase bridges (as in Figure 41.19(a)) can be connected to transformers that have phase-displaced outputs. Star- and delta-connected windings have a relative  $30^\circ$  phase shift and a converter bridge connected to each transformer would give 12-pulse operation and eliminate 5th and 7th harmonics from the line currents for balanced operating conditions. The transformers may be operated in parallel, in which case 5th and 7th harmonic currents will circulate between the converters, limited by the transformer reactance. Alternatively the transformers can be connected in series so that their respective 5th and 7th harmonic voltages

**Figure 41.18** Single-phase multi-level voltage-sourced converter

will cancel out and so prevent any flow of the corresponding currents.

With four transformers having relative phase displacements of  $15^\circ$  24-pulse operation can be obtained; with eight transformers having  $7.5^\circ$  phase shift, 48-pulse operation results. It is usual to employ a simple transformer to provide the step-down duty from the high voltage system to an appropriate intermediate voltage; several different designs of phase-shifting transformers are then required to supply the individual converter bridges.

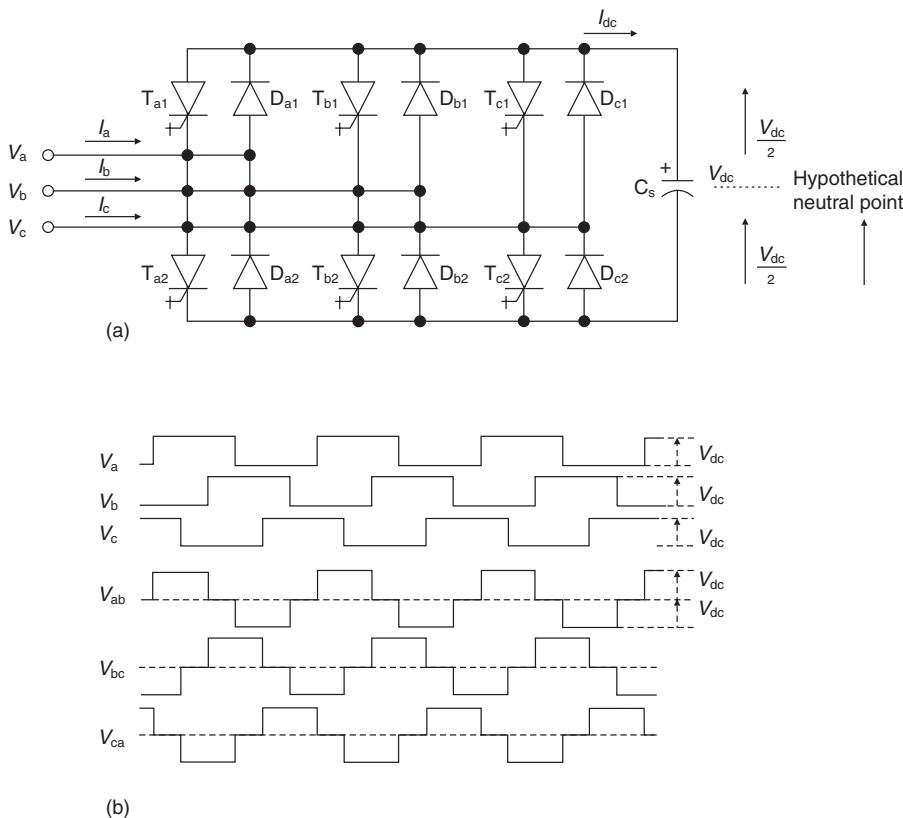

A simplified arrangement is illustrated in Figure 41.20. Two star-star and two star-delta transformers are connected with their primary windings in series and each secondary winding is connected to a 6-pulse bridge converter. All four of the converters utilise the same d.c. voltage source but they are operated effectively with relative phase-displacements of  $15^\circ$  to produce a quasi 24-pulse configuration. The 12-pulse harmonics which are characteristic for each pair of converters are not perfectly cancelled, but the residual magnitude is acceptably small. For practical applications of this kind of STATCOM, the Graetz bridges must use several GTOs in series in each leg of the bridge to obtain an adequate rating. The GTOs in each leg must be arranged to turn on and off at precisely the same instant (within microseconds) to ensure good voltage sharing between the individual GTOs.

#### 41.5.6.5 Pulse width modulation

Pulse width modulation (PWM) is an alternative method of harmonic control. The power electronic switches are repetitively turned on and blocked several times during each half cycle. The sequential switching instants are selected in a co-ordinated manner, to satisfy simultaneous requirements, i.e. to develop the desired fundamental voltage and to eliminate selected low order harmonics. Figure 41.21 illustrates how two poles of a converter (such as that shown in Figure 41.17) can be controlled, each with 5 on/off actions per cycle, to eliminate both 5th and 7th harmonics together. Extra, correctly timed, switchings can eliminate additional higher harmonic components. IGBTs and IGCTs require much lower switching energy than GTOs and are better suited to applications that use PWM techniques. Multi-module arrangements are necessary to obtain high ratings.

#### 41.5.6.6 Multi-level converters

By combining sets of GTOs and their diodes in series, additional steps can be added to the output voltage waveform. Co-ordinated control of the switching instants of the series levels increases the controllability of the fundamental and harmonic content of the waveform. One important form of multi-level converter is the 'chain circuit' in which several

**Figure 41.19** Simple three-phase voltage-sourced converter circuit and voltage waveforms

converter bridges, each with its own source capacitor, are connected in series. By appropriate switching of the GTO and diode pairs, the d.c. sources are connected into the circuit with either positive or negative polarity or are bypassed to give zero voltage contribution.

This is illustrated in *Figure 41.22* that shows that a single-phase chain with only three links can produce seven output levels. Each link in the chain produces its own rectangular block of voltage, with an amplitude equal to its own source voltage (normally all these source voltages are controlled to have the same value). Each voltage block therefore makes a contribution to the total fundamental voltage and to the total spectrum of harmonics. The more links there are in the chain, the more closely the overall waveshape approximates to a sinusoid. This stepped waveform appears broadly similar to the current waveform of a conventional multi-pulse a.c. to d.c. rectifier. However, the rectifier waveform consists of a series of pulses of varying height but equi-distant in time, whereas for the chain circuit, the pulses are of equal height and the interval between switching instants varies. In principle there is no limit to the number of converter bridges (or 'links') that can be connected in series in a chain to generate, directly, a high value of alternating voltage with a small content of harmonic distortion.

#### 41.5.6.7 DC source voltage ripple

The d.c. source should preferably be strong enough for its voltage to remain effectively constant at the chosen level,

under steady state conditions. In practice, especially for capacitor voltage sources, a compromise is necessary to allow the capacitor to charge and discharge to some extent between each switching operation, i.e. a constant average voltage is maintained but with a super-imposed ripple voltage of a few per cent, *Figure 41.23*. This ripple must be taken into account in selecting switching instants and in evaluating the overall harmonic behaviour of the converter system.

## 41.6 Shunt compensation

### 41.6.1 General

The load carried by a power system is continuously changing. Major variations in total load occur quite slowly, over a period of tens of minutes or longer in a daily cycle see *Figure 41.24*, which itself changes with a weekly and yearly variation. Normally any very rapid changes of load are only a small proportion of the total and do not affect the overall pattern.

For a system operating under normal conditions the overall var compensation requirements also change relatively slowly. In a well-proportioned system the var flows are not sensitive to small load changes and it is generally possible to use fixed shunt reactors or capacitor banks to balance the vars for average load conditions. Often, however, it is advantageous to arrange that some or all of these shunt compensation elements are switchable, so as to give better control and to reduce unnecessary losses. These discretely

**Figure 41.20** Multi-pulse operation using phase displacement transformers

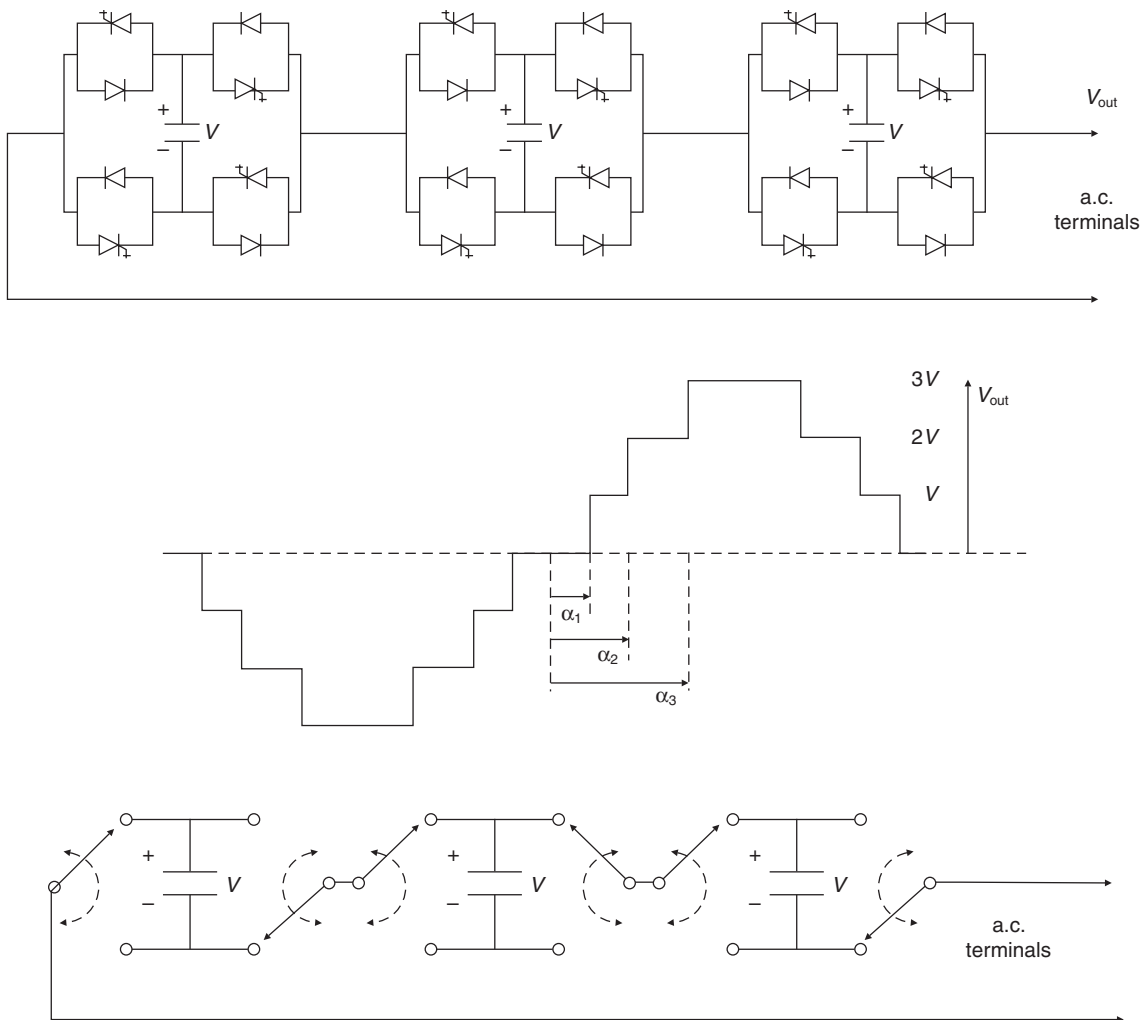

**Figure 41.21** Pulse-width-modulated (PWM) converter voltage waveforms

variable devices are the simplest and the most common var compensators.

Many power systems now take advantage of the benefits offered by continuously variable var compensators. These can be used for particular categories of application such as:

- (1) the compensation of rapidly varying loads that could otherwise cause unacceptable voltage disturbances on the power network;
- (2) providing emergency voltage support in response to a circuit fault that increases the load current through each of the transmission lines that remains in service;
- (3) giving continuous voltage control at a weak point of a network, where voltage variations due to normal load changes could otherwise become excessive and pose a threat of voltage instability;
- (4) giving almost instantaneous overvoltage control in the event of a major load rejection on a long-distance transmission system;

**Figure 41.22** Single-phase chain circuit type of multi-level converter

- (5) giving continuous fast control where transient stability is important, particularly on long-distance transmission; and
- (6) on a tie line between two systems, damping out load swings which otherwise could lead to dynamic instability.

These different applications call for different characteristics of the variable var compensator. The types of compensator are reviewed in this section, with particular reference to their operating characteristics and applications, a comparative summary of which is given in *Table 41.1*.

#### 41.6.2 Mechanically switched reactors and capacitors

Mechanically switched reactors and capacitors are used at all voltage levels, from the highest voltage transmission systems down to the correction of power factor on a works distribution system. Both technical and economic factors influence the decision to install switched reactive compensation. In many cases, operational considerations would permit the units to be permanently connected, but at the expense of continuous losses. The losses can be reduced by the installa-

tion of a switch suitable for fairly frequent operation, but this entails additional capital and maintenance costs.

If the compensation unit is permanently connected to other equipment (e.g. to a load or to a line), that equipment's protective circuit-breaker will also serve for clearing faults in the compensation plant. In assessing the economics of var balance it is desirable to know for what proportion of the time a unit could be switched out, but this data is often difficult to obtain from the existing loading information and even more difficult to predict for the future.

##### 41.6.2.1 Shunt reactors

In transmission systems with very long lines, shunt reactors are often installed at the ends of each line section to control its voltage under energisation and light-load conditions. During times of heavy loading, when the line var gain due to the shunt capacitance is offset by its series var loss, it becomes desirable to switch these reactors out. This helps both to increase transmission capability and to minimise system losses.

**Figure 41.23** Converter output voltage and current waveforms and d.c. capacitor current and voltage during var generation and absorption

However, this requires transmission-voltage switches or circuit-breakers, which are expensive. Moreover, in the event of a large loss of load it would leave the system with a large excess of vars, leading possibly to excessively high voltage levels which could be unacceptable even for the short time necessary to reconnect the shunt reactors. As described later, a combination of fixed and continuously variable reactors may be a beneficial solution in these circumstances.

Where transmission or distribution systems include substantial lengths of cables, particularly at higher voltages,

shunt reactors are sometimes installed at bulk supply points to compensate for the excess of vars under light-load conditions. To reduce the cost of losses inherent in all compensation devices, these are normally switched off as the load builds up.

#### 41.6.2.2 Shunt capacitors

A very common and important application for shunt capacitor banks is in power factor correction (pfc) for industrial and commercial consumers. Here a straightforward economic evaluation is used to decide on the optimum reduction of var demand. The pfc capacitor banks usually consist of several separate units, or groups of units, each with its own contactor or switch. The load demand and power factor are, effectively, continuously measured and capacitor units are switched in and out as necessary to achieve the desired overall power factor for each successive tariff period, which may be only 15 or 30 min, for example.

Capacitor units have a very small inherent inductance and when units are switched back-to-back, without regard for the stored charges that each possesses at the instant of switching, there is a very large transient current flow between the units as the voltages are equalised. It is usual to limit the amplitude of the transient current by adding very small inductors into the circuit of each capacitor unit. These inductors may reduce the natural frequency of the capacitor circuits to perhaps 1 or 2 kHz. However, the installation of a pfc bank may result in a resonance between its capacitance and the system reactance at a prevalent low order harmonic, e.g. fifth or seventh; the switching inductors will not have a significant effect at such frequencies. Resonances of this kind can cause possible overvoltages or excessive currents. The capacitor bank may (because of its very low impedance at harmonic frequencies) act as a sink for harmonic currents produced by pre-existing voltage distortion in the network, and so become overloaded by them unless suitable series reactors are included. Before installing power factor correction banks and their associated series

**Figure 41.24**

**Table 41.1** Comparison of the characteristics of different var compensators

<i>Item</i>	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>	<i>E</i>
<i>Type of compensator</i>	<i>Synchronous</i>	<i>Harmonic-compensated self-saturated reactor/fixed capacitor</i>	<i>Thyristor-controlled reactor/fixed capacitor</i>	<i>Thyristor-switched capacitor/thyristor-controlled reactor</i>	<i>STATCOM</i>
<i>Features</i>					
Steady-state characteristic	Automatic voltage regulator (AVR) easily adjustable	Restricted adjustment possible on site	Controller easily adjustable	Controller easily adjustable	Controller easily adjustable
Harmonic content of current	Negligible	Internally compensated in balanced three-phase system	Six-pulse design usually requires filters, particularly if reactance is <100% on rating	TSC, negligible TCR, smaller than in C	Low order harmonics usually small; high order harmonics can be large
Fault infeed	Approximately 4–6 times the rating	Nil	Nil	Nil	Nil
Overload capability	Gives both generation and absorption up to approximately two times normal during swings	Generation overload limited to capacitor bank rating unless special star–delta switching used  Inherent very high absorption (e.g. three times normal)	Absorption limited by full conduction of thyristors		Generation and absorption overload only available if deliberately included
Losses	High at full output; low at zero var output (float condition)	Low at full generation; high at zero var output (float condition) and at full absorption		High at full output; low at zero var output (float condition)	
Maintenance requirements	As for any large rotating plant	Small; as for conventional outdoor equipment	Moderate for special electronic (indoor) equipment when properly designed small for conventional outdoor equipment		
Approximate response time in typical complete system	0.2 s	0–0.05 s	0.02–0.06 s	0.02–0.06 s	0.01–0.04 s
Response to rapidly fluctuating loads	Relatively slow	Inherently fast	Normally less rapid than B, but some control improvement possible	Slower than C	Faster than C
Voltage control under load rejection (i.e. potential over-voltage condition)	Poor to fair, liable to self-excitation and loss of synchronism below minimum excitation limit	Very good with inherent fast response	Fair, controlled absorption limited by full conduction of thyristors	Poor, limited by the low rating of the reactor of the TCR	Limited by the installed rating of voltage-sourced converter (VSC)

*cont'd*

<i>Type of compensator</i>	<i>Synchronous</i>	<i>Harmonic-compensated self-saturated reactor/fixed capacitor</i>	<i>Thyristor-controlled reactor/fixed capacitor</i>	<i>Thyristor-switched capacitor/thyristor-controlled reactor</i>	<i>STATCOM</i>
Voltage control under line outage (i.e. potential under-voltage condition)	Good, but relatively less rapid	May require switched capacitors to support voltage	May require switched capacitors to support voltage	May require switched capacitors to support voltage	Limited by the installed rating of voltage-sourced converter (VSC)
Behaviour following system fault	Machine inertia could cause swinging and loss of synchronism	Inherent response as a constant voltage device	Auxiliary controls could be used to damp load swings	Auxiliary controls could be used to damp load swings	Auxiliary controls could be used to damp load swings

reactors, measurements or estimates of pre-existing harmonic voltages in the network should be made and the effects of the capacitors on the remainder of the system should be studied.

In some networks it is the practice to install shunt capacitor banks at critical points of distribution systems with long overhead feeders, such as those supplying rural areas; the capacitors at the substations are usually switchable, whereas those part-way down the feeders are often pole-mounted and permanently connected. In the UK, owing partly to tariff incentives, load power factors tend to be high and there is no general application of this type of shunt capacitor compensation.

In the UK, power is delivered to distribution companies at bulk supply points, usually at 132 kV. Switched shunt capacitors are connected at some of these bulk supply points and are often used to compensate for var imbalance on the transmission network in addition to the var demand of the l.v. connected loads. Bank ratings are generally 60 Mvar and several are installed at some substations. In the last few years there has been an interesting development, resulting in the connection of switched capacitor banks of 150 Mvar and 225 Mvar directly on the 275 kV and 400 kV systems. In order to eliminate any possibility of adverse consequences due to amplification of pre-existing harmonic distortion, these banks are arranged as selectively damped harmonic filters, with very low losses at the rated power frequency but strong damping of any third harmonic currents.

#### 41.6.2.3 *Technical aspects of switching reactors and capacitors*

Any switchgear installed to control a shunt capacitor bank or a reactor, be it circuit-breaker or load switch, must be carefully chosen, as the switching duties, even though the load currents are normally small, are not easy. The number of operations is often high.

With reactor switching, de-energisation may present difficulties if the current does not decrease smoothly to zero as the switch contacts separate and the arc is quenched. If there is current chopping and the current collapses to zero almost instantaneously, even from a very small current, the high rate of change of current can generate extremely high

voltages across the reactor. In order to avoid damage to the reactor, the circuit-breaker and other equipment, it is necessary to ensure either that overvoltages cannot be generated, or that they are limited to levels which do not surpass the insulation withstand levels of the system, for example, by means of surge arresters.

When capacitors are energised, high transient inrush currents are produced which may severely stress both the switch and the capacitor. Circuit-breakers, or switches, that are designed to provide point-on-wave switching for each phase are able to reduce these inrush transients to very much lower magnitudes.

De-energisation is also a severe duty for any switch because the interruption process leaves the capacitor charged to the peak value of the system voltage. Within a half-cycle of the instant of interruption, the polarity of the system voltage will have reversed and the voltage across the opening contacts of the switch will be twice the normal crest voltage of the system. If the insulating medium does not recover sufficient dielectric strength, the arc re-strikes and there is a short pulse of current, which leaves an even higher level of voltage trapped on the capacitor (with reversed polarity). In the worst case, this process continues until there is a failure of major insulation on the capacitor or other equipment. Special tests are conducted on switchgear intended for capacitor switching to validate its suitability for the purpose. In some cases special discharge circuits are connected into the capacitor circuit to ensure that the capacitor voltage decays very rapidly after the current is interrupted and that, even if arc re-ignition occurs, there is no magnification of voltage.

#### 41.6.3 *Synchronous compensators*

The synchronous compensator has a more positive action than most types of compensator in supporting a weak system, as it has both a generated voltage and inertia that enable it to act transiently as if it were coupled to a prime mover. The synchronous compensator can maintain full rated current independent of its terminal voltage and may be arranged to increase its var output temporarily to provide transient assistance to the system. This has been of value in certain applications; for example, where power is

supplied by h.v.d.c. to a system having minimal generation, the receiving system has usually been strengthened by a synchronous compensator.

When synchronous compensators have been used for dynamic compensation of high voltage systems it has been necessary either to provide a dedicated transformer or, in some cases, to utilise a tertiary winding on a transformer which links two voltage levels within a system. With tertiary connection, the inter-winding reactance distribution of the transformer determines the high voltage bus-bar to which the compensator is most closely coupled.

The main limitations of synchronous compensators compared with static alternatives are a notably slower speed of response, typically 0.2 s, higher losses, inertia that can cause underdamped oscillations or loss of stability in some transient conditions, higher maintenance requirements (and lower availability) and higher capital costs. Because of their inherent limitations, synchronous compensators have now been almost completely superseded by static controllers.

## 41.6.4 Static var compensators

### 41.6.4.1 Saturated reactors

Saturated reactors are normally used in conjunction with shunt capacitor banks to provide var generation as well as absorption. Some of the shunt capacitors are configured as harmonic filters that are permanently connected in parallel with the SR; other shunt capacitor banks may be permanently connected or switched, as appropriate to the duty of the SVC.

A significant feature of the SR type of SVC is that, because of its transformer-like construction, the SR has very low maintenance/operational requirements and also a high short-time-rated overload capability of up to 4–5 times rated load for 1 second, or longer if necessary. This can be of use in networks with long transmission lines, where the Ferranti effect following a loss of load can produce excessively high temporary overvoltages. The SR, by swinging rapidly into a high var absorption mode, can balance the var production of the line and so reduce the inherent overvoltage.

The SR is normally operated as a fixed-voltage device, though adjustment of its saturation voltage over a range of a few per cent is possible in principle. If it is to be connected to a system whose voltage level must be adjustable, then a regulating transformer is normally connected between the SR and the system bus-bars, *Figure 41.25*. Where a step-up

transformer is necessary to match the SR voltage (normally 6–69 kV) to the system voltage, this can include an on-load tap-changer to provide any regulation that is needed.

The  $V-I$  slope typically required at the terminals of a SVC for transmission applications is around 3–5%, whereas the total slope obtained from a SR plus step-up transformer may be 15–25%. To compensate for this difference, a slope-correcting capacitor is connected in series with the SR as shown in *Figure 41.25*. To avoid the possibility of sub-harmonic oscillations after energisation, a damping filter is fitted across this capacitor.

The current drawn by a SR depends directly on the time-integral of the voltage applied to its terminals and its speed of response is therefore extremely fast, responding to voltage changes within the same half-cycle. Owing to the poly-phase construction and the interconnection of its windings, a SR operates in a manner different from that in a linear shunt reactor. The latter absorbs the capacitive energy of the system as electromagnetic energy and returns it all every half-cycle, phase by phase. In contrast, the treble-tripler reactor, by virtue of its nine-active cores and inter-connected windings, transfers about 90% of its energy from phase to phase as the magnetic flux commutates from one core to the next every 1.1 ms at 50 Hz ( $2 \times 9 = 48$  transitions per period). The inclusion of the slope-correcting capacitor slightly slows the effective overall response and a slope-corrected treble-tripler reactor SVC responds effectively to a step change within one to two cycles, dependent on the system impedance and on the rating of its sub-harmonic damping circuit. An alternative method of achieving the slope-correction effect without time delays has been used for lamp flicker compensation in *Figure 41.46(b)*.

### 41.6.4.2 Thyristor-controlled reactors

The simplest design of TCR, *Figure 41.26(a)*, uses three single-phase valves, usually connected in delta, giving a six-pulse unit: hence, it produces appreciable levels of fifth and seventh harmonic currents and in most cases will require the use of harmonic filters. Shunt capacitors are needed to provide var generation and, for large SVCs, it is usual for some of these banks to be thyristor switched. Although for some ratings it may be possible to connect the TCR directly to the power system bus-bar, for most applications an interconnecting transformer is required to match the optimised valve voltage to the system voltage; on-load tap-changers are very rarely included.

A few installations have used a step-up transformer with two phase-displaced secondary windings connected star and delta, each with a delta-connected set of thyristor valves and reactors, *Figure 41.26(b)*. This 12-pulse design gives better harmonic compensation, the principal harmonics being now the 11th and 13th, and simpler filtering can be used.

The control system of a TCR can produce any desired voltage-current characteristic derived from various input signals. A basic characteristic for a transmission compensator having a closed-loop voltage control, with current compounding, is shown in *Figure 41.27*. When the valve reaches maximum conduction, the characteristic follows the slope set by the impedance value of the linear reactors plus coupling transformer (typically 0.7–1.0 p.u. on the basis of full load rating) up to the point of the thyristor current thermal limit, when by phasing back the firing angle the current is held constant up to the maximum voltage limit of the thyristors. The actual relative positions of these constant-current and continuous-conduction parts of the characteristic may be changed to suit the design requirements.

**Figure 41.25** Saturated reactor compensator

**Figure 41.26** (a) Six-pulse TCR; (b) twelve-pulse TCR

**Figure 41.27** Voltage-current characteristics for a thyristor-controlled reactor

A speed of response to small disturbances of 1 to 3 periods is achievable with this type of control system. A slightly faster response may be obtained by using an open-loop current control; this can be useful for certain industrial applications where the highest speed is required and some sacrifice of control accuracy can be tolerated.

#### 41.6.4.3 Thyristor-switched capacitors

Thyristors can be used to switch on a large bank of capacitors faster than is possible with a mechanical switch; therefore a potential application of a TSC is for fast boosting of a transmission-line voltage to maintain system stability. A TSC, perhaps having several steps, as in *Figure 41.15*, could also be used on its own to provide swing damping in a transmission system.

TSCs are commonly used in conjunction with TCRs to give much reduced losses at zero var output (float condition) compared with the losses of a scheme using a fixed capacitor and a larger TCR; they are also used to provide an increased operating range in the var generation region where speed of capacitor energisation is of importance and a high frequency of operation is required. In these applications the TSC

provides the coarse steps, seldom exceeding four, whereas the TCR gives a fine continuous control in between.

In order to obtain a fine control of output using only TSCs, there must be a series of small steps, each with its own capacitor bank and thyristor switch. The number of steps and hence the fineness of control are dictated by economics in the cost of separate valves for each step and the complexity of controls. TSCs have occasionally been used for power-factor control of loads with frequently varying var demand; here the capacitor banks and thyristor valves were at a low voltage and a large number were used in parallel to approximate to a stepless control.

In the last decade, it has been found necessary to provide increased capacitive support for the National Grid in the UK. Because network requirements can change substantially over periods of a very few years, it is also desirable to be able to relocate equipment quickly to an alternative location. It is rarely possible to arrange for a high voltage connection to be quickly available, but transformers with 13 kV, 60 MVA tertiary windings are commonly available in Grid substations. The h.v. system may be either 400 kV or 275 kV and the l.v. may be 275 kV, 132 kV or 66 kV. Relocatable SVCs (RSVC) were specified, for connection to tertiary windings, and these only needed to provide capacitive Mvar; stepwise control of the output was permissible.

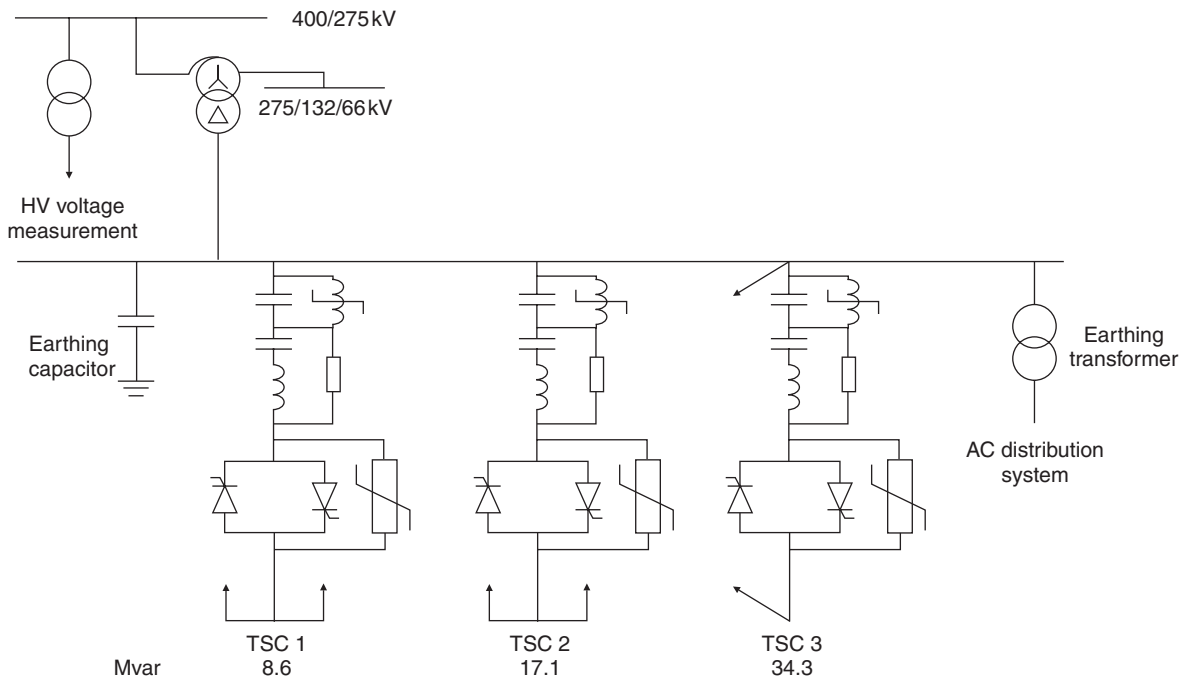

The specification for the RSVCs lent itself to an arrangement consisting of three TSCs, with binary ratings of 8.6, 17.1 and 34.3 Mvar, which are controlled in a co-ordinated way to provide the 60 Mvar output in seven steps of 8.6 Mvar, *Figure 41.28*. Twelve such RSVCs have been installed, in seven substations.

The ability of TSCs to reduce voltage fluctuations is very limited compared with that of other types of SVC and they cannot be controlled fast enough to be effective in reducing lamp flicker caused by arc furnaces.

### 41.6.5 STATCOM

#### 41.6.5.1 Some practical implications

It would clearly be inappropriate to connect a voltage-sourced converter directly to the supply system, which will

**Figure 41.28** Relocatable SVC (RSVC) arrangement used for the National Grid in the UK

generally have a very much higher short-circuit power than the rating of the converter. As shown in *Figure 41.16*, there is normally coupling reactance between the system bus-bar and the converter terminals. When the converter is connected to the system via a transformer, this may provide sufficient inherent coupling reactance for satisfactory operation of the STATCOM.

In some applications where there is a stringent harmonic performance requirement, it may be necessary to include shunt capacitors or harmonic filters on the converter bus-bar, in which case buffer reactors (separate from the step-down transformer) may be needed to limit the flow of harmonic currents from the converter into the capacitors.

As well as limiting harmonic currents, the coupling reactance limits fault currents into the STATCOM; it also ‘softens’ the transient current response from the STATCOM when there is a fault on the supply system which collapses the voltage, or when there is a large magnitude dynamic overvoltage. Inevitably, the presence of the coupling reactance requires the voltage generated by the converter to be higher than that of the system when the STATCOM is acting as a capacitor and to be lower than the system voltage when the STATCOM is acting as an inductor. The vars absorbed by the coupling reactance (and the supply transformers) must be taken into account in the design and rating of the converters.

#### 41.6.5.2 STATCOM operating characteristics

The ‘natural’ voltage–current characteristic at the terminals of a STATCOM, *Figure 41.29(a)*, is entirely dependent on the converter source voltage  $V_e$  and on the coupling reactance,  $X_e$ , see *Figure 41.16*. In general the coupling reactance has a typical value between 10% and 20%, i.e. the voltage drop (or rise) across it is about 10 to 20% of the nominal system voltage at the rated current of the STATCOM.

The continuous current rating of a GTO, IGBT or IGCT is almost independent of whether the current lags or leads the voltage. These devices usually also possess a short-time, or transient, overcurrent rating, which may exceed the safe turn-off (or turn-on) current for the STATCOM valve components. If, by accident or design, the safe turn-off current is exceeded, then turn-off signals must be prevented from being issued until the current returns to below the safe switching level.

The nominal maximum steady state voltage for a supply system is 1.1 p.u. of its nominal value and this presents no difficulties for the design and rating of a STATCOM. However, a STATCOM must also withstand dynamic over-voltages and transient overvoltages up to the protective level provided by the STATCOM’s surge arresters. During transient conditions in which the instantaneous applied voltage exceeds the d.c. source voltage, the diodes of the STATCOM will allow current to flow, and this current will charge the d.c. source capacitors to a higher voltage.

For most practical applications, a SVC needs to operate with a slope reactance typically of between 2% and 5%, which is much lower than the value of the coupling reactance. Because the coupling reactance is fixed, the converter source voltage must therefore be changed as shown in *Figure 41.29(b)*, raising it to obtain the desired loading (capacitive) current conditions or reducing it for lagging (inductive) conditions. This can be done very quickly, initially by changing the switching pattern and then followed, if appropriate, by changing the magnitude of the d.c. source voltage. The desired control characteristic is thus achieved by changing the source voltage in precisely the same way as for a synchronous compensator, but very much faster.

Both target voltage and slope reactance can be set in the STATCOM control. A set of voltage–current characteristics, for a range of target voltage settings with constant slope, is shown in *Figure 41.29(c)*. For comparison, the  $V$ – $I$

(a)

(b)

(c)

**Figure 41.29** (a) Natural  $V$ - $I$  characteristic of a STATCOM; (b) controlled  $V$ - $I$  characteristic of a STATCOM; (c) family of  $V$ - $I$  characteristics for a STATCOM

characteristics of a conventional SVC are shown in *Figure 41.30*. At reduced voltage, the STATCOM can continue to be operated at rated leading (or lagging) current, with a constant transient overload current margin. These capabilities are available down to very low voltages. In contrast, the current limits for conventional SVCs are proportional to voltage. A STATCOM is better able to provide reactive/current support for a supply system whose voltage is severely depressed, whereas a conventional SVC can generally do more than a STATCOM to limit dynamic overvoltage.

#### 41.6.5.3 Transient response

Because the operation of a STATCOM is based on the generation of a sinusoidal voltage, its response to transient

**Figure 41.30** Family of  $V$ - $I$  characteristics for conventional SVC

**Figure 41.31** Response of a STATCOM to a depression in system voltage

disturbances is inherently good and extremely rapid. *Figure 41.31* illustrates how a STATCOM responds to a voltage disturbance. Prior to the voltage dip, the STATCOM is operating at about its rated lagging current. A dip of system voltage suddenly occurs, to about 50% of its steady state value. The STATCOM inherently responds to this disturbance by generating a capacitive current to support the system voltage but, even on the natural characteristic, there would be a capacitive overload current. To prevent this, the STATCOM control system detects the sudden change and reduces the target voltage to limit the STATCOM current to its rated capacitive value.

When the fault is cleared and the system voltage recovers to its pre-fault value, this will tend to cause an inductive overload current in the STATCOM. Again, the STATCOM control system is able to detect the change and adjust the target voltage appropriately. Although there is unavoidable transient distortion of the STATCOM current at each step change it can be seen that the changes from inductive to capacitive and capacitive to inductive current take place within a half cycle.

#### 41.6.5.4 STATCOM losses

The forward voltage drop of GTO thyristors is greater than that of conventional thyristors because of the more complex system of semi-conducting junctions and the energy required for the turn-off duty. *Figure 41.32* shows the approximate variation of STATCOM losses (% of rated current) through the operating range from rated leading to rated lagging current.

Figure 41.32 Typical loss curve for a STATCOM

Figure 41.33 Typical loss curves for STATCOM applications

In many cases, the STATCOM output will need to be biased—generally towards the capacitive side for SVC applications. Figure 41.33 shows the loss patterns for an output range  $+1.0$  to  $-0.5$  p.u. current.

If the STATCOM is rated for an output of  $\pm 1.0$  p.u. current, but the upper half of the inductive range is not used, then the losses in the float condition (0 Mvar) and within the lagging range are quite low, but become quite high in the upper part of the capacitive range. These capacitive losses can be reduced by halving the rating of the STATCOM and combining it with a TSC of about 0.6 p.u. to reduce the losses (and generally also the overall costs).

An intermediate option is also illustrated with a STATCOM of  $\pm 0.75$  rating, to cover the total dynamic range, biased by a fixed capacitor (or filter bank) of 0.25 p.u. output. This may give a better overall optimisation of cost and losses especially if the predominant range of operation of the compensator is in the typical range from about 0.1–0.6 p.u. capacitive current.

#### 41.6.5.5 Other types of STATCOM source

In addition to voltage sources using batteries and capacitors, STATCOMs can be operated with an inductor, which provides a source of direct current rather than voltage. A three-phase, current-sourced converter then generates a set of three-phase output currents which, by appropriate switching action, lag or lead the system voltages. The basic output current is a square or block wave and harmonic

reduction requires PWM, or multi-level or multi-pulse techniques, and/or harmonic filters. The output current magnitude may be controlled by diverting part of the source current through a bypass circuit. The energy in the current source can be sustained by drawing energy from the supply system or by using an external energy source. However the losses of a current-sourced converter tend to be higher than those of a voltage-sourced converter.

### 41.6.6 STATCOM applications

#### 41.6.6.1 Transmission applications

In order to demonstrate the features of STATCOMs and to gain practical operating experience, several prototype STATCOM installations were put into service in transmission networks. In addition, several smaller STATCOM installations have been used (particularly in Japan) to reduce flicker caused by electric arc melting furnaces. However, many of the conventional applications of SVCs do not need to take advantage of many of the particular features of STATCOMs, such as equality of lagging and leading outputs, faster response time, possible active harmonic filtering capability and smaller site area.

Nevertheless, confidence in the STATCOM principle has grown sufficiently for several utilities to adopt them for normal commercial service. As an example, in 1996, the National Grid Company plc of England invited tenders for relocatable dynamic reactive compensation equipment for its 400 kV transmission network, capable of generating 0–225 Mvar at 0.95 p.u. system voltage. A particular requirement was the inclusion of a STATCOM of 150 Mvar range. The design adopted includes a  $\pm 75$  Mvar STATCOM in conjunction with a 127 Mvar TSC and 23 Mvar fixed capacitor to provide a full controlled range of output  $+225$  to  $-52$  Mvar, Figure 41.34.

This STATCOM design is required to meet stringent harmonic emission levels and immunity to existing and future prospective harmonic levels. It uses multi-level converters in a chain circuit configuration. Typical voltage waveshapes are shown in Figure 41.35. The control system incorporates voltage control, reactive setpoint regulation, and a co-ordinating control for the STATCOM and the associated TSC. Provision is also made to include power oscillation damping control in the future, if it should be necessary.

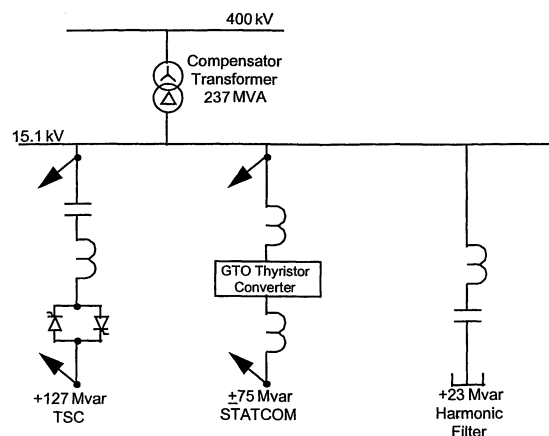

Figure 41.34 STATCOM arrangement for  $+225/-52$  Mvar at 400 kV

**Figure 41.35** Voltage waveshapes of STATCOM at 15.1 kV bus-bar and at GTO converter

All the controls and power electronic equipment are housed in weatherproof, transportable GRP (glass reinforced plastic) cabins and the outdoor components are grouped together on frameworks to satisfy the requirement for easy relocation to another substation when this is required.

#### 41.6.6.2 Specialised applications

Other applications of smaller STATCOMs, in service or under consideration, are for the reduction of lamp flicker due to arc furnaces, for voltage and var control for wind-farms and for balancing of single-phase traction loads. These smaller units generally use PWM to obtain a satisfactory harmonic performance.

#### 41.6.6.3 Energy storage applications

Some manufacturing processes require absolute continuity of supply to maintain product quality and/or safety, for example, float glass, paper, semi-conductor devices, and some chemical and nuclear processes. The cost of disruption may be so great that auxiliary or emergency power sources are economically justified. Uninterruptible Power Supplies (UPS) of moderate ratings are now very widely used to

enable some processes to ride through brief voltage dips and interruptions. Where larger power ratings are required, STATCOMs, with enhanced energy storage or auxiliary power sources, offer a potential solution.

Batteries have already been mentioned as voltage sources, but for stored energies of many megawatt seconds, present designs of battery are bulky and expensive. Very large capacitor banks might be used but are not efficient for bulk energy storage. Super-conducting magnetic energy storage sources (SMES), together with current-sourced converters have also been used in prototype format (*Figure 41.36*) and, in the future, might be very suitable for energy storage. A very attractive energy source of the future is the fuel cell.

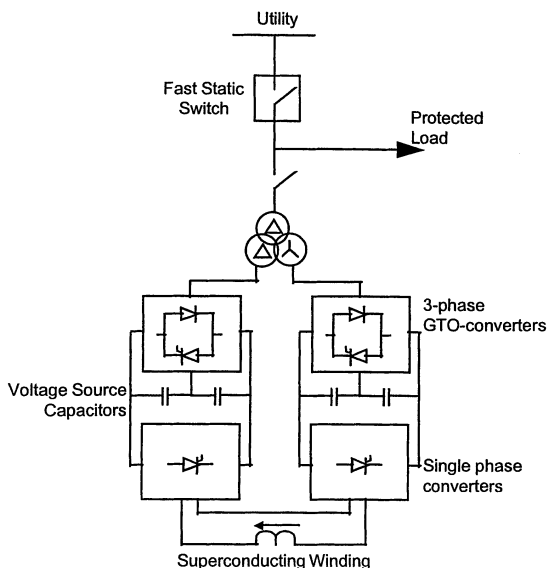

## 41.7 Series compensation

Series compensation may consist of capacitor banks with a single fixed value, or adjustable in steps, capacitors with one or more stages that are continuously variable or it may be provided by a synchronous voltage source. All equipment that is intended for series connection must have suitable insulation to ground and be designed and rated for or protected against faults that can cause severe overcurrents through it.

### 41.7.1 Series capacitor compensation

Series capacitors have, for many years, provided the only practicable means of compensating the series inductance of transmission lines. Nevertheless, the application of series capacitors in large power systems requires caution at the system design stage, because series capacitors always introduce natural frequencies below the power frequency. Series capacitors resonate with the generator and line inductances at subharmonic frequencies and the subharmonic oscillations which follow any transient disturbances can lead to self-excitation of generators, to rotor hunting and to shaft oscillations. The possible danger of this phenomenon was illustrated in the early 1970s when the shaft of a large turbo-generator was twice damaged in service, owing to subsynchronous resonance (SSR) excited by series capacitors in the transmission system.

The SSR phenomenon is now well understood as being due to near coincidence of a shaft torsional resonance frequency and the complement of an electrical subharmonic frequency. It can be fully analysed using non-linear differential equations of the complete electrical-mechanical system. For studying such phenomena more economically, however, digital computer programs have been developed, based on either eigenvalue analysis or frequency-response

**Figure 41.36** SMES circuit arrangement

analysis of the complete system of linearised machine and network equations, including any shaft torsional equations of the turbine prime movers.

#### 41.7.1.1 Subsynchronous/subharmonic resonance damping

Methods of damping subsynchronous oscillations include the use of SVCs, damping filters, dynamic control of the series capacitor impedance and generator excitation control signals. The awareness of the possible danger of SSR, the improved methods of study and the available methods of damping such oscillations have enabled the application of series capacitors to continue successfully, albeit with some constraints.

Subharmonic oscillation phenomena may also occur when capacitors are in series with devices that have a non-linear reactive characteristic because they use saturable iron in the magnetic path, for example transformers, gapped-core 'linear' reactors and self-saturated reactors. These phenomena are amenable to non-linear or linearised analysis, but generally with only limited accuracy. Model studies using transient network analysers or simulators are employed in assessing individual applications involving transformers or linear reactors. Theoretical analysis of ferroresonance phenomena has not resulted in generally applicable conclusions. The performance of harmonic-compensated saturated reactors with slope-correcting series capacitors can be analysed satisfactorily and appropriate subharmonic damping filters can be designed accurately.

### 41.7.2 Controllable series compensation

#### 41.7.2.1 Thyristor switched series capacitor (TSSC)

In a practical installation of series capacitors it is common for the overall bank to consist of several sections, each with its own protection, isolation and bypass switchgear. This subdivision provides an improvement in availability and more flexible adaptation to changing circumstances, including the possibility to avoid using capacitance values that would give undesirable resonance frequencies under particular system conditions.

It is impossible to obtain rapid or frequent bypassing and re-insertion of capacitor sections using conventional mechanically operated switchgear, but faster switching can be achieved using thyristor switches for one or more sections, *Figure 41.37(a)*. There is a large discharge current when a capacitor is bypassed and a current limiting reactor (not shown) is needed to reduce the current to within the transient rating of the thyristor switch. Changing the capacitance value in discrete steps is suitable only for de-tuning SSR conditions but is not a satisfactory method of applying positive damping for SSR oscillations.

#### 41.7.2.2 Thyristor controlled series capacitor (TCSC)

The TCSC is similar to the TSSC but the thyristor switch is converted into a TCR, *Figure 41.37(b)*. By using point-on-wave switching of the reactor, two ranges of continuously variable impedance can be obtained, *Figure 41.37(c)*. The controlled reactor has a significantly lower impedance than the capacitor so that when the thyristor valve is fully conducting, the overall impedance of the capacitor section becomes inductive; the current through the reactor is greater than the line current and the capacitor current is smaller. At the other extreme, when the thyristor valve is blocked, the line current flows only through the capacitor.

At some intermediate level of valve conduction, the effective inductive impedance of the reactor would be equal to the capacitor impedance and the combination would form a blocking circuit, with a very large voltage across it. Obviously, this condition must be avoided. Nevertheless, a range of satisfactory operating conditions can be obtained near to minimum conduction, giving the continuously variable capacitive effect that is desired from this circuit. There is another operating range near to continuous conduction, with a continuously variable inductance effect, but this is generally unimportant. *Figure 41.37(d)* illustrates the continuous and short-term capabilities of a single section of a TCSC.

Several TCSCs have now been installed in transmission systems. They can be controlled to apply positive damping to SSR conditions, if these arise.

#### 41.7.2.3 Static synchronous series compensator (SSSC)

The advantages of series capacitors could be obtained and the major disadvantages could be avoided by using a FACTS controller to behave as a true negative inductance (i.e. with a reactance equal to  $-j\omega L$  instead of  $j\omega L$ ). This can be done by means of a voltage-sourced converter, as described in Section 41.5.6.2, and controlling it so that the voltage across it lags the current through it by  $90^\circ$ ; *Figure 41.38*. This gives negative inductance, not only at the system frequency, but also at lower frequencies and for the more important of the low order harmonic frequencies.

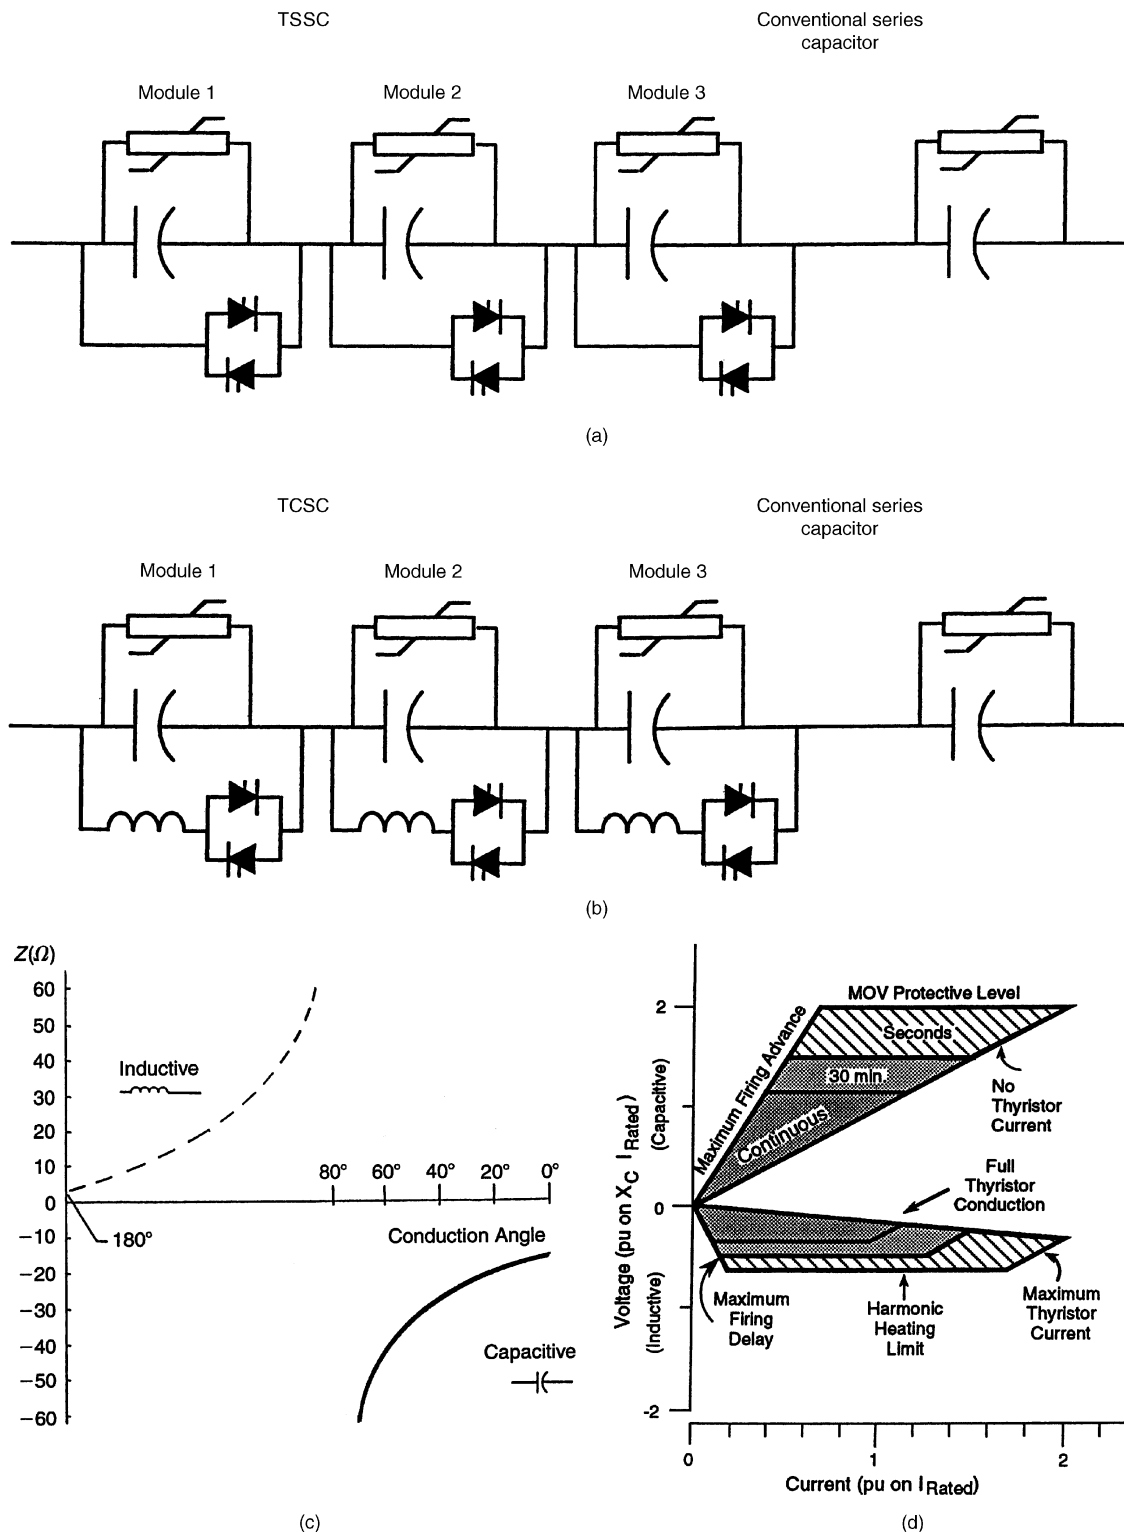

If the d.c. source is only a voltage but not an energy source, the voltage across the controller will only deviate from  $90^\circ$  by an amount sufficient to supply the losses of the controller itself. The controller will cancel out part of the inductance of the line, reducing the voltage across the line and reducing the apparent surge impedance. The stability limit for the line will be increased and a greater power may be transmitted—or a longer line may be used at the same power level.

Other control functions could be used in response to a variety of system and network conditions and contingencies. The control could be used, for example, to prevent the line being overloaded by acting as a variable positive inductance. It could be used as a fixed voltage source to drive a circulating current around a particular part of the network in order to avoid overload in another circuit. With an energy source, other methods become possible for controlling power flow in the line. If the energy source is a shunt connected FACTS controller, the combination is called a universal power flow controller (UPFC) and is described in Section 41.8.2. The interline power flow controller (IPFC) uses another series connected FACTS controller, in a parallel line, as the energy source, as described below, *Figure 41.39*.

#### 41.7.2.4 Interline power flow controller (IPFC)

It is not uncommon for two lines, that are of similar construction and rating, to follow different routes between major substations and so to have different lengths and different impedances. The sharing of current will be unequal. Furthermore, one or both circuits may link into additional load centres en route, with the result that one circuit becomes overloaded while the other has plenty of spare capacity. In such a situation an IPFC could be a far simpler and less disruptive solution than upgrading the overloaded circuit. It is very important in this application that the phase angle of the injected voltage should force sharing of the in-phase as well as the quadrature components of current in the circuits which are being equalised.

**Figure 41.37** (a) Thyristor switched series capacitor (TSSC); (b) Thyristor controlled series capacitor (TCSC), (c) Usable ranges of TCSC conduction; (d) Typical TCSC V-I capability characteristic

Figure 41.38 SSSC

### 41.7.3 Buffering of loads from system disturbances

There are many industries and industrial processes that are intolerant to voltage dips and even brief interruptions. If critical drive motors are shut down because the voltage falls below about 85% of rated voltage, or inverters suffer commutation failures because of voltage dips or distortion in one phase, the disruption can result in a serious loss of production. There may be an extended shut down of the plant while the rescue and re-start processes are undertaken. A device that sustains the voltage on the load bus-bar in the face of disturbances on the system has great potential value for protecting the sensitive loads.

#### 41.7.3.1 Short-circuit limiting coupling (SLC)

One system employed in the 70s was the short-circuit limiting coupling (SLC, sometimes also called the 'resonant link'). The main elements were a series capacitor and reactor, of approximately equal ohmic values, connected between the consumer's bus-bar and the utility bus-bar.

Figure 41.40 DVR

If a fault, or a major disturbance, occurred in the utility system, auxiliary components automatically changed the capacitor impedance and converted the link to a large magnitude inductive impedance. This buffered the customer's bus-bar from the effects of system faults and the critical plant continued to be supplied, without experiencing a disturbance, from customer's in-house generating plant. The design and implementation of the SLC included measures to guard against SSR effects between the series capacitor and the local generating plant.

#### 41.7.3.2 Dynamic voltage restorer (DVR)

The advent of voltage-sourced converter technology has enabled another buffering technique to be applied, which avoids the disadvantages of series capacitors and does not rely on local generation being present, the Dynamic Voltage Restorer (DVR), Figure 41.40. This can be designed to be effective for voltage dips down to about 50% of rated voltage, which is sufficient for most dips caused by lightning. Energy to maintain the level of the source voltage is usually derived from a simple rectifier on the input side. In order to deal with larger, prolonged voltage dips, it would be necessary to use an energy source of sufficient capacity to supply the load demand for the duration of the voltage dip.

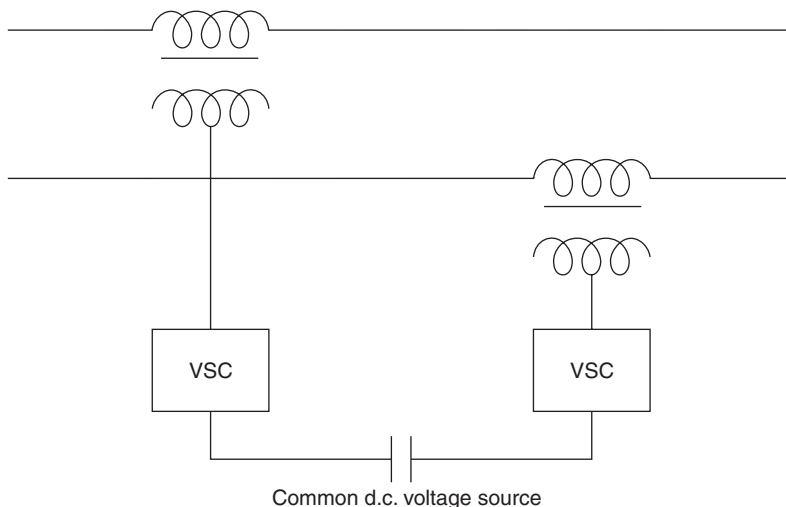

Figure 41.39 IPFC

## 41.8 Controllers with shunt and series components

It was shown in Section 41.3.5 that the power flow through a simple transmission line is given by

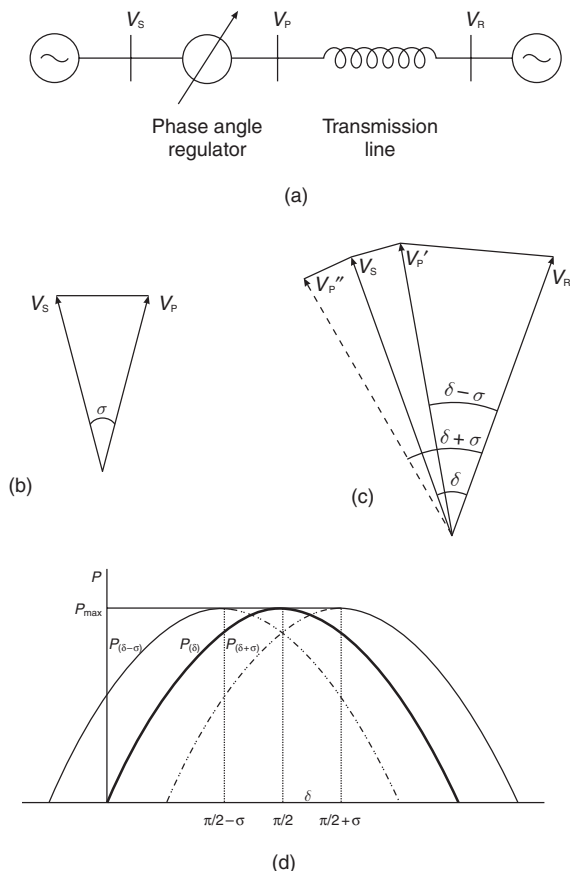

$$P = (V_S V_R / X) \cdot \sin \delta$$

Although this power flow is dependent on the voltages at the ends of the line, these voltages can be varied only within a small range and therefore cannot be used to exert a strong control over power flow. Section 41.7 showed that the effective value of line reactance,  $X$ , could be changed by series compensation and that this provided a strong control over power flow for a given value of phase angle  $\delta$ .

An alternative form of series connected controller for controlling the power flow is the phase angle regulator (PAR) *Figure 41.41(a)*. The input and output voltages of the ideal PAR are equal in magnitude, *Figure 41.41(b)*, but the phase angle,  $\sigma$ , between them can be controlled either to increase or decrease the effective phase angle across the line and hence the power flowing through it, *Figure 41.41(c)*. Thus, with  $V_S = V_P = V_R = V$

$$P' = (V^2 / X) \cdot \sin(\delta \pm \sigma) \leftarrow$$

*Figure 41.41(d)* shows that, although the power flow for a given  $\delta$  is changed by the addition or subtraction of  $\sigma$ , the

**Figure 41.41** Phase angle regulator (PAR) circuit and operation

maximum power transfer of the line is not changed. With a very fast, power electronic, tap-changer a rapid control of  $\delta$  could improve the transient stability margin by providing a valuable prolongation of maximum synchronising power through the line during the first post-fault swing. Fast control could also be used to make an effective contribution to the damping of system power oscillations.

In the practical implementation of a PAR, shunt and series connected transformers are used to inject a voltage in series with the line to give the desired change of phase angle (which, for small angles, is proportional to the injected voltage). The magnitude of the injected voltage is usually made variable by means of a tap-changer. The PAR is a special case of a more general range of phase shifting transformers for which the input and output voltage magnitudes are not always constrained to be equal; the phase angle of the injected voltage depends on the chosen winding configurations of the two transformers. By incorporating power electronics, the speed of control and the flexibility of the series/shunt arrangement can be greatly increased, including unrestricted control of the phase angle in addition to the voltage magnitude.

### 41.8.1 Quadrature booster transformer (QBT)

One of the simplest types of phase shifting transformer is the quadrature booster transformer; *Figure 41.42(a)* shows

**Figure 41.42** Quadrature booster transformer (QBT) circuit and operation

the basic arrangement. One transformer is connected with its primary winding in series with the transmission line, its secondary being fed from the secondary winding of a transformer connected in shunt to the system. The magnitude and polarity of the injected voltage is usually controlled by means of an on-load tap-changer.

The phase angle of the injected voltage is in quadrature with the system voltage, *Figure 41.42(b)*, and therefore the magnitude of the voltage at the output terminals of the QBT is slightly different from that at the input terminals. For a typical maximum injected voltage equal to 20% of the shunt voltage, the difference will be about 2%; the phase shift is about  $11^\circ$ . The NGC has installed about a dozen QBTs, with ratings up to 2750 MVA, at critical points within the transmission network on England and Wales. Phase shifting transformers are commonly used by utilities in the US to control power flow in parallel, long distance, circuits.

QBTs are usually connected in substations where they can control the power flow in one or more circuits to prevent thermal overloading. As thermal time constants of lines are measured in minutes, a conventional mechanical tap-changer can be operated quickly enough to prevent such overloads.

If there were a requirement to improve transient stability with the aid of a phase shifting transformer, the injected voltage would have to be changed much more rapidly, for example, using a thyristor-based tap-changer instead of a mechanical tap-changer.

#### 41.8.2 Unified power flow controller (UPFC)

The UPFC, *Figure 41.43(a)*, is a combination of a STATCOM and an SSSC and offers great flexibility of operation. In this case the secondary winding of each transformer is connected to a three phase voltage-sourced converter. The two converters are connected back-to-back as a d.c. link with their d.c. capacitors acting as a common d.c. voltage source so that, with an appropriate co-ordina-

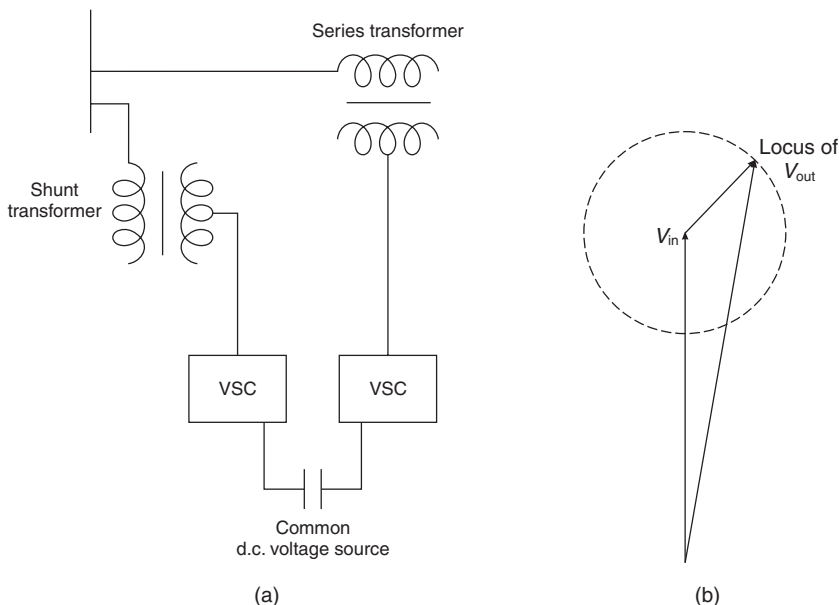

tion between the control systems for the two converters, power can be exchanged in either direction between the shunt and series systems. In addition, each converter can be controlled to supply or absorb Mvar independently to the series and shunt systems.

Thus, whereas a series impedance device, such as SSSC can only develop a voltage in quadrature with the current, the UPFC can generate a voltage in the series circuit with a phase angle that is controllable throughout the full range of  $360^\circ$ , as shown in *Figure 41.43(b)*. When the voltage is not in quadrature with the current, power will flow out of or into the series connected converter, via the d.c. link, into or out of the power system through the STATCOM. The series converter can therefore provide impedance compensation and/or phase shifting. The STATCOM can provide voltage regulation at its point of connection independently of the power being transferred, subject only to its limits of rating.

A UPFC was commissioned in 1998 at the Inez substation of American Electric Power (AEP) in Kentucky, USA. The series and shunt units can be operated together as a UPFC or may be operated independently as STATCOM and SSSC respectively. The converters are rated at  $\pm 160$  MVA and use GTOs; they are identical. A spare shunt transformer has been provided so that the converter provided for the series application is also capable of being operated as a STATCOM.

### 41.9 Special aspects of var compensation

The power demand of industrial loads, such as arc melting furnaces or thyristor drives for rolling mills and mine winders, varies rapidly in both magnitude and power factor. In an arc furnace the impedance of the arc can change completely from one half-cycle to the next. The changes may be particularly large during the early part of a melt; the arc can become short-circuited by scrap metal, when the furnace current is limited only by the circuit reactance, or may be interrupted completely for brief periods. This gives

**Figure 41.43** Unified power flow controller (UPFC) circuit and operation

a current demand which fluctuates very rapidly, in an unpredictable random manner, and may take any value between zero and short-circuit current.

In thyristor drives, very large changes in energy are required during acceleration and deceleration. For instance, in a rolling mill, the drive motor is initially running at low speed and therefore at a low voltage. When an ingot enters the rolls, the drive motors are accelerated to full speed by phasing back the thyristors; this increases the current very rapidly to its rated maximum value, typically 2 to 2.5 times rated current at about 0.2–0.3 power factor lagging. The current demand falls to its full load value when the motor has accelerated to full speed. Unlike the situation in the arc furnace, the changes in power and var requirements are much more predictable, as they occur in a regular cycle and most are relatively slow.

Both kinds of load can cause voltage fluctuations due to the fast changes of var flow through the system reactance. These voltage fluctuations may be unacceptable unless the network is strengthened or reactive compensation applied. The severest limitations usually arise due to lamp flicker and sometimes due to interference with electronic control circuits of other equipment. Different types of lamp have different sensitivities to voltage change. For lamps used in a domestic environment, filament lamps are the most sensitive; their percentage brightness change is about 4 times the percentage voltage change. In comparison, for fluorescent lamps, the ratio of brightness change to voltage change is about 1. Sodium lamps are even less sensitive with a ratio of about 0.5; although high-pressure mercury vapour lamps have a ratio of about 3 they are normally found only in an industrial and not a domestic environment. Because lamp flicker caused by arc furnaces is very difficult to deal with, it will be emphasised in this section, but the general principles are applicable to the compensation of other fluctuating loads.

#### 41.9.1 Lamp flicker compensation

The spectral density of voltage fluctuations produced by an arc furnace is approximately in inverse proportion to the square root of the frequency. People experience a subjective response to lamp flicker; generally, human sensitivity peaks just below 10 Hz for 230 V filament lamps. As can be seen from Figure 41.44, a weighted combination of these characteristics shows that the frequencies most liable to cause visual annoyance lie in a band from about 2 to 25 Hz. If the voltage fluctuations at 10 Hz are greater than about 0.2%, then they are likely to cause a noticeable flicker on the luminous output of a 230 V filament lamp. A 110 V lamp of the same wattage has a heavier filament with a

Figure 41.44 Eye sensitivity to arc-furnace-induced flicker

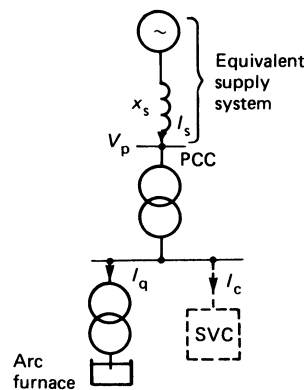

Figure 41.45 Simplified arc furnace supply circuit. PCC is point of common coupling (with other consumers)

greater thermal capacity, which results in a smaller response to voltage fluctuations and the most disturbing frequency is reduced to about 5 to 6 Hz.

A circuit supplying an arc furnace can be simplified to that shown in Figure 41.45, where the point of common coupling (pcc) is the point in the network at which other consumers are connected. The resistance of the supply is usually small compared to the reactance,  $X_s$ , and the voltage dip at this point,  $V_p$ , is predominantly due to the variation of arc furnace var demand. If there is no SVC installed, the reactive current,  $I_s$ , in the supply is the same as the furnace reactive current,  $I_q$ , and we get:

$$V_p = \frac{I_q}{X_s} = \frac{I_q}{X_s}$$

It is thus relatively easy to estimate the magnitudes of the voltage dips caused by var fluctuations, but the annoyance caused by a sequence of rapid voltage dips is difficult to assess. In order to assess and quantify the effects of fluctuating voltage dips on the human eye and brain, a flicker meter has been developed by the International Union for Electroheat (UIE) and has been accepted by the IEC. The flickermeter measures the successive voltage fluctuations and, by means of algorithms worked out from first principles, converts them into numerical values that are compared with what 50% of the population would regard as the threshold of perceptibility for lamp flicker. For this threshold level of lamp flicker, the UIE flickermeter would give a numerical output of 1.0 for 'short term flicker severity' (Pst).

A flickermeter can only be applied when a furnace comes into service and cannot be used directly to predict flicker levels. However, a simple estimating procedure for planning purposes, has been derived empirically from records of complaints of flicker on many installations. This procedure evaluates the 'short-circuit voltage depression' (SCVD) for a proposed arc furnace; this is the change of voltage at the pcc that would be caused by a change in furnace var demand from no-load to a steady three-phase short-circuit on the electrodes. If the SCVD is greater than about 2%, consumers are likely to suffer sufficient annoyance to complain about lamp flicker. For an arc furnace installation with an SCVD of about 1.3%, the UIE flickermeter would typically indicate a maximum Pst value of about 1.

The SCVD criterion can be used to assess the maximum furnace rating that should be connected to a given system, but it can only be used to determine the rating of a compensator for flicker reduction provided that the compensator is capable of reducing all flicker frequencies in the visual

annoyance range reasonably equally. Where a compensator has an acceptably linear fluctuation frequency versus speed of response characteristic up to about 25 Hz, then, if connected as shown in *Figure 41.45*, a steady state calculation of SCVD can be used to estimate its rating, i.e. the compensator current  $jI_c$  makes up the difference between the allowable  $-jI_s$  and the value of  $-jI_q$ . A high speed of response is essential for flicker reduction. It has been shown that if the compensator has a control-time delay of 10 ms, no matter what its rating, it can give very little reduction of flicker; with a time delay of 20 ms or greater, a range of frequencies within the visual annoyance range will be strongly accentuated. A thyristor switched capacitor compensator, for example, cannot achieve the necessary speed of response to reduce the arc-furnace flicker in the frequency range above 5 Hz, where the human eye is most sensitive.

The harmonic-compensated saturated reactor without a slope-correction circuit has been used to give flicker reduction of up to 3:1. It has been employed successfully in many installations as a bus-bar compensator (*Figure 41.46(a)*), having been designed on the basis of the SCVD criterion. The tapped-reactor/saturated-reactor scheme (*Figure 41.46(b)*) has been used to obtain a flicker reduction of up to 7:1 for a single arc-furnace. In this scheme the saturated reactors are single-phase devices and the slope correction is achieved by the

tapped reactor winding ratios; this compensator inherently compensates for the unbalance loadings of the arc furnace and gives an instantaneous response. It produces considerable harmonic distortion and requires substantial filtering.

The TCR used as a bus-bar compensator can be made suitable for arc-furnace compensation with a flicker reduction of about 2:1. Voltage-sourced converters, because of their lower reactances and capability for much faster response, can outperform conventional TCRs; present indications point to a flicker reduction of about 4:1 being obtainable.

### 41.9.2 Phase balancing

Three-phase a.c. systems are intended to operate in a balanced mode. Unbalance can have detrimental effects on equipment connected to the system; rotating plant is particularly sensitive due to additional losses and consequent excessive heating. Most rotating plant is able to accept only 1% of negative phase sequence voltage continuously and 2% for short periods.

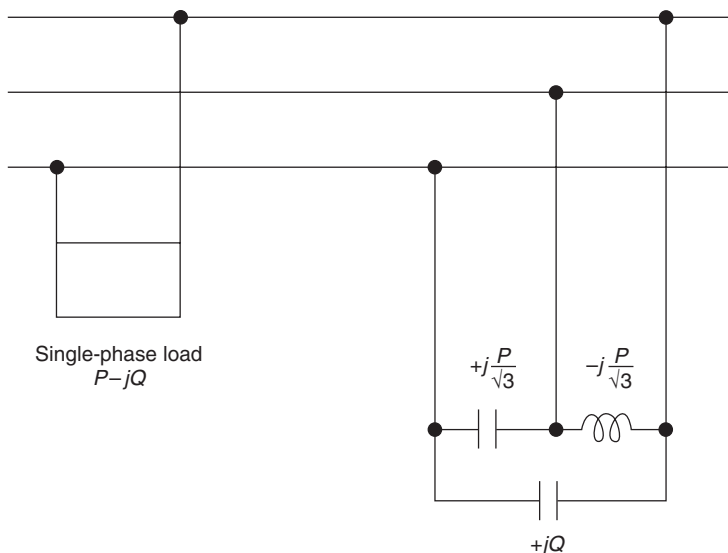

Most loads of significant size are 3-phase and operate in a balanced manner. The main exceptions are arc furnaces, mentioned above, and substations supplying a.c. traction loads. Unbalance is also caused by the physical asymmetry of transmission lines; on long lines it is usual to minimise this unbalance by regular transposition of the conductors. In rural distribution systems, unbalance is sometimes caused by unequal distribution of the many single-phase loads between the three phases.

Arc furnaces are unlikely to cause adverse unbalance effects without first causing complaints of lamp flicker. The corrective action of any flicker suppression equipment will normally also limit unbalance contributions to acceptable levels.

The unbalance caused by traction systems has sometimes been corrected by means of conventional thyristor controlled equipment with one phase providing conventional power factor correction and the other two acting as a controllable Steinmetz circuit, *Figure 41.47*, for balancing the power component of traction load. The asymmetrical

**Figure 41.46** Arc-furnace compensation: (a) bus-bar compensation; (b) tapped reactor/saturated reactor compensator

**Figure 41.47** Steinmetz circuit for balancing single-phase loads

operation of the three phases of the SVC requires the shunt capacitors to be arranged to filter low order harmonics.

Converter technology now provides an alternative method of phase balancing with a nominally lower rating of equipment. A voltage (or current) sourced converter is used to generate an nps current which is equal in magnitude but in phase opposition to the nps current of the traction load. It thus acts as an active filter for unbalance.

### 41.9.3 Switched resistors

Switched resistors do not come under the strict heading of reactive power plant but have been used in certain situations to complement such plant. In situations where system transient stability is threatened by loss of synchronism due to the acceleration of a suddenly unloaded generator, switched braking resistors can provide a temporary substitute load for the generators and prevent excessive acceleration. By using thyristor switches instead of mechanical switches, fast repetitive switching can be used to aid in damping system swings.

Thyristor switched resistors have also been used with an arc furnace which comprised a significant proportion of the load on a set of gas turbine generators. In order to reduce maintenance requirements, it was desirable to operate the generators at a fairly steady load and to smooth out the rate of change of load when the furnace was suddenly switched off. This was done by thyristor switching of shunt resistors.

### 41.9.4 Harmonic currents and harmonic filter design

Many types of plant draw a distorted, non-sinusoidal current from the supply system, as, for instance, large rectifiers (aluminium smelters), controlled converters (traction drives, mine winders, rolling mills) and discharge lamps. The millions of low power, harmonic-producing devices used in the home and workplace, such as light dimmers, television receivers and personal computers also make a surprisingly large contribution to the total voltage distortion on many systems. Power transformers (due to magnetising currents), h.v.d.c. converter stations, SVCs and many other FACTS controllers are sources of waveform distortion in the network itself. These currents and the consequent voltage waveform distortions can be described in terms of fundamental and harmonic frequency components using Fourier analysis.

The harmonic content of voltages and currents can have undesirable disturbing effects on the system and its loads and on adjoining telecommunication circuits. Inductive or capacitive coupling between telephone and power lines induces harmonic interference over the audio-frequency range, and appropriate weighting factors are applied to the individual frequencies when assessing total distortion effect using measures such as telephone interference factor (TIF). The increased use of fibre-optic communication circuits has reduced the extent of this telephone interference.

Rotating generators and induction motors experience increased power loss due to the flow of harmonic currents. Waveform distortion can sometimes cause maloperation of electromagnetic as well as static protective relaying equipment. Shunt capacitor banks primarily for power factor correction are particularly affected by harmonics, as their impedance falls inversely with frequency so that they tend to act as 'sinks' for high frequency harmonic currents and may overload due to increased losses. Shunt capacitors form a resonant circuit with respect to the rest of the system

at some frequency above the fundamental (i.e. at a super-synchronous frequency); if the resonant frequency is close to that of a local source (or sometimes even a remote source) of harmonic current, large and potentially damaging harmonic overvoltages and current magnifications can occur. For these reasons, harmonic distortion must be limited to acceptable levels by careful system design and, where necessary, by installation of shunt harmonic filter equipment at appropriate system bus-bars.

In order to minimise adverse harmonic effects, supply authorities apply harmonic current and voltage distortion limits, based on observed disturbances and on a desire to protect other consumers and telecommunication services. Compliance with the limitations at the point of common coupling with other loads may require reduction of system impedance by addition of lines or transformers, or the connection of the distorting load to a different point in the network. In case of converter loads the pulse number may have to be increased from 6 to 12, or even 24.

Connection of a properly designed harmonic filter consisting of a combination of inductive, capacitive and resistive elements at a suitable bus-bar will provide a low-impedance shunt path to the flow of harmonic currents generated by the distorting loads. The filter and the system will share the harmonic current injected by the load in the inverse ratio of their respective impedances. The desired impedance pattern of the filter circuit can usually be achieved by an appropriate combination of single-frequency tuned arms and broadband damped arms, *Figure 41.48*.

The system impedance varies with harmonic frequency in a complex manner, as most systems are not purely inductive. Systems have intrinsic resonant frequencies and, at these frequencies, there are dramatic changes in impedance from inductive to capacitive for only a few per cent variations in frequency. The supply system will, in general, have many different operating configurations and, to take account of the worst conditions, the system impedance vector is sometimes assumed to lie within a circular segment limited by maximum impedance angles. In simpler industrial circuits, the supply impedance is usually dominated by transformer impedance; this transformer impedance is assumed to increase in proportion to frequency to give the system harmonic impedance. This simplifying assumption can also be made (in the absence of other data) if the system up to the point of connection of the filters is not primarily composed of long lines or cables.

The system may contain several harmonic sources other than the particular known loads, or SVCs, or h.v.d.c. converters; in the assessment of the voltage distortion levels and filter component current ratings the effects of such 'pre-existing' harmonics must be included.

The high-pass damped filter shown in *Figure 41.48* is sometimes advantageous compared with sharply tuned arms if the filter is to be satisfactory over a wide range of

**Figure 41.48** Harmonic filters

system operating frequency (e.g. from 49 to 51 Hz); but such damped arms can have greater losses. The modified damped filter is of particular use if the frequencies of the harmonics to be passed are low, as the loss in the resistor can then be excessive at the fundamental frequency unless it is shunted by the series  $L$ - $C$  circuit tuned to the fundamental frequency. Such a filter is specifically useful for suppressing unintended resonances at 'non-characteristic' frequencies (e.g. second harmonic) which are inherently low in current magnitude and thus would not give large loss in the resistor at these harmonic frequencies.

The optimum design of a combination of different filter arms (tuned, damped, etc.) to achieve a particular harmonic impedance pattern requires an economic assessment of the effects of choosing different relative proportions (in terms of fundamental Mvar) of the filter arms. The choice is governed not only by the harmonic performance requirements, but also by the fundamental plus harmonic ratings of the filter components—in particular, the capacitor banks. The effects of variations in the filter impedance with system frequency, temperature and component tolerances should be taken into account. The choice of the filter combination should also ensure that the non-characteristic harmonics (e.g. second, third or fourth order), which may be relatively small, are not excessively magnified by unintended resonances between the filter itself and the system. The need to minimise fundamental plus power-frequency losses in the filters also plays an important role in the final choice of the design.

## 41.10 Future prospects

### 41.10.1 Recent progress

There has been considerable progress in the field of var control during the last few years. A number of 'future prospects' of only 10 years ago have now been developed into practical FACTS controllers. In the field of shunt var compensation, several different types of voltage-sourced converter are being used in the various STATCOMs that are now in service in transmission systems. TCSCs are being used to provide series compensation of long transmission lines. The concept of the SSSC combined with a STATCOM to form a UPFC has been realised in a unit rated at  $\pm 160$  MVA and progress has been made towards the installation of an IPFC. In distribution systems there are a number of DVRs providing protection against voltage dips for sensitive loads. Several active filters have been put into service.

### 41.10.2 Further advances

#### 41.10.2.1 Development of power electronic devices

Many of the developments of power electronic switching devices that have already taken place have been in response to the needs of the large market for industrial drives rather than the needs of the supply industry; this situation is likely to continue. Developments are generally directed towards the reduction of forward voltage drop and overall losses, improved ratings, increased switching speeds and smaller physical size.

#### 41.10.2.2 Development of converter designs

It must be anticipated that converter designs for FACTS controllers will evolve to incorporate the improved devices

as they become available. Switching and control using conventional thyristors is mature technology and is likely to continue to be applied in FACTS controllers for many years, with relatively minor improvements. In contrast, voltage sourced converters will continue to be developed and improved as their application becomes more widespread. A particular target for improvement is likely to involve the reduction of harmonic generation by the converters and/or active filtering of harmonic distortion. In order to accommodate some types of energy storage systems, there may be increased activity in developing current-sourced converters.

#### 41.10.2.3 Development of energy sources and storage systems

With sufficient capacity, energy storage systems could contribute to spinning reserves, peak lopping requirements and system frequency control. Battery energy storage systems (BESS) lend themselves to providing energy input to the voltage sourced converters of STATCOMs and superconducting magnetic energy storage (SMES) is under development but improvements in the economics of energy storage are still needed. Fuel cells offer an alternative type of energy source and regenerative fuel cell systems are currently being developed.

#### 41.10.2.4 Thyristor tap-changers

The technique of using thyristors instead of mechanical switches is available for controlling transformer tap ratios and hence for fast control of voltage and vars. The magnitude as well as the phase angle of the voltage can be made rapidly controllable, but the considerably higher cost has so far not justified their use. New types of power electronic device might improve the viability of thyristor tap-changers.

### 41.10.3 Future applications of FACTS controllers

#### 41.10.3.1 Long distance transmission

Series capacitor compensation is an economic way of increasing the power transfer capacity of a line, but some of the potential gain in additional capacity may be lost when linear shunt reactors are permanently connected. Subsynchronous resonance conditions must be evaluated at the design stage, but techniques are now available for damping out SSR.

Shunt compensation using SVCs provides good voltage control along the line and at its terminals and can also result in increased transmission capacity. Further benefits arise from the combination of shunt and series compensation, which is likely to be more widely used as transmission companies seek to maximise the utilisation of their assets.

#### 41.10.3.2 HVDC applications

It is increasingly difficult for utilities to obtain permission for the construction of new circuits, or even the up-grading of existing a.c. transmission lines. Undergrounding is extremely expensive. In such situations, the only practical way to increase the power transfer along a particular corridor may be to convert circuits from a.c. to d.c. operation. The easy controllability of d.c. can also enhance the flexibility of the rest of the a.c. system and can contribute to the damping of a.c. system phase angle oscillations. H.v.d.c. can also be used to couple adjacent, non-synchronised systems to provide mutual benefits from shared reserve generating capacity.

These applications of d.c. technology should become increasingly common.

#### 41.10.3.3 Power quality

Power quality is judged on a range of criteria including interruptions to the continuity of supply and disturbances to the voltage magnitude, waveshape and frequency. Customers are increasingly concerned about these aspects and demanding improvements (and reduced tariffs). FACTS controllers will increasingly be used to assist in improving power quality.

#### 41.10.3.4 Energy management systems

Modern energy management systems (EMS) provide an operator with up-to-date information on the state of his system and enable him to obtain very rapid answers to his 'What if?' questions. These systems can provide valuable information for longer-term system planning purposes, especially in respect of the requirements for voltage control and var management. They can also be used to supply control data for the FACTS controllers already operating within the system so that system operation can be made more robust and reliable under both normal and emergency conditions.

## 42.1 Introduction

Like any commodity or good, electrical energy can be bought and sold in an established market place. Hence buying and selling infrastructures are required to enable quantities and prices to be publicised and contracts negotiated between various groups or individuals. The difference between electrical energy and other commodities is the delivery system—rather than delivering by some form of road, rail, air or sea transport, once generated, electricity can only be delivered by wires over a transmission and distribution (T&D) system (see Chapter 39 for details). For such a system to function, at all times the energy input must be equal to the energy taken out plus the system losses (10% or so). This is an added complication for which the consumer has to pay extra to a system operator as well as a charge to the T&D asset owners for use of the system (UoS). In many countries the T&D asset owner is also the system operator, but this need not be so (compare the transporter as a separate entity to the manufacturer, retailer or road owner). Consequently the economics of electricity supply has not only to include the cost of providing a primary fuel (e.g. for gas, coal or oil fired power stations) or even for the provision of renewable energy production (wind generators, solar cells, hydropower, etc.) it must also cover the cost of delivery over a reliable and secure network, right down to each consumer's supply terminals. There are many components to electricity supply chain economics which will be identified in this chapter, finishing with processes for trading in electrical energy markets.

It should be noted that in many developing countries the production and delivery of electricity is still centrally controlled by the government through a state run industry where planning, operation and prices are organised according to the economic and social welfare priorities of the legislature. Until the 1980s this form of electricity supply industry (ESI) control was common in Europe, S. America and Japan but since then many governments have realised that to obtain investment from the financial markets to develop and expand the ESI some 'unbundling' and 'privatisation' of the businesses bound up with electricity production and supply could be beneficial in reducing prices for the consumer through competition and kick-starting new kinds of economic activity. As a result, deregulation and restructuring of the ESI is taking off in many countries where separate utilities have been run as businesses with private investors for many years, but subject to government or state imposed regulation.

## 42.2 Summary of electricity pricing principles

### 42.2.1 Economic efficiency

It is obvious that the price of any commodity in a 'free' market will determine the purchase and use of that commodity. With electrical energy, since storage by the consumer is prohibitively expensive, the price per kWh is important but so is the time of day that it occurs. Over a 24 hour period, electricity is usually priced in one hour or half hour 'slots' for prescribed or transacted amounts delineated in kWh. If this amount is exceeded at the end of the slot, a penalty price could be charged for the excess. To calculate the resulting bill the actual energy taken over the time slot must be metered in quantity and time; this

requires a modern electronic meter which can be interrogated for all the slots since the last bill was calculated. Such a meter, preferably with a 2-way communication link to the reading and billing agency, is 5 to 6 times the cost of a simple kWh meter as fitted in residential and small business premises. Consequently, time of day pricing is normally only available where the metering costs are justified such as for customers with annual energy bills of £1000 (\$1500) or more. Any customer wishing to keep control of business running costs will no doubt be influenced by the time-of-day energy price and adjust energy use accordingly. As an alternative, the limitation of energy use may be delegated to the supplier for a negotiated reduction in tariff, e.g. off-peak night storage heating tariff. The electricity generator will be charging a price for energy to cover the cost of production plus overheads and profit but over a period of time the customer will adjust requirements to minimise total costs, so in the absence of other factors, a balance between generation and consumption will be achieved. This is called a *Pareto* balance named after the 19th century economist, Alfredo Pareto. It is also one definition of *economic efficiency* as sought after by economists with a free market.

Unfortunately, although the market may be efficient it does not follow that everyone using the market is getting good value for money. Some participants may be constrained in their ability to offer lower prices because of their geographical position in respect of the delivery of their goods or alternatively consumers may be paying more for their energy than if they installed and ran their own generator (e.g. a CHP scheme) provided they could find the capital to purchase it. *Social welfare* is an attempt to measure the benefits of having an infrastructure in place which maximises the sum of the monetary benefits accruing to every individual or group (producers and consumers) in the country or state, including any tangible but useful benefits to which a monetary value can be given. A good measure of useful benefits is the willingness to pay, thereby suggesting that the optimal alternatives or *choice* for both parties as brought about by *competition* is desirable. It is at this stage that the government, state or regulator may step in to limit choice so that some societal group (e.g. the poor) is not disadvantaged. This can be done by *subsidy* from government or by *price capping* by a regulator, just two among many possibilities.

### 42.2.2 Marginal pricing and risk

Any commodity sold in the market place will become dearer as its availability diminishes. Electrical energy is no exception because its price per kWh for a particular period will rise as generators contract to produce more and more energy, starting with the cheapest plant until the most expensive plant is contracted during some periods. If some production capability is not contracted over, say, a season, it can be mothballed or scrapped. Consequently, at any particular time slot not only can the price per kWh available be recorded but also its rate-of-change with total demand. This rate-of-change is called *short-run marginal cost* (SRMC) and indicates the cost of supplying the next kWh of energy. It can be applied to a single generator, a portfolio of generators or to a whole integrated system. In the latter case it is known as *system marginal price* (SMP) or *system lambda* recognising that it is derived from equalising the marginal costs of all part loaded generators by differential calculus. (Note: in a centrally controlled and integrated network such plant would be loaded by the system operator

in ascending order of notified or bid prices—the so-called *economic dispatch*.)

In practice the SRMC, if charged, although more than the average cost of generation, will not bring in sufficient revenue to cover the repayments on the invested or asset cost to enable producers to survive and make a reasonable profit. When these necessary repayment costs are included in the price per kWh, they are called *long run marginal costs* (LRMC). If sufficient revenues are to be made to include LRMC, economic theory requires that over several years SRMC and LRMC should be equal for profit maximisation. However, the usual case is that SRMC is less than LRMC requiring that the producer or supplier must charge a 'supplement' to cover the capital repayment cost of installed plant and any new plant—this supplement is known as *revenue reconciliation*. In market trading it is expected that the seller will include a *mark-up* in the negotiated price to enable the business to continue. The mark-up is a matter of judgement depending upon competition in the market and is part of the *risk taking* strategy adopted by the business. There is a wealth of economic literature and many useful theories such as Ramsey pricing, inverse elasticity rule, benefit maximisation etc. which businesses indulging in markets should take on board. (see Hunt & Shuttleworth, 1996, Schweppe *et al.*, 1989).

#### 42.2.3 Delivery charging

With physical commodities such as grain, coal, packaged goods etc. a haulier or transporter is engaged at a contract price to carry out delivery to the customer. Who pays for the delivery is a matter for the contract to specify. With electrical energy there are several complications to take into account, the most important being the *instantaneous* nature of electricity and the need for the existence of a continuous wire path between generators and consumers. A further complication is that as the power system network (at least as far as transmission is involved) is a *meshed* system there is no defined path between a producer and a consumer. Consequently, any delivery charge (known as *use-of-system* charge) in all fairness must depend upon some measure of quantity, based on the provision of installed plant and circuits with adequate capacity and the 'wear & tear' on the system due to the flow of power through the wires. The only reason for system equipment, including overhead lines, cables and transformers, to deteriorate and require maintenance or replacement is that the power flow involves some heating due to losses, the raised temperature thereby causing faster deterioration of insulation than if no heating occurred. Over the power system as a whole, the owners and operators require to recover their costs in an equitable manner. This is done by a use-of-system (UoS) charge agreed with the regulator as competitive delivery systems are unlikely and delivery is a monopoly business.

It is usual for the power network to be split between various owners through which power flows by a path determined by basic electrical laws from the generator to the consumer. Each owner will expect to recover the cost of installing and maintaining equipment (amortised over say 20 years) and for controlling the flows, including voltage control at all parts of the owned network. This requires metering at input and output points such that the delivery charge can be apportioned dependent upon the chosen or agreed rate. Suffice to say, there are a number of established methods for charging based on capacity (kW) and metered energy (kWh), the main requirement being the recovery

of sufficient monies to keep the utility owner in business or to satisfy any governmental or regulatory target set for rate-of-return on the service. Details of UoS charging methods can be found in Schweppe, *et al.* 1989 or Weedy & Cory, 1998.

### 42.3 Electricity markets

A commodity market is where buyers and sellers can negotiate a contract for a designated 'block' of electrical energy. It also enables everyone trading in the market to 'discover' the price that other traders are paying or are prepared to offer their blocks of energy so that an auction can be conducted under established rules. An electricity market has effectively only one commodity on offer but its price is very dependent on the period over which it has to be delivered. This is because the price of electricity is higher at peak times than at other periods of the day, week or season (see Chapter 39 on Planning). In the market through negotiation, contracts can be drawn up with the usual penalties for non-delivery etc. under market rules. The market must be efficiently organised and include mechanisms for collecting revenues due under the contracts and any penalties for non-compliance. This can be a complicated procedure, often requiring legislation to enforce the rules and to deal with disputes.

One of the most difficult features markets need to enforce is that of preventing particular traders setting prices because they have monopoly or near monopoly power due to their size or the lack of effective competition. Also they must police the traders to ensure that collusion on price is outlawed. If natural monopolies exist e.g. in transmission and distribution, then a regulator is appointed to control prices that can be charged. In many cases the same market may deal with a number of different businesses such as generators (producers), shippers (transporters) and suppliers (retailers) to end users. In electricity the markets are now used to dealing with four types of traders, namely generators (single or multiple utilities), transmitters (usually high voltage transmission companies), distributors (lower voltage) and suppliers (retailers to the individual consumer, factory, commercial building, etc.). Up to now, transmitters and distributors have been thought of as natural monopolies implying that other shippers would find it too expensive to offer an alternative means of delivery, but with the growth of small embedded generators who might find it worthwhile to construct their own local distribution network, this natural monopoly could be gradually eroded.

Nowadays, everyone expects markets in commodities or services to be run over the internet by established market-makers and the electricity forward market is no exception. Traders can either switch around to various internet sites to discover what prices and trades are available, or they can stay with one market maker if they have a good reason. The internet market is often global in extent although trades between producers and suppliers would need to ensure that delivery could be made and the delivery charge accounted for. Since some markets include other types of energy e.g. gas, oil, coal, bulk shipping across the world or through another country is well established. Delivering electrical energy via another utility's or country's power system (known as 'wheeling') is now becoming possible with the opening up of many grids for third party access under liberalisation rules or legislation.

## 42.4 Market models

As the ESI in most industrialised countries begins to open up to trading, the 'model' of generation, transmission, distribution and supply moves from a 'vertically' integrated system often with central government control to the separated 'unbundled' system with each part being run as an independent business (see Hunt & Shuttleworth, 1996). In this latter case, economists insist that in a truly competitive market with many buyers and sellers for all time periods, prices for energy and delivery will become based on marginal cost and the most economic means of providing all consumers with electricity will ensue. Unfortunately, as we have seen, transmission and distribution (T&D) are never likely to become fully competitive and, as monopolies, they will have their prices set by a regulator who is required by legislation to set fair prices with a fair return on assets for the owners. With T&D prices added, the market operates with two prices—a generation price and a delivery price for each geographical zone of the power system. The price differential between zones reflects the cost of delivery including payment for losses and service costs for arranging the delivery by the T&D operators. It is implicitly assumed that all trades can be delivered, but if the delivery system is congested (usually on the transmission network) then the system operator can order up (at a price) extra generation to clear or balance the market. The extra cost of this service must be added to the delivery charge in an agreed manner. In some systems it may be possible to buy priority transmission rights, thereby ensuring that at congested times a trade can be completed. In the extreme event that the negotiated energy quantities in a given time slot cannot be delivered, then some form of load shedding is necessary to save the system from collapse. This will certainly incur penalty payments from the supplier to the consumer for lost production or inconvenience, thereby acting as a ceiling on any traded prices. Although most ESIs are now in some transition stage between government controlled vertically integrated operation and a form of generation and supply competition, the final form of the ESI may well take on different features to those expounded here.

## 42.5 Reactive market

Besides ensuring that trades can be delivered, the system operator (SO) must keep the 'nodes' or 'bus-bars' in the system running within at least  $\pm 10\%$  of their designated voltages. This is a tricky job when the power flows through the network can vary by up to 60% during the course of the day. The mechanism for voltage control is through the injection or extraction of volt-ampere reactive (Var) at the main network nodes. Briefly, Var is not real power but is a controlled oscillation of electrical energy between the capacitance and inductance of the network. Any imbalance of Var must be corrected on a local basis through Var producing or absorbing devices, because if Var has to be transmitted over any distance (e.g. 50 km or more) it can produce a considerable voltage change between adjacent nodes, thereby worsening the voltage control problem.

Although no net energy is required to produce or absorb Var, it can lead to small extra losses due to the resistance of the network or inherent in the devices it flows through. It can be measured as kVarh by a suitable meter in a similar fashion to kWh and is conventionally considered positive if injected into the network or negative if extracted from the network. A surplus of Var occurs naturally in most networks (consisting of cables, overhead lines and transformers) under light load conditions leading to higher than normal voltages and a deficit of Var occurs under heavily loaded conditions, leading to lower than nominal voltages.

Fortunately, all synchronous generators are designed to run either underexcited or overexcited through control of the rotor currents from the excitation system associated with each generator. When they are overexcited they produce Var (or operate at a lagging power factor in order to satisfy an inductive load); underexcited they have a limited capacity to absorb Var (run at a leading power factor for a predominantly capacitive load). The penalty, as far as the generator plant owner is concerned, is that overexcitation being the more usual of the two running conditions, incurs extra heating of the generator rotor and a drain on the excitation supply, whilst in the long term it causes a more rapid deterioration of the rotor and stator conductors. Both of these considerations require that the plant owner should be compensated based on the net kVarh metered at the generator terminals. At the consumer's terminals, loads normally consist of circuits requiring magnetisation in some form or other e.g. a motor, power supply with input transformer, thereby demanding a lagging current (Var absorbing). The kVarh absorbed can be metered and charged for if there is an economic case to do so, particularly for large 3 ph. loads supplied at high voltage.

However, unlike real power, Var can be locally produced by inserting a capacitor in shunt with the system i.e. in parallel connection to the load. Hence it is considered that a reactive market (£/kVarh) could encourage consumers to reduce their reactive demand, thereby aiding voltage control of the system. In any case, the SO will need to recover any expenditure on kVarh and this would obviously need to come from consumers. Additionally, the transmission & distribution owner could also enter the reactive market by installing compensation devices (known traditionally as power factor correction) at strategic nodes in the system and covering their amortisation costs with a negotiated charge. In most cases, it is expected that the price per kVarh will be of the order of one tenth that of the average kWh energy price.

## 43.1 Introduction

Power quality is an issue that is becoming increasingly important to electricity consumers at all levels of usage. Sensitive equipment and non-linear loads are commonplace in both the industrial and the domestic environment, because of this a heightened awareness of power quality is developing. Occurrences on the supply network that were once considered 'normal' by electricity companies and users are now considered a problem to the users of more sensitive equipment.

## 43.2 Definition of power quality terms

### 43.2.1 Voltage dip

By definition a voltage dip is a reduction in the rms voltage in the range of 0.1 to 0.9 p.u. (retained) for duration greater than half a mains cycle and less than 1 minute.

Often referred to as a 'sag'. Caused by faults, increased load demand and transitional events such as large motor starting (*Figure 43.1*).

### 43.2.2 Voltage swell

By definition an increase in the rms voltage in the range of 1.1 to 1.8 p.u. for a duration greater than half a mains cycle and less than 1 minute. Caused by system faults, load switching and capacitor switching.

The magnitude of a voltage swell is dependent upon the fault location, relative to the point of measurement, the

system impedance and system earthing. An earthed system with delta-star connected substation transformer will ensure little change in the un-faulted phases voltages due to a low impedance path from fault to transformer (*Figure 43.2*).

### 43.2.3 Short interruptions

An interruption is defined as a reduction in the supply voltage, or load current, to a level less than 0.1 p.u. for a time of not more than 1 minute. Interruptions can be caused by system faults, system equipment failures or control and protection malfunctions.

Because the magnitude of the supply voltage drops below 0.1 p.u. during an interruption, the magnitude of the interruption is considered to be zero, the interruption is defined only by duration. The length of short interruptions is generally governed by the type of protection equipment utilised on the system such as auto-reclosers (*Figure 43.3*).

### 43.2.4 Transients

A transient is an undesirable momentary deviation of the supply voltage or load current. Transients are generally classified into two categories, impulsive and oscillatory. An impulsive transient is an abrupt change in the steady state voltage and/or current, that occurs outside the power frequency range and is unidirectional in polarity.

Impulsive transients are characterised by the rate of change of voltage or current magnitude, i.e. the rise and fall times. Oscillatory transients are generally characterised by their frequency content and duration. They are often due to the network response to an impulsive transient (*Figure 43.4*).

Figure 43.1 Waveform showing a voltage dip

Figure 43.3 Waveform showing a short interruption

Figure 43.2 Waveform showing a voltage swell

Figure 43.4 Waveform showing an impulsive transient event

**Figure 43.5** Waveform showing harmonic distortion

### 43.2.5 Harmonics

Harmonics are periodic sinusoidal distortions of the supply voltage or load current caused by non-linear loads. Harmonics are measured in integer multiples of the fundamental supply frequency. Using Fourier series analysis the individual frequency components of the distorted waveform can be described in terms of the harmonic order, magnitude and phase of each component. The quantity total harmonic distortion (THD) is commonly used, it represents a summation of all the harmonic components present in a waveform ( $n \neq 1$ ) (Figure 43.5).

### 43.2.6 Inter-harmonics

Distorted voltage or current waveforms containing periodic distortions of a sinusoidal nature that are not integer multiples of the fundamental supply frequency are termed inter-harmonics.

### 43.2.7 Flicker

A term used to describe the visual effect of small voltage variations on electrical lighting equipment (particularly tungsten-filament lamps). The frequency range of disturbances affecting lighting appliances, which are detectable by the human eye, is in the range of 1 to 30 Hz.

Flicker severity is the intensity of flicker annoyance defined by the UIE-IEC flicker measuring method and evaluated by the following quantities:

- short term severity ( $P_{st}$ ) measured over a period of ten minutes
- long term severity ( $P_{lt}$ ) calculated from a sequence of 12  $P_{st}$  values over a two hour interval, according to the following expression:

$$P_{lt} = \sqrt[12]{\sum_{j=1}^{12} P_{stj}^3}$$

### 43.2.8 Voltage imbalance

Voltage imbalance is defined as a deviation in the magnitude and/or phase of one or more of the phases, of a three-phase supply, with respect to the magnitude of the other phases and the normal phase angle ( $120^\circ$ ). Voltage imbalance is more commonly a problem in rural areas where one, or two, phase(s) of a three-phase supply is/are being loaded

more than the other(s). Can be expressed as a percentage of the ratio of either zero or negative phase sequence components to the positive phase sequence.

### 43.2.9 Frequency deviation

A variation in frequency from the nominal supply frequency above/below a predetermined level normally  $\pm 0.1\%$ .

## 43.3 Sources of problems

### 43.3.1 Power electronic devices

Power electronic devices both cause and are susceptible to power quality disturbances. The most common 'economically damaging' power quality problem encountered involves the use of variable speed drives (see below). All computers contain a power electronic switched mode power supply (SMPS, see below) which is a cheap and convenient method of converting mains supply into low voltage d.c. without expensive transformer windings. These supplies are the cause of a significant increase in the level of 3rd, 5th and 7th harmonic voltage distortion.

#### 43.3.1.1 Variable speed drives

Variable speed motor drives or inverters are highly susceptible to voltage dip disturbances and cause particular problems in industrial processes where loss of mechanical synchronism is an issue. The ideal solution to problems of this nature would be for planning engineers to install equipment that has a 'reasonable level' of susceptibility to voltage dips from the outset, this does not happen for two reasons:

- Manufacturers of these drives often don't publish detailed information concerning their equipment's level of susceptibility to voltage dips.
- Where optional equipment filters are offered by manufacturers at the installation stage, many customers opt not to fit them for economic reasons.

#### 43.3.1.2 SMPS (including IT equipment)

A large range of equipment, mainly office and domestic, use switch mode power supplies to convert mains to the required d.c. level. Many of these converters draw a non-linear current from the supply which is high in third and fifth harmonic content.

Because the third harmonic is a 'triplen' harmonic it is of zero order phase sequence and therefore adds in the neutral of a balanced three-phase system. The increasing use of IT equipment has led to concern of the increased overloading of neutral conductors and also overheating of transformers.

Recent developments have seen the use of switch mode power supplies in fluorescent lighting applications, these lighting applications typically represent in the region of 50% of a modern building's load. Many commercial modern buildings have large neutral conductors to cope with the levels of third harmonic, which can theoretically reach three times the magnitude of the fundamental.

### 43.3.2 Arcing devices

Electric arc furnaces, arc welders and electric discharge lamps are all forms of electric arcing device. These devices

are highly non-linear loads the current waveform of which is characterised by an increasing arc current limited only by the network impedance. Large arc furnace installations have typical current requirements of 10s of thousands of amps, welding sets draw current in the range of 100s of amps, individual electric discharge lamps draw only fractions of an amp but when it is considered that a large percentage of the domestic and commercial load requirement is contributed by lighting requirements this has a significant impact.

All arcing devices are sources of harmonic distortion, the arcing load can be represented as a relatively stable source of voltage harmonics. The effects of arc furnaces are difficult to mitigate, balancing the phases with other furnaces will not always be effective as arc furnaces are operated in various modes leading to phase imbalance. Arc welders commonly cause transients in the local network due to the intermittent switching, some electronic equipment should be protected from the effects of these impulsive spikes. Because of the requirement to limit the current within fluorescent lights a ballast is fitted which can add to the level of harmonic distortion of the supply, of particular concern is the level of the third (or higher order triplen) harmonic. Balancing the phases to have equal harmonic load is a good way to minimise the level of the triplen harmonics, but on a star-star connected transformer connection no cancellation will occur.

### 43.3.3 Load switching

The effect of heavy load switching upon the local network is a fairly common problem causing transients to propagate through to other 'electrically close' equipment. These transients can be of surprisingly large voltage magnitude, but have very little energy due to their short duration which is normally measured in terms of milliseconds. Electronic devices which may be sensitive to these voltage impulses can have their operation impaired.

The effect of load switching on the voltage is typically encountered in the form of transient activity (as seen in *Figure 43.4*). This type of transient might occur as the result of switching in a heavy single-phase load, the effect seen on the voltage measured nearby. Other equipment can be protected from these switching transients by electrically isolating them from the affecting equipment.

### 43.3.4 Large motor starting

Because of the dynamic nature of an induction machine it draws a current depending upon the mode of operation, during starting this current can be as high as six times the normal rated current. This increased loading on the local network has the effect of causing a voltage dip, the magnitude of which is dependent upon the system impedance. It can take several seconds for motors to reach their rated speed, for this reason measures are taken to reduce the level of current drawn during motor starting. These measures are dependent upon the type of motor and drive, most modern motors employ a sophisticated power electronic converter 'drive' which in most cases will control the motor's starting current to a reasonable level. Some lower cost types of motors use series capacitors or resistors to reduce the starting current, these components are then switched out once the motor's rated speed has been reached. Autotransformers are used to start some older motors, these have a variable secondary winding which allows the

motor stator voltage to be controlled and hence the current drawn from the supply.

### 43.3.5 Embedded generation

Increasing levels of embedded generation predicted in the future are likely to have an effect on power quality. Although it can not be stated that this increased level of dispersed generation on public distribution networks will degrade or improve power quality (this is an issue of some contention) it can be said that there are both advantages and disadvantages to the more widespread application of embedded generation where power quality is concerned.

An increased amount of embedded generation at substation level and below will lead to increased fault levels in the feeders. This increased fault level is one of the major concerns when considering embedded generation issues leading to calls for increased protection.

The voltage of embedded generators, when located at some distance from a substation, must be controlled to ensure power flow from the high voltage (substation bus) to the lower voltage (embedded generator connection).

With wind turbines voltage fluctuation due to variations in wind speed leads to problems with voltage regulation and therefore potential power quality problems on a local level. When a wind turbine blade, rotating at relatively low speed, passes the supporting pylon, the blade is momentarily inefficient in converting the airflow into rotational velocity, this leads to a low frequency 'pulsing' causing a continuous flicker problem at the generator output. This effect can be quite extreme in areas electrically close to a windfarm connection.

### 43.3.6 Sensitive equipment

If it were not for sensitive equipment, power quality would not have become such an issue in recent years as it has. Equipment manufacturers are designing and manufacturing ever more sophisticated equipment as time goes on much of which is increasingly susceptible to variations in power quality. There are many issues relating to the subject of equipment sensitivity, the main areas of concern are:

- Reduced equipment operating life.
- Instantaneous equipment malfunction.
- Equipment malfunction to data corruption.
- Reduced process quality.
- Process stoppage.
- Equipment damage.
- Economic damage to operators.
- Safety issues.

As mentioned previously variable speed drives are a major problem. These drives are power electronic converters and are prone to voltage dips of relatively small magnitude.

Any device which depends upon a volatile memory chip for information storage is potentially at risk from power quality events, IT equipment therefore requires protection. Computer central processing units are prone to damage from power quality and quality of supply disturbances, the repeated thermal shock of being energised and de-energised can lead to permanent damage and early failure. Many processes in industry depend upon automated microprocessor control systems. Solutions to the power quality problems encountered with this type of equipment often consists of protection for the control system alone, the actual process not being sensitive to the more common disturbances.

A large part of the problem with sensitive loads is down to inadequate legislation. The EMC limits EN 61000-3 series cover many electromagnetic compatibility requirements that manufacturers of equipment must meet.

The area of susceptibility to voltage dips is not covered in enough depth, manufacturers are being allowed to sell equipment that is too sensitive to voltage dips. There are reasons why these 'loop-holes' in the EMC directive exist, one is that the regulations are based on statistical occurrences, another is that the regulations have to account for existing equipment.

### 43.3.7 Storm and environment related damage

Lightning strikes are a cause of transient overvoltages often leading to faults. Lightning does not have to strike a conductor in order to inject transients on to the local network, 'impulses' can be induced if lightning strikes near a conductor. The local ground potential can be raised by a nearby strike leading to neutral current flowing to earth via a remote ground, this can have destructive effects on sensitive equipment. Lightning strikes which hit overhead lines often cause 'flashovers' to neighbouring conductors as the insulators break-down, the strike will therefore not only consist of a transient overvoltage but also fault clearing interruptions and dips.

High winds and storm conditions cause widespread disruption to the supply networks. Where disruptions are caused by faults that can be cleared in less than one minute, by the use of auto-reclosers for example, the effect on the network is seen as a power quality issue. Long interruptions, above one minute, are generally seen as reliability or quality of supply issues.

Snow and ice build-up have a severe effect on the reliability of overhead lines, this has obvious power quality/quality of supply consequences.

Sea mists in the vicinity of overhead lines can lead to flashover between conductors, insulators must be cleaned on a regular basis in these areas to avoid these problems. In hot and humid climates dust and heavy dew can cause similar flashover problems requiring non-intrusive insulator cleaning methods.

Damage due to wildlife and trees is common in rural areas, particularly in the spring. As with any faults these are potential causes of power quality problems.

### 43.3.8 Network equipment and design

Auto-reclosing circuit-breakers are commonly used on rural radial networks to allow faults time to clear and supply to continue without the requirement for manual intervention. The circuit-breakers have the purpose of increasing the security of supply, fuse saving and reducing outage time. As far as customers are concerned they can however cause power quality problems due to the way in which they operate. Fast tripping is the use of circuit-breakers or line reclosers to trip in a very short period of time under fault conditions, this is another method of saving fuses, but has an adverse effect on power quality. As most faults on rural networks are of a transient nature, when such a fault occurs the auto-recloser will trip, after a predetermined time delay the circuit-breaker will reclose. If the fault has cleared then the supply is fully restored and no more disruption will occur, if the fault was not cleared then the breaker will trip again (for up to 4 times). It is this repeated reclosing that is a power quality issue, customers will have their supplies reconnected for each of the instants when the auto-recloser

re-connects the supply, this can lead to equipment damage in extreme circumstances. To reduce the level of customer annoyance caused by the repeated operation of auto-reclosers these devices are normally set with a built in 'dead-time' which allows the fault more time to clear prior to recloser operation. A 'lock-out time' can also be set which will stop the unit from reclosing if a certain number of operations have taken place within a pre-set time window.

Capacitor switching is a major cause of transients on the supply network. Capacitors are used to provide reactive power compensation (vars) hence reduce system losses. Some capacitors are permanently connected to the network, others are switched to suit the load conditions. When capacitors are switched in to a supply, voltage transients occur due to the interaction of the network inductive elements and the additional capacitance. Where power factor correction capacitors are installed at a customer's site and utility capacitor switching is taking place the effect of the switching transient can become magnified and oscillatory in nature. This 'voltage magnification' is a function of the impedance of both the capacitance's, the network, end user circuit inductance and the capacitor switching 'frequency'. If the resonance frequency of the end-user circuit and the network resonance in response to the capacitor switching are equivalent, then the maximum voltage magnification will occur. This can amount to double the nominal supply voltage in extreme cases.

Tap-changing transformers are used for the purpose of voltage regulation. They can have either mechanical or electronic devices for changing the transformer tapping to vary the secondary voltage level. Electronic tap changers can respond to load changes in a very short time frame, mechanical devices are more suited to more predictable slower changing loads.

Current limiting fuses are used where the fault current is high and have the effect of improving the overall power quality by isolating such a fault in a very short time frame. Typically rated in thousands of Amps the fuses will isolate a faulted connection in less than half a mains cycle.

Transformer energisation causes large oscillatory inrush currents that have an adverse effect on power quality each time a transformer is switched in to the network. The energisation of a transformer can cause dynamic overvoltages for up to one second after it is switched in, the inrush current is highly distorted. Particular problems are encountered when transformers are connected to power factor correction capacitors, the problem can be eliminated by switching the devices in separately. Ferro-resonance can occur in distribution networks, at frequencies below 300 Hz, as the result of transformer inrush current harmonic components and series connected capacitors resonating with the transformer magnetising inductance. To combat this effect capacitors are de-tuned from known resonance frequencies.

Network sectionalising on a radial distribution network consists of the use of line reclosers in strategic positions which will allow increased probability of continued supply to more critical loads under fault conditions.

Surge arresters are used in areas where lightning strikes are a frequent occurrence. They have non-linear characteristics which allow current surges, induced by lightning to be 'bled-off' to earth. Surge, or lightning, arresters are typically fitted on every few poles on LV systems in lightning prone areas.

Line shielding is another method of reducing the effect of lightning on overhead lines in storm-prone areas. More commonly used on transmission lines, the ground conductor is supported above the phase lines thus reducing the

possibility of faults caused by lightning strikes. Line shielding adds substantial cost to a distribution line because the poles must be higher and the benefits of having neutral conductors beneath the phase lines are removed.

### 43.4 Effects of power quality problems

Power quality can have a large detrimental effect on industrial processes and the commercial sector. Industrial processes differ in their requirements, from a power quality perspective, each having particular 'weaknesses' in terms of power quality attributes. The important power quality considerations to be accounted for to the industrial end-user centre around costs associated with machine down-time, clean-up costs, product quality and equipment failure. Solutions to power quality problems must be implemented by industrial end-users which reflect the cost versus benefit case for implementation.

Domestic customers tend not to be so adversely affected by power quality problems in that equipment in the home tends to depend less upon a high degree of power quality in its normal operation. However, trends in home ownership of IT equipment and sophisticated communications equipment for home entertainment purposes will mean a shift in power quality requirements for worst affected customers in the near future.

Table 43.1 shows power quality quantities and their most common effects on end-users.

### 43.5 Measuring power quality

The first consideration after having identified a PQ problem is the economic case for solving the problem, it is therefore important to try and quantify the cost of the problem to the end user. It would be useful if the customer could provide information of:

- The nature of the power quality problem
- The estimated cost of the disturbance
- The frequency of occurrence
- The times at which the problem occurred
- Information about the equipment affected
- Information about equipment nearby
- Previous monitoring carried out at the site

**Table 43.1** Power quality, quantities and effects

Quantity	Effect
Voltage dips	Machine/process downtime, clean up costs, product quality and repair costs all contribute to make these type of problems costly to the end-user.
Transients	Component failure, hardware reboot required, software problems, product quality.
Harmonics	Transformer and neutral conductor heating leading to reduced lifespan. Audio Hum, Video 'flutter', software glitches, power supply failure.
Flicker	Visual irritation.

In order to quantify the less obvious or hidden costs associated with a PQ problem it is necessary to implement a scheme of monitoring at the site of the problem.

A thorough site survey should be carried out prior to adopting a scheme of monitoring, this should consist of:

- Review of site circuit diagrams.
- Obtain detailed information of loads affected.
- Obtain detailed information of suspect loads.
- Equipment failure/malfunction logs.
- Identify the 'significant' problem areas.
- Discussion with relevant personnel involved.
- Preliminary monitoring where necessary.

After all the above information has been collected and considered, if no obvious cause is apparent, then a scheme of monitoring should be adopted to suit the power quality problem. A detailed scheme of monitoring will require some important decisions to be made from the outset, if the outcome of the monitoring is to be of maximum benefit:

- The type of monitoring equipment to be used.
- Where to connect the monitoring equipment.
- Over what a period to monitor.
- What quantities to measure.
- Analysis of disturbance data.

Measurable quantities in power quality include; supply voltage variations, short/long interruptions, voltage dips and swells, harmonics, inter-harmonics, flicker, voltage imbalance, frequency deviation.

### 43.6 Amelioration of power quality problems

#### 43.6.1 Earthing practices

A large number of reported power quality problems are caused by incorrect earthing practices. Verification of earthing arrangements, particularly when harmonics problems are reported, should always be conducted early in a power quality investigation.

#### 43.6.2 Standby UPS

Consisting of a rectifier, battery, inverter and static switches, the standby UPS is the most popularly used UPS available today. The static transfer switches will be controlled to allow the load to be fed from the mains supply under normal operation, when there is a mains disturbance leading to a reduction in the mains voltage below some pre-determined level the switches will open and close respectively. The load will then be fed from the battery, via the inverter ensuring continuation of supply to the load. The inverter output of a standby UPS must always operate in

**Figure 43.6** Standby UPS schematic arrangement

synchronism with the supply frequency to ensure a smooth transition from one supply to the other (*Figure 43.6*).

### 43.6.3 On-line UPS

An on-line UPS is configured such that the load is always fed from the UPS, in this way the load is isolated from the mains supply at all times. These systems are in general expensive and have high operating losses. Very similar to a standby system to view schematically, but with a manual transfer switch in place of the static transfer switches.

### 43.6.4 Hybrid UPS

The hybrid UPS system has a configuration similar to standby UPS systems, with the exception that some form of voltage regulator, such as a ferro-resonant transformer, is used in place of the static switch device(s). The transformer provides regulation to the load and momentary ride-through when the transfer from mains supply to standby UPS is made.

### 43.6.5 Local or embedded generation

A form of local generation, such as a diesel generator, can be connected to allow for any shortfall in the mains capacity and also to provide ride-through for power quality disturbances. This will in most circumstances be viewed as an expensive solution, as the cost to keep a diesel generator running on-line indefinitely would be a high price to pay for improved power quality. However, some forms of embedded generation, such as micro-turbines, fuel cells and Stirling engines, are likely to have increased domestic usage in the near future.

### 43.6.6 Transfer switches

Transfer switches are used to transfer a load connection from one supply to another, allowing the choice of two supplies for the load (or sub network), should one supply suffer power disturbances then the other supply will be automatically switched in reducing the possibility of supply disruption to the load.

### 43.6.7 Static breakers

The power electronic equivalent of a circuit-breaker with a sub cyclic-response time. The static breaker will allow the isolation of faulted circuits in the shortest possible time frame, other nearby loads will therefore have improved power quality.

### 43.6.8 Active filters and SVCs

The control of reactive power, and therefore harmonics, can be achieved by controlling a proportion of the power systems current through a reactive element. Conventionally this is achieved by switching inductors and capacitors in shunt with the power system, using thyristors. With the SVC the control of the current is achieved by controlling the output voltage magnitude of an inverter. SVCs are used to absorb or inject reactive currents to eliminate the harmonic distorting currents drawn by non-linear loads.

Unified power flow controllers (UPFCs) are similar to SVCs but allow both series and shunt compensation.

### 43.6.9 Passive filters

Passive filters or power line filters are simple filters consisting of discrete capacitors and/or inductors. Normally designed to attenuate high frequencies (low pass filters), fitted to equipment to remove higher order harmonic frequencies from the supply.

### 43.6.10 Energy storage system

All electrical energy storage systems have the same basic components, interface with power system, power conditioning system, charge/discharge control and the energy storage medium itself. Each storage medium has different characteristics, energy density, charge/discharge time, effect of repeated cycling on performance and life, cost, maintenance requirements etc. These characteristics help to make the decision of what storage medium is best suited to which application, each medium having merits that make it the most suitable in different circumstances. Energy storage systems available:

- (1) Super-conducting magnetic energy storage.
- (2) Flywheel energy storage.
- (3) Battery/advanced battery energy storage.
- (4) Capacitor or ultra-capacitor storage.

### 43.6.11 Ferro-resonant transformers

A constant voltage, or ferro-resonant, transformer is normally a transformer with a 1:1 turns ratio and with a core that is highly magnetised close to saturation under normal operation. The variation of primary voltage has a much-reduced effect on the secondary voltage, hence the output is not significantly effected by voltage sags.

## 43.7 Power quality codes and standards

Below is a list of the most commonly used standards and recommendations used in the field of power quality within the European community and USA.

- (i) **EN 50 160 (2000)** *'Voltage characteristics of electricity supplied by public distribution systems'*.
- (ii) **EN 61000-2-2 (1993)** *EMC Environment section. 'Compatibility levels for low-frequency conducted disturbances and signalling in public LV power supply systems'*.
- (iii) **EN 61000-3-2 (1999)** *EMC Limits. 'Limits for harmonic current emissions (Equipment input current less than or equal to 16 A per phase)'*.
- (iv) **EN 61000-3-3 (1998)** *EMC Limits. 'Limitation of voltage fluctuations and flicker in low voltage supply systems for equipment with rated current less than or equal to 16 A'*.
- (v) **EN 61000-3-4 (1998)** *EMC Limits. 'Limits for harmonic current emissions (Equipment input current greater than 16 A per phase)'*.
- (vi) **EN 61000-3-5 (1994)** *EMC Limits. 'Limitation of voltage fluctuations and flicker in low voltage supply systems for equipment with rated current greater than 16 A'*.
- (vii) **EN 61000-3-6 (1996)** *EMC Limits. 'Assessment of emission limits for distorting loads in MV and HV power systems'*.
- (viii) **EN 61000-4-7 (1995)** *'EMC testing and measurement techniques—General guide on harmonics and inter-*

- harmonics measurements and instrumentation, for power supply systems and equipment connected thereto'.
- (ix) **EN 61000-4-11 (1994)** 'EMC testing and measurement techniques—Voltage dips, short interruptions and voltage variation immunity tests'.
  - (x) **Engineering recommendation G.5/4 (2001)** 'Planning levels for voltage harmonic distortion and the connection of nonlinear equipment to transmission systems and distribution networks in the UK'.
  - (xi) **Engineering recommendation P28 (1989)** 'Planning limits for voltage fluctuations caused by industrial, commercial and domestic equipment in the United Kingdom'.
  - (xii) **Engineering recommendation P29 (1990)** 'Planning limits for voltage unbalance in the United Kingdom for 132 kV and below'.
  - (xiii) **ITIC (Information Technology Industry Council) Curve—the ITI (CBEMA) curve**, published by the technical committee 3 (TC3), of the information technology industry council Supersedes CBEMA (Computer and Business Equipment Manufacturers Association) curve.
  - (xiv) **IEEE Std 1159 (1995)** 'Recommended practice for monitoring electric power quality'.
  - (xv) **IEEE 446 (1995)** 'Recommended practice for emergency and standby power systems for industrial and commercial applications—IEEE orange book'.
  - (xvi) **IEEE 519 (1992)** 'Recommended practice and requirements for harmonic control in electrical power systems'.
  - (xvii) **IEEE 1100 (1993)** 'Recommended practice for powering and grounding electronic equipment—IEEE Emerald Book'.
  - (xviii) **IEEE 1159 (1995)** 'Recommended practice for monitoring electric power quality'.
  - (xix) **IEEE 1250 (1995)** 'Guide for service to equipment sensitive to momentary voltage disturbances'.
  - (xx) **IEEE 1346 (1998)** 'Recommended practice for evaluating electric power system compatibility with electronic process equipment'.

## 44.1 Electrical equipment of road transport vehicles

Within the framework of the modern automobile there is an elaborate mechanism to enable energy to be changed readily from one form to another. Although the electrical equipment is only a small proportion of the whole, its satisfactory operation is essential for the normal running of the automobile.

The chemical energy in the fuel is changed within the engine to provide primarily the propulsion of the automobile. A small portion of the transformed energy is taken to operate the electrical equipment. In its turn the electrical apparatus may have to convert this energy into heat (demister), light (legal requirements) and sound (horn), or back to mechanical energy (starter motor).

In addition, the electrical equipment may be called upon to supply energy when the automobile engine is at rest; so an energy storage system is necessary. To store this energy an accumulator or storage battery is used. Electrical energy is converted into chemical energy and is stored in this form in the battery. *Figure 44.1* shows the various energy conversions concerned.

### 44.1.1 Batteries

The type of battery used in automobile work has been designed to withstand severe vibration and give maximum capacity for minimum weight. A large discharge current for a short duration is required by the starter motor and the battery must be able to meet this requirement.

The two main types of batteries used in automobile work are the lead-acid and the nickel-alkaline.

The former has been more extensively used for private cars. The type developed has a large number of thin plates of suitable mechanical strength giving a large surface area for a given weight and volume. This construction enables the heavy current demands of the starter motor to be met. The magnitude of the discharge current is a function of the plate area exposed to the electrolyte. The specific gravity of the sulphuric acid used in these batteries is higher than that for stationary batteries: it lies between 1.150 and 1.300. Between these density limits the electrolyte has minimum resistivity—a desirable condition in view of the occasional heavy discharge rates. Too high a density may cause damage to the plates and separators. If the discharged battery is in a healthy condition, it is permissible, in urgent cases, to recharge in less than an hour to about 75% of its

fully charged state by giving a boosting charge or a fast rate of charge, provided the battery temperature is not allowed to exceed 80°C. Typical voltage/time relations for a lead-acid cell are shown in *Figure 44.2*.

The nickel-alkaline battery is of much more robust construction than the lead-acid battery. The plates do not buckle when short circuited. The electrolyte is a solution of caustic potash, and unlike the lead-acid battery, no indication of the state of charge is given by the specific gravity. The normal working value is 1.200. After about 2 years service the gravity will fall to 1.160, owing to absorption of impurities from the atmosphere. The action of the battery will become sluggish, and complete renewal of the electrolyte is required.

### 44.1.2 Charging systems

A generator driven by the automobile engine supplies the energy to charge the battery. If a commutator-type generator is used, an automatic switching device (the cut-out relay) is embodied in the circuit to connect the generator and battery when the generator voltage is of the correct value for charging purposes, and to disconnect the generator when the speed of the automobile engine drops below a certain figure or when the engine is at rest. No cut-out is required in an alternator charging system, since the semiconductor diodes built into the alternator for converting a.c. to d.c. output prevent current reversal.

The automobile driving the generator has a wide speed range, so that the electromotive force produced by the generator, which is proportional to the product of the flux and the speed, would vary considerably unless otherwise prevented. If the required charging current was obtained at low speeds, then the battery would receive a charging current in excess of requirements at the normal driving speeds on the open road.

To keep the generator voltage within the limits set by the battery, a reduction in field current is required for increasing speed. The following systems of control have been adopted for d.c. generators: (1) compensated voltage control; and (2) current voltage control.

#### 44.1.2.1 Compensated voltage control

The compensated voltage control system has a single vibrating-contact regulator which carries both a shunt and a series winding. The shunt winding is connected across the generator output and controls a pair of contacts which, in the normally closed position, short out a high-value resistor in the generator field circuit. Ignoring for the moment the compensating action of the regulator series winding, the shunt winding enables a constant voltage to be obtained

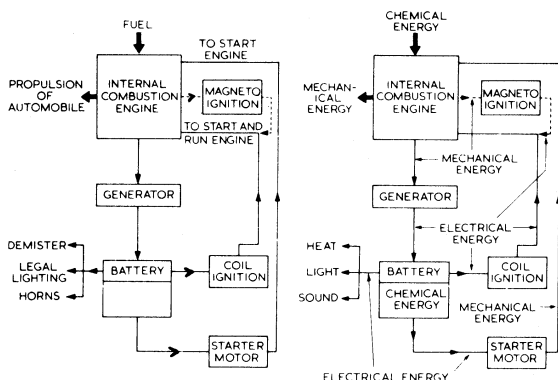

Figure 44.1 Energy transformations in automobile equipment

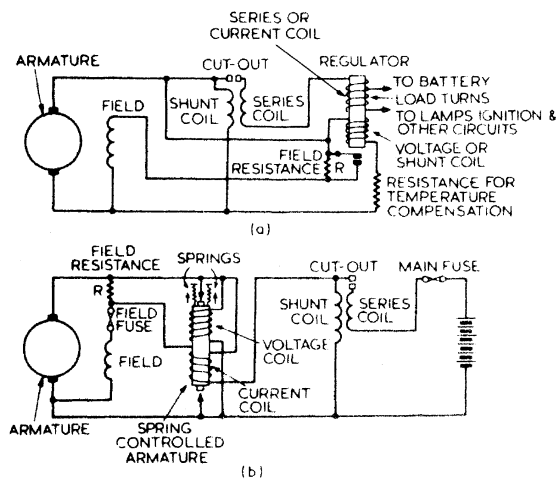

Figure 44.2 Charge and discharge curves of a lead-acid cell

**Figure 44.3** (a) Voltage regulator with single contact: minimum field current with  $R$  in series with the field winding; maximum field current with no resistance in field circuit; (b) Voltage regulator with double contact: minimum field current when the field winding is short circuited; intermediate field current when  $R$  is in series with the field winding; maximum field current when there is no resistance in the field circuit

from the generator. At low speeds the contacts are held together by a spring and generated voltage is applied to the field windings. As speed and voltage rise, the pull of the shunt wound electromagnet overcomes that of the spring and the resistor is inserted into the field circuit, causing the voltage to drop (*Figure 44.3(a)*), beginning the next contact opening and closing cycle. This vibratory movement of the contacts takes place some 50 times per second and results in a practically constant voltage, the contacts remaining closed for a shorter period of time as speed rises. For applications where the insertion of resistance does not cover requirements over the whole range of speed, a second pair of contacts, which short circuit the field winding, are arranged to close at the higher speeds, which enables constant voltage to be maintained in two stages. *Figure 44.3(b)* shows a barrel-type double-contact voltage regulator.

Constant voltage regulation has to be modified in practice to ensure that current demand by battery charging and other loads is not so high as to overload the generator. In the compensated voltage control system, current control is effected by adding a series winding to the regulator to assist the shunt winding. The voltage characteristic of such a regulator will be a falling one—the voltage will drop with increase of load and thus prevent overloading of the generator. Variation of voltage setting with rising temperature of the voltage coil is prevented by having an armature spring of bimetallic strip type. This temperature compensating device is arranged to give a somewhat higher voltage when cold, to assist in replacing the energy taken from the battery by the starter motor.

The tapering charge characteristic obtained (*Figure 44.4*) means that the compensated voltage control system is unable to utilise those occasions when spare generator capacity is available for increasing the charging rate. This drawback is overcome by current voltage control.

#### 44.1.2.2 Current-voltage control

A regulator of the current-voltage type (*Figure 44.5*) allows the generator to give its safe maximum output into a

**Figure 44.4** Comparison of charging characteristics

discharged battery and to continue to do so until the battery approaches the fully charged condition, when the charging current is reduced to a trickle charge. A constant charging current is maintained until a certain battery voltage is reached; then the voltage regulator operates to give constant voltage control. The charging current will decrease until finally a trickle charge is passing through the battery. This type of regulator is used when the vehicle has a heavy electrical load and a more definite regulation is required than that given by the compensated voltage regulator.

In this type of control two separate regulators are used. These are mechanically separate but electrically interlocked. One regulator is shunt wound and so responsive to voltage conditions; the other is series wound and responsive only to current. Their contacts are connected in series with the generator field circuit.

When current from the generator flows to the battery, it passes through the current regulator winding, and on reaching the maximum rated value, it operates the armature of the current regulator, thus inserting resistance into the field circuit of the generator and decreasing the output current. The vibrations of the armature of the current regulator will prevent the rated output current being exceeded. As the battery voltage rises, the voltage regulator takes over, causing the second pair of contacts to operate, thus controlling the output according to the load and the state of the battery.

If, however, the battery is fully charged with little or no load switched on, then as the speed of the dynamo rises, the terminal voltage will increase to the operating value for the voltage regulator, the resistance will be inserted into the generator field circuit by the operation of the voltage regulator armature and the output current will be a function of the potential difference between generator and battery.

#### 44.1.2.3 Cut-out or reverse-current relay

The cut-out relay is a simple automatic relay and is used to connect the battery to the generator when the latter's voltage is just in excess of the battery's. It also disconnects the battery from the generator when a discharge current flows from the battery and the generator tends to run as a 'motor'.

**Figure 44.5** Current-voltage regulator

Two coils are provided on the relay: the first, a voltage or shunt coil connected across the generator terminals; and the second, a series coil carrying the generator output current. The fine-gauge wire coil has a large number of turns, but the current is small. This produces the required magnetic effect. When the current flowing in the voltage coil reaches a predetermined value proportional to the generator voltage, the armature is pulled down and the contacts close, allowing current to flow to the battery. This current flows through the series coil and the combined magnetic effect produced by the two coils pulls the contacts close together. The current coil assists the shunt coil as long as a changing current flows. When the generator speed and voltage fall, the current in the series coil decreases, then reverses, so that the resulting magnetic flux produced by the two coils together decreases. With a further fall in generator voltage the magnetic pull exerted on the armature will be overcome by the pull of the spring and the contacts will open, allowing no further discharge current to flow to the generator.

### 44.1.3 A.c. generator

The continuing increase in the use of electrically operated components on automobiles calls for higher generator outputs. Higher outputs are also required for vehicles which have long periods of idling or frequent stopping and starting.

The increased currents to meet these needs give rise to commutation difficulties if the size, weight and speed of the dynamo are to be consistent with a reasonable service life. An alternative to increasing the size of the d.c. generator is to produce an a.c. in the generating machine and convert to direct current by means of rectifiers. The a.c. machine can have a higher maximum operating speed, so a higher drive ratio can be chosen which will allow a greater output at lower road speeds.

The alternator has a stationary three-phase output winding wound in slots in the stator so that the generated current can be taken directly from the terminals of the stator winding. There is, therefore, no problem of collecting the heavy current from a commutator. The rotating portion of the alternator carries the field winding, which is connected to two slip-rings with associated brush-gear mounted on the end bracket. The field current is small and can be introduced into the windings without arcing at the brushes. The alternator is not affected by the polarity of the magnetic field or the direction of rotation of the rotor, as in the case of the d.c. machine.

A field pole system of the imbricated type is preferred to salient poles by most alternator manufacturers, as it enables a relatively large number of poles (typically 8–12) to be energised by a single field winding.

The alternator cutting-in speed is about the same as that of the d.c. generator; consequently, it provides a useful charge at engine idling speed. The advantage for the alternator is derived from the higher drive ratio.

**Rectifier** Rectification of the alternating current output is by means of six silicon diodes in a full-wave three-phase bridge connection. The diodes are usually built into the bracket at the slip-ring end of the machine.

**Control** Since the alternator is designed to be inherently self-regulating as to maximum current output and since the rectifiers eliminate the need for a cut-out relay, the only form of output control necessary is a voltage regulator in the field circuit.

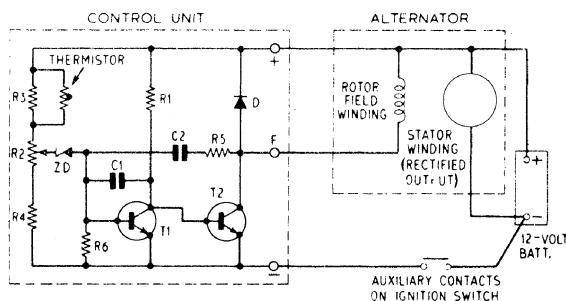

The conventional type of electromagnetic vibrating-contact voltage regulator, with either single or double

contacts, has been used. Also employed to enable higher field current to be used and to give longer contact life has been a vibrating-contact regulator with the contacts connected in the base circuit of a transistor, the transistor being protected by a field discharge diode against inductive voltage surges.

To eliminate all maintenance and wear problems, it is now general practice to use solid state components in all parts of the voltage control unit.

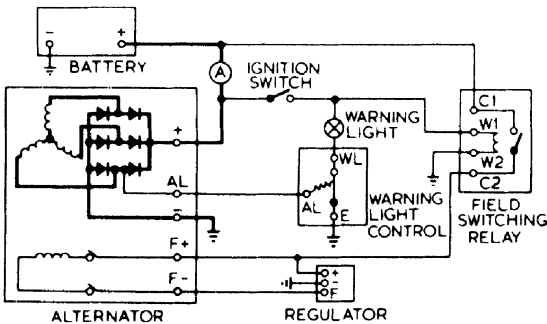

#### 44.1.3.1 Separately excited alternator systems

Fitted to a number of passenger cars and light commercial vehicles are Lucas 10AC and 11AC alternators, which have field systems energised from the battery as opposed to directly from the machines. The fully transistorised control employed for these alternators is shown in *Figure 44.6*. Used in place of the voltage coil and tension spring of a vibrating-contact regulator are two silicon transistors for field switching and a Zener diode (voltage control diode) for voltage reference. The Zener diode is a device that opposes the passage of current until a certain voltage is reached, known as the breakdown voltage. When the ignition is switched on, the base current required to render the power transistor T2 conducting is provided through resistor R1; as a consequence, current flows in the collector-emitter portion of T2, which acts as a closed switch in the field circuit and applies battery voltage to the field winding. Rising voltage generated across the stator output winding is applied to the potential divider (R3, R2 and R4) and, according to the position of the tapping point on R2, a proportion of this potential is applied to the Zener diode ZD. When the breakdown point of the Zener diode is reached, the diode conducts and current flows in the base circuit of a driver transistor T1. The base current of T2 is reduced and so is the alternator field excitation. To limit power dissipation, it is desirable to switch the voltage across the field winding rapidly on and off instead of using the transistors to provide continuous regulation; this oscillation is achieved by the positive feedback circuit comprising resistor R5 and capacitor C2. Transistor T2 is protected from very high inductive voltage surges by the surge quench diode D connected across the field winding, which also serves to provide a measure of field current smoothing. Radio interference is eliminated by negative feedback provided by capacitor C1. Resistor R6 provides a path for any small leakage currents through the Zener diode that would otherwise flow through the T1 base circuit at high temperatures and adversely affect regulator action. Automatic compensation for changes in ambient temperature is provided by the thermistor connected in parallel with resistor R3.

**Figure 44.6** Fully transistorised control for a Lucas 10AC or 11AC alternator (positive earth circuit)

**Figure 44.7** A Lucas 10AC or 11AC alternator charging system

Figure 44.7 shows a typical Lucas 10AC or 11AC alternator charging system diagram, including a field switching relay and warning light control unit of 'hot wire' type. The hot-wire resistor is connected to the centre point of one of the pairs of diodes in the alternator; when hot, it lengthens and allows the contacts to open under spring tension, extinguishing the warning lamp.

#### 44.1.3.2 Self-excited alternator systems

The majority of present-day alternators employ what is known as the nine-diode system, and are self-excited at normal operating speeds. The nine-diode arrangement has become popular owing to the simplicity of the warning lamp circuit, which, if combined with an in-built electronic regulator, provides a machine with the minimum of external wiring (Figure 44.8). The three field excitation diodes for supplying the field with rectified a.c. are included in the rectifier pack. Operating voltage is built up at starting by energisation of the field winding from the battery through an ignition (or start) switch, a non-charge warning lamp and the voltage regulator.

Lucas manufacture a series of alternators of this type—all with built-in electronic control units—having outputs ranging from 28 to 75 A. An exploded view of a typical alternator is shown in Figure 44.9.

**Control** In the simple self-excited system shown in Figure 44.8 the regulator controls the voltage at the field diodes' output terminal and, therefore, controls battery voltage only indirectly. For systems employing high-output alternators or having significant cable resistance between battery and alternator—for example, because the battery is remotely sited—indirect control of battery voltage becomes unacceptable. For such applications, progressive levels of control can be provided as follows: (1) the regulator can be designed to sense and control the voltage at the alternator output terminal; or (2) the sensing lead of the regulator can

**Figure 44.8** Charging system with self-excited alternator

**Figure 44.9** Exploded view of a typical nine-diode alternator with a built-in regulator

be brought out of the machine to sense and control battery voltage directly. Method (2) is the most appropriate for remote-battery/high-power systems.

Figure 44.10 shows a Lucas regulator designed to sense alternator output terminal voltage. Field drive transistor  $T_2$  is an integrated Darlington-pair device giving increased gain. This enables the circuit resistor values to be substantially increased, thereby reducing the permanent battery drain (taken through the sensing lead) to an acceptable level. Base drive resistor  $R_4$  is fed from the sensing lead so that, in the event of the latter being disconnected or broken,  $T_2$  is turned off, shutting down the alternator. If  $R_4$  were fed from the field diodes, an open-circuit sensing lead would result in continuous maximum output from the alternator and destruction of the battery.

Figure 44.11 is an example of a regulator designed for remote voltage sensing. It includes the safety feature which affords protection against an open-circuit sensing lead (described above) and, in addition, protection against damage from disconnection of the alternator output lead. In the latter event, since the battery is no longer being charged, the battery/sensing lead voltage falls and the regulator therefore increases the alternator field excitation. This increases the alternator output voltage, which further increases field excitation. Without protection this cumulative effect can result in the destruction of the field drive transistor  $T_2$ . Protection is provided by way of resistor  $R_6$  and diode  $D_2$ .  $R_6$  is chosen so that under normal regulating conditions insufficient current flows through the potentiometer chain to reverse-bias diode  $D_2$ , which is therefore conducting: hence, the regulator controls the sensing lead voltage. The rise in alternator output terminal voltage, which occurs with a break in the output lead, increases the current through  $R_6$ , causing  $D_2$  to become reverse-biased. Regulation of the output terminal voltage now takes place at a safe level dictated by  $R_6$ ,  $R_1$ ,  $R_2$ ,  $R_3$  and  $ZD_1$ , and  $T_1$

**Figure 44.10** Regulator used to sense alternator output terminal voltage

**Figure 44.11** Regulator for remote voltage sensing

base-emitter voltage. This secondary regulation level is typically 4 V above the normal regulating voltage.

This regulator can be designed to work with a remote network providing battery temperature compensation. The network, which includes a thermistor, is connected in series with the voltage sensing lead and is mounted to sense battery temperature directly.

Lucas alternators incorporating nine-diode systems are also protected against surge voltages arising from disconnection of the alternator at high output currents, and from switching transients resulting from other equipment (e.g. the ignition system). The protection takes the form of a high-power Zener diode connected between the field diodes' output terminal and earth. Surge voltages are thereby limited to a safe level of typically 35 V. If the Zener diode is overloaded, its normal failure mode is short-circuit. This cuts off the field excitation and switches on the warning lamp. No other damage occurs and the normal charging function of the alternator is restored on the Zener diode's being renewed. A detailed discussion of transient causes and protection is given in SAE paper number 730043, 'Transient overvoltages in alternator systems'. Later alternators incorporate regulators whose semiconductor devices can withstand overvoltage surges. On these alternators the separate overload diode is deleted.

#### 44.1.4 Ignition systems

The ignition of the compressed charge in a cylinder of an internal combustion engine with petrol as the fuel is brought about by an electric discharge. This discharge takes place across the points of a sparking plug. The voltage required to produce this spark will vary between 7000 and 25 000 V. The equipment may be self-generating, as in the magneto (seldom used on automobiles), or battery powered, as with coil ignition. The high-voltage impulses must be delivered to each cylinder as required and at a precisely controlled time in accordance with engine speed and load. There are several systems now in use to satisfy these requirements.

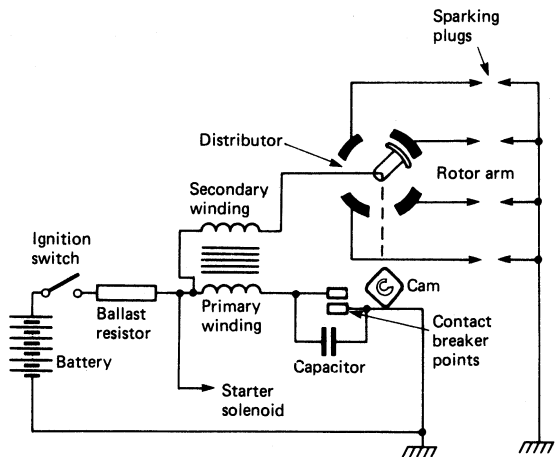

##### 44.1.4.1 Contact breaker ignition

The major components of a modern coil ignition system are shown in *Figure 44.12*.

**Storage battery** The source of low-tension current.

**Primary winding** A coil of a few hundred turns of relatively heavy wire connected to the battery through a contact-breaker.

**Secondary winding** A coil of many thousand turns of fine wire in which the high-tension voltage is induced. One end

**Figure 44.12** Elements of a coil ignition system

is usually connected to the more positive end of the primary winding, the other to the sparking plugs through the distributor.

**Contact-breaker** A switch for opening and closing the primary circuit at the required instants. It is operated by a cam driven at half engine speed.

**Capacitor** Connected across the contact-breaker points to suppress arcing.

**Rotor arm** Together with the distributor head, it forms a rotary switch to distribute the high voltage to each of the cylinders in correct order of firing. The rotor arm may incorporate a resistor to aid radio interference suppression.

**Ballast resistor** A device to aid starting. It is a resistor of 1–2  $\Omega$  connected in series with the primary winding and arranged to be short-circuited when the starter motor is operated.

**Sparking plug** The high voltage is led to the insulated central electrode of the plug (one per cylinder) and the spark passes across the gap at the required instant. The gap must be maintained within certain limits, usually 0.3–1.0 mm. In selecting a sparking plug for a given engine, attention must be given to the engine manufacturer's recommendations. The reach of the plug must be such that the correct amount of projection into the combustion chamber is achieved. The correct heat grade is also important: otherwise pre-ignition (overheating) or misfiring (too cold) may occur.

**Distributor** 'Distributor' is a generic term used to describe the assembly of contact-breaker, a capacitor, rotor arm and distributor head. It contains a shaft driven at half engine speed on which is mounted a centrifugally operated mechanism coupled to the cam. The mechanism is restrained by two springs and is so designed as to maintain the relationships between spark timing and speed. The cam has as many lobes as there are cylinders.

Usually incorporated is a vacuum control which automatically advances the ignition timing as the engine load falls. Control is achieved by a spring loaded diaphragm which moves in response to changes in depression in the carburettor venturi. As the depression increases, the diaphragm

moves the contact-breaker mounting plate contrary to cam rotation and so advances the ignition. Occasionally, more complex vacuum control devices are employed having facilities to retard the ignition timing under certain engine operating modes (usually closed throttle deceleration) to reduce hydrocarbon exhaust emissions.

#### 44.1.4.2 Electronic (contactless) ignition

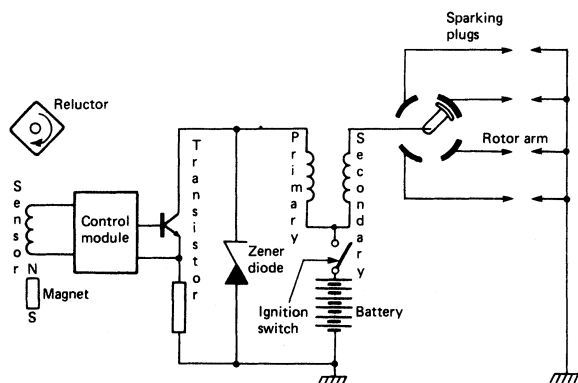

In contact-breaker ignition systems, it is necessary for consistent performance to adjust and, if necessary, to replace the contact points at regular intervals. Failure to do so may result in misfiring and/or excessive levels of exhaust emissions, which in most countries are now controlled by legislation. As a result, electronic (contactless) ignition is used on many vehicles—especially in countries with severe exhaust emission regulations. A general circuit is shown in *Figure 44.13*. The current interrupting function of the contact breaker is now performed by a power transistor, whereas the timing requirement is handled by a sensor in conjunction with a control module.

Many forms of timing transducers are in use. That in *Figure 44.13* is of variable reluctance type. A permanent magnet drives a flux through a magnetic circuit which includes a pickup coil and the distributor shaft. As the shaft revolves at half engine speed, the flux is modulated by a reluctor (replacing the cam of conventional ignition), which is shaped like a cog with as many teeth as there are cylinders. The varying flux generates in the pickup coil a voltage waveform which, after modification by the control module, switches off the power transistor (and, therefore, the coil primary current), to produce a spark. Timing and distribution of the spark are identical with a conventional contact breaker system.

Other forms of timing transducers are:

- (1) a photoelectric sensor which is switched by an infra-red light beam interrupted by a shutter;
- (2) a Hall-effect device in which a magnetic field is interrupted by a steel shutter—the varying flux in the Hall device causes a proportional voltage change across it; and
- (3) radiofrequency differential transformers and eddy-current transducers in which the output voltage is varied by rotating magnetic devices.

In its simplest form the electronic control module may be an amplification circuit to drive the switching transistor, and the duty ratio of the sensor signal—equivalent to dwell

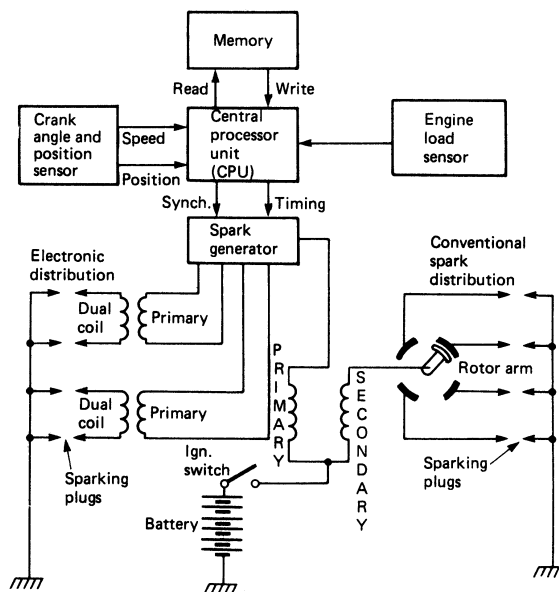

**Figure 44.13** Electronic (contactless) ignition system

angle in conventional systems—remains unchanged. More complex systems are in use in which the control module calculates the point of current switch-on in the primary winding according to engine speed. This allows use of special ignition coils having a very short time constant. The module also has a current-limiting facility of usually 5–7 A and a device which switches off the current when the engine is stalled. The advantage of such systems is that the ignition spark energy is constant over wide speed and battery voltage ranges. Hence, they are usually referred to as ‘constant-energy systems’.

#### 44.1.4.3 Electronically timed ignition systems

Contactless ignition systems overcome the problems of contact point degradation but the limitations of spark timing by centrifugal and vacuum operated mechanisms remain. As legislation on exhaust emission levels and energy conservation increases in severity, there is an urgent need to improve the efficiency of internal combustion engines, and a greater accuracy and flexibility in spark timing is required. This is possible with computer control of spark timing. A typical arrangement is shown in *Figure 44.14*.

The timing information for the engine is contained in a semiconductor memory unit. Typically the timing values for over 500 points of the engine speed/load characteristic may be stored permanently in the memory. Sensors placed at the engine crankshaft and in the inlet manifold generate signals in accordance with engine speed, crankshaft position and engine load. These signals are processed by the central processor unit (microprocessor) into a binary form suitable for addressing the memory. The nearest timing value in the memory for the particular speed and load of the engine is read into the spark generator unit, where, by means of a count-down procedure, the current in an ignition coil primary winding is interrupted at precisely the instant to produce a spark in the correct cylinder.

**Figure 44.14** Digitally timed ignition (mechanical and electronic distribution systems are shown)

The spark generator unit may include a constant energy circuit as previously described, although other more complex energy control circuits may be employed and can be programmed by instructions also held in the memory.

Distribution of the high voltage to the sparking plugs may be achieved by a distributor head and rotor arm, or obtained electronically by sequential switching of the primary windings of dual output ignition coils (two for a four-cylinder engine).

The crankshaft sensors are usually of the eddy current type but occasionally variable reluctance devices are used. Because of their exposed position, a robust construction is essential. A segmented disc fastened either to the rear face of the flywheel or at the crankshaft pulley is used to generate the signals. Where electronic distribution is used, two crankshaft sensors are necessary, the second being required to generate a suitable synchronising signal.

Load signals may be derived from a simple diaphragm operated potentiometer or by a more sophisticated silicon strain-gauge device. Usually the inlet manifold depression is measured rather than that in the carburettor venturi.

More ambitious systems may include programmed timing offsets for ambient temperature, engine coolant temperature, atmospheric pressure and exhaust-gas circulation.

#### 44.1.5 Starter motor

A starter motor is required to run the internal combustion engine up to a speed sufficient to produce satisfactory carburation.

The starter motor is mounted on the engine casing and a pinion on the end of the starter motor shaft engages with the flywheel teeth. The gear ratio between pinion and flywheel is about 10:1. A machine capable of developing its maximum torque at zero speed is required. The series wound motor has speed and torque characteristics ideal for this purpose.

The engagement of the pinion with the flywheel is effected in different ways. Perhaps the two most commonly used are the inertia engaged pinion and the pre-engaged pinion methods.

In inertia engagement the drive pinion is mounted freely on a helically threaded sleeve on the armature motor shaft. When the starter switch is operated, the armature shaft revolves, causing the pinion, owing to its inertia, to revolve more slowly than the shaft. Consequently, the pinion is propelled along the shaft by the thread into mesh with the flywheel ring gear. Torque is then transmitted from the shaft to the sleeve and pinion through a heavy torsion spring, which takes up the initial shock of engagement. As soon as the engine fires, the load on the pinion teeth is reversed and the pinion tends to be thrown out of engagement. Inertia drives are usually inboard, i.e. the pinion moves inward towards the starter motor to engage with the ring gear; an inboard is lighter and cheaper than an outboard starter.

To obtain maximum lock torque (i.e. turning effort at zero speed), the flux and armature current must be at a maximum, so resistance in the starter circuit (windings, cables, switch and all connections) must be a minimum; any additional resistance will reduce the starting torque. Generally, the inertia engaged starter motor is energised via a solenoid switch, permitting the use of a shorter starter cable and assuring firm closing of the main starter-switch contacts, with consequent reduction in voltage drop. The use of graphite brushes with a high metallic content also assists in minimising loss of voltage.

While inertia drive has been the most popular method of pinion engagement for British petrol-engined vehicles, the

use of outboard pre-engaged drive is increasing. The pre-engaged starter is essential on all vehicles exported to cold climates and for compression ignition engines which need a prolonged starting period.

The simplest pre-engaged type of drive is the overrunning clutch type. In this drive, the pinion is pushed into mesh by a forked lever when the starter switch is operated, the lever often being operated by the plunger of a solenoid switch mounted on the motor casing. Motor current is automatically switched on after a set distance of lever movement. The pinion is retained in mesh until the starter switch is released, when a spring returns it. To overcome edge-to-edge tooth contact and ensure meshing, spring pressure or a rotating motion is applied to the pinion. An overrunning clutch carried by the pinion prevents the motor armature from being driven by the flywheel after the engine has fired. Various refinements may be incorporated, especially in heavy-duty starters. Among these are: a slip device in the overrunning clutch to protect the motor against overload; a solenoid switch carrying a series closing coil and a shunt hold-on coil; an armature braking or other device to reduce the possibility of re-engagement while the armature and drive are still rotating; a two-stage solenoid switch to ensure full engagement of the starter pinion into the flywheel teeth before maximum torque is developed (*Figure 44.15*).

Two other pre-engaged types of starter are used for heavy compression ignition engines—the coaxial and axial types.

The compact size of the coaxial starter is achieved by mounting a two-stage operating solenoid and switching mechanism inside the yoke, coaxial with the armature shaft. When the starter solenoid is energised, the plunger is attracted into the solenoid, which causes the pinion sleeve and integral pinion to move axially along the armature shaft. At the same time the first-stage contacts close, to energise the starter windings through a built-in resistor (*Figure 44.16*). The armature rotates under reduced power and the pinion is driven into engagement by means of the armature shaft helix. When the pinion is almost fully engaged, the second-stage contacts close, to cut out the resistor, which enables full power to be developed.

The axial starter employs a sliding armature, which is moved axially against spring pressure to bring the pinion into mesh. The starter also has a two-stage switching arrangement (*Figure 44.17*) to ensure that pinion/ring gear engagement occurs before maximum torque is developed.

#### 44.1.6 Electronic fuel-injection systems

To comply with exhaust regulations and to optimise fuel consumption, the modern petrol engine requires a fuel system of extreme accuracy, reliability and flexibility. To meet this need various electronic fuel injection systems have been developed, the one shown in *Figure 44.18* being typical. The system consists principally of an air-flow meter, engine speed sensor, throttle switch, air and coolant temperature sensors, control unit and fuel injectors. Fuel is delivered to the injectors at constant pressure, so that the amount of fuel to be injected is determined solely by the time for which the injectors are held open. Both the time of opening of the injectors and the period for which they are held open are determined by the electronic control unit from the various sensor signals it receives.

*Fuel injectors* There is one injector per cylinder with each injector clamped between the fuel rail and the inlet manifold. An injector consists of a solenoid-operated needle valve (*Figure 44.19*). The movable plunger is attached to

(c)

**Figure 44.15** Operation of a two-stage switching solenoid: (a) The solenoid is energised in the conventional manner to move the pinion towards the gear ring on the vehicle flywheel: 1, engagement spring; 2, return spring; 3, solenoid hold-on winding; 4, switch-operating spindles (concentric); 5, first set of contacts; 6, second set of contacts; 7, fixed contacts; 8, battery; 9, solenoid operating winder; 10, plunger; 11, operating level and pivot; 12, armature shaft; 13, pinion; 14, field system (four field coils in parallel); 15, roller clutch; 16, gear ring; (b) If tooth-to-tooth abutment occurs, the first set of solenoid contacts close and energise one field coil only, thus giving low power indexing to move the pinion teeth into a meshing position; (c) On full drive engagement, the second set of solenoid contacts close, giving full cranking power. If the pinion teeth, on moving forward, can mesh immediately with the gear ring, full drive engagement takes place with the simultaneous closing of both contacts in the final stage

**Figure 44.19** Model 8NJ fuel injector

the needle which is held in the closed position by a helical spring. The solenoid winding is located in the rear of the injector body and may be either 16 or 2.5  $\Omega$  resistance, depending upon engine design, size and number of cylinders.

The electronic control unit energises the injector solenoid winding, creating a magnetic field which attracts the plunger away from the nozzle seat. This allows pressurised fuel to flow through the injector via an inbuilt filter, into the inlet manifold.

Injectors should always be replaced at the intervals specified by the vehicle manufacturer.

**Air-flow meters** The basic fuel requirement of the engine is determined from engine load data supplied by the air-flow meter, which is situated between the air filter and the induction manifold. In *moving flap air-flow meters* air flow through the meter deflects a movable flap, which takes up

a defined angular position depending upon the force exerted on it by the incoming air. A potentiometer operated by the flap converts the angular position to a corresponding voltage. In the control unit this voltage is divided by engine speed to give the air intake per stroke, from which the basic fuel requirement is then derived.

Since the air-flow meter is used to determine the total mass of air drawn into the engine, adjustments to the basic fuel requirement have to be made for variations in air density (which is temperature dependent). An air temperature sensor is incorporated within the air-flow meter and is connected to the control unit for this purpose.

The *hot-wire air-flow meter* (Figure 44.20) has a cast alloy body with an electronic module mounted on the top. Air from the air cleaner is drawn through the body of the air-flow meter and into the engine. Some of this intake air flows through a small bypass in which two wires are mounted, a sensing wire and a compensating wire. A heating current is passed through the sensing wire via the electronic module. The compensating wire is also connected to the module, but is unheated.

As air is drawn over the wires, a cooling effect occurs which alters the value of the resistance and current in the sensing wire. The compensating wire reacts only to the temperature of the intake air. The electronic module monitors the reaction of these wires, thus measuring the air-flow rate, and sends details of air-flow rate to the electronic control unit.

Note: each air-flow meter module is matched to its sensor and body during manufacture; therefore repair of the unit is not possible if a fault occurs.

Adjustments to the basic fuel quantity are also necessary during engine cranking, cold starting and warm-up, idling, full-load operation and acceleration.

**Cranking** During cranking at any engine temperature, a signal from the starter switching circuit is provided to the control unit in order to increase the 'open' time of all

**Figure 44.20** Hot-wire air-flow meters

the injectors above that required to supply the basic fuel quantity.

**Cold starting and warm-up** During cold starting a greatly enriched mixture is required to offset the effect of fuel condensing on the walls of the inlet port and cylinders. This extra fuel is provided by a cold-start injector which delivers a finely atomised spray into the inlet manifold. The cold-start injector operates only when the starter is energised and the thermotime (bimetallic) switch—which is sensitive to coolant temperature—completes the electrical circuit. Additional air required during cold starting and warm-up is controlled by an extra-air valve which bypasses the throttle butterfly. The valve aperture is adjusted by the action of a bimetal strip, which is responsive to the combined temperatures of the engine and an internal heater. The valve becomes fully closed when normal running temperatures are reached. During engine warm-up the control unit steadily decreases fuel enrichment in accordance with signals received from the coolant temperature sensor.

**Idling, full-load and accelerating modes** In Figure 44.18 a throttle position switch with two sets of contacts is used to signal engine idling or full-load operating conditions to the control unit and thereby obtain the necessary fuel enrichment. Some applications use a potentiometer instead of a throttle switch. Opening of the throttle is then detected by the control unit as an increasing voltage from the potentiometer, causing acceleration enrichment circuits to be triggered.

#### 44.1.6.1 Closed-loop electronic fuel injection systems

To obtain the very low exhaust emissions required by stringent legislation, a closed-loop electronic fuel injection system may be employed in conjunction with a three-way exhaust catalyst (Figure 44.21). The catalyst works at optimum efficiency in converting carbon monoxide and hydrocarbon emissions into carbon dioxide and water, and nitrogen oxides into oxygen and nitrogen when the exhaust gases are from an engine operating near to the stoichiometric air/fuel ratio. The operating condition will be indicated by the amount of oxygen present in the exhaust gases, and is monitored in the closed-loop system by an oxygen (lambda) sensor mounted in the exhaust manifold. The sensor provides a feedback signal to the control unit which

continuously adjusts the fuelling level to maintain engine operation at the stoichiometric air/fuel ratio.

#### 44.1.6.2 Digital electronic fuel-injection system

Until recently, all electronic fuel injection systems have employed analogue computing techniques. This has meant that for reasons of unit size and cost the complexity of the fuelling schedule stored in the analogue control unit has had to be limited and significant compromises made (Figure 44.22). In contrast, the latest Lucas electronic fuel injection system employs a digital control unit (incorporating large-scale integrated circuits) in which it has been possible to match very accurately the fuel requirements of an engine under all operating conditions: moreover, this has been achieved in a control unit which has a size readily accommodated on the vehicle.

A key part of the control-unit information-processing capability is a digital read-only memory (1024 bit) which contains the fuel schedule. The latter is stored as a function of 16 discrete values of engine speed and 8 of load. The fuel requirement at each of these memory sites is identified by an 8-bit number. The fuelling characteristic is smoothed between the points of inflexion (i.e. the discrete value stored at each memory site) by a 32-point interpolation procedure which operates on the load and speed signals to effectively increase the memory size by a factor of  $16 \times 46$ .

The basic steps in the processing of information within the control unit are shown in Figure 44.23. The engine-speed signal (obtained from the ignition system) and the load signal are each converted into a digital word which is modulated by the interpolation function. The modified numbers representing speed and load are then used to select the site in the memory that stores the fuel requirements for these operating conditions. The memory output number (fuel quantity) is fed into a number-to-time counter, where it is stepped to zero by the fuel trim oscillator. The time taken to count down to zero will therefore be proportional to the memory output and will determine the 'open' period of an injector. Signals of air and coolant temperatures and acceleration adjust the fuel quantity read-out of the memory by modifying the frequency of the fuel trim oscillator. The solenoid operated injectors are energised (usually in groups) through power circuits for the countdown period of the number-to-time counter, when fuel is delivered to the engine.

## 44.2 Light rail transit

### 44.2.1 Introduction

Such has been the rapid development of light rail technology that inevitably it has become subject to many misconceptions. It has also been heavily oversubscribed in written terms and has therefore been the subject of transport 'hype'. It has varyingly been referred to as light weight railway suburban stock at one end of the scale and as an up-market successor to the tram on the other. Whilst in the formative years there is an element of truth in this sort of statement, nevertheless the developing forms of transport have crystallised into its recognisably present status of light rail transit.

Present day light rail transit systems fall into a number of defined categories—the older systems used in many parts of the world (particularly Europe), and the new systems to be found in the UK and the USA, where the public transport renaissance is most marked. These new systems have greatly benefited from the new technologies manifest in traction power supply and collection, suspension and running gear, and control and traction equipment, but in many respects more importantly in the public recognition of the advantages of light rail transit in a country where urban and peri-urban congestion with its environmental pollution, noise, congestion, and attendant loss of working hours has taken dramatic toll of our lifestyles. The new system with light-bodied energy-efficient vehicles and effective operating specification is now firmly established.

The new systems originate from the 1920s and 1930s where, in the UK, design and construction was fragmented and standards were at variance. This situation was rectified in the early 1930s by introducing standard types of tram, mainly as a standardised product in the USA arising from the President's Conference Committee. The present light rail transit systems are designed to form an integral link within an overall transport system. They will support the distributive role which the motor bus still fulfils and provide a fast and efficient carrier system between centres of population, as well as an interface with heavy rail systems.

### 44.2.2 Definition

Light rail transit is derived from the old tramway or street-car systems. These operate mostly on the street in mixed

traffic but sometimes also have limited separation from other traffic by preferential treatment at junctions or separate rights of way. Although tramways were almost totally abandoned in the UK, they continued to be developed elsewhere in the world into the higher quality light rail systems. These used higher capacity vehicles which made greater use of separated rights of way outside the central urban areas to avoid road congestion and thus offer shorter journey times. In some instances, separate rights of way were created even within the central areas.

Light rail transit applications range from on-street operation using small vehicles (100 passengers) through to fully segregated operation with large vehicles (200 passengers or more). Light rail transit uses steel-wheeled articulated vehicles propelled by rotary traction motors which normally collect power from an overhead wire at up to 750 V d.c.

The vehicles may have single or double articulated bodies and may operate in trains of up to four vehicles, limited by station platform length, and by traffic management restrictions on street-running sections. Vehicles are manually driven and may have driving positions at each end, and doors on each side, to permit bidirectional working. Some systems use single-ended vehicles with driving positions at one end and doors on one side only. These offer greater passenger capacity for a given size of vehicle, but require space for turning loops at the ends of the line. Vehicles are usually manually driven, although automatic driving is possible. Vehicles run on conventional railway track of either 1000 or 1435 mm gauge, although new systems almost invariably use 1435 mm (standard gauge). For segregated operation, conventional railway rails and turnouts may be used, although grooved rail and special turnouts are need for street running.

Light rail transit is used in many European cities and elsewhere in the world and is growing in popularity in the UK. At present, for example, there are over 100 systems in the CIS, 58 systems in Germany, 19 in Japan, 14 in the USA, 14 in Romania, 13 in Poland, 10 in Czechoslovakia, 6 in Switzerland, and 5 in each of Austria, France and Italy.

In the UK, Blackpool operates the oldest system on the mainland, being the only remaining tramway system. The Tyne and Wear Metro uses vehicles based on light rail technology, but in most other respects this system is operated like a heavy rail system, being segregated and fully signalled. The original Docklands Light Railway also used vehicles based on light rail technology but was also fully segregated, taking advantage of this segregation to use automatically controlled, driverless vehicles and third rail, low level conductor rails. Following its planned expansion and extension it will become even more atypical.

A scheme has been opened in Manchester; the Midlands Metro has an Act of Parliament for its first line, and has Bills for two further lines currently before Parliament. A system for Sheffield is under construction with a grant from the Department of Transport under Section 56 of the Transport Act. Advanced Transport for Avon has obtained one private Act of Parliament and deposited two further Bills in November 1989. At present in the UK more than 40 other schemes are being considered.

Light rail transit can operate on elevated or in tunnelled sections to provide segregation. However, constructing a new segregated alignment would involve almost as much demolition and land acquisition as building a new road. Elevating the route would add some £7 million to £11 million per double-track kilometre to the capital costs of the system as well as posing severe environmental problems in installing the guideway over existing roads. Tunnelling would cost between £20 million and £30 million per double-track

kilometre and, in addition to this civil cost, the system would have to be designed to the same standards as an underground railway from the point of view of safety, which would increase the cost further.

In the UK, HM Railway Inspectorate has defined three types of operation:

- (1) *LRT1* for street running where light rail vehicles share the carriageway with other road users;
- (2) *LRT2* for street running where the light rail vehicles run in a road where the track is not shared with other traffic, but is available for use by other road traffic in an emergency; and
- (3) *LRT3* where the light rail tracks are fully segregated from all other road users.

The main advantages include an ability to move a large volume of people quickly, quietly and comfortably whilst being pollution free at the point of operation. It fills the gap in the transport spectrum between buses and heavy rail, i.e. between about 4000 to 12 000 passengers an hour. Its main disadvantage is its inflexibility as it runs on set track, although the tracks themselves do not create a physical barrier to pedestrians crossing the road in street running sections.

## 44.2.3 Rolling stock

### 44.2.3.1 Examples

Two typical light rail vehicles are shown in *Figure 44.24*. *Figure 44.24(a)* shows a vehicle which is widely used in Germany on systems with extensive street running. It is available in either a single or double articulated form. It is 2.3 m wide and in its single articulated form it is 20 m long overall and accommodates 101 passengers of whom 36 are seated. *Figure 44.24(b)* shows a larger vehicle which is more widely used on systems which have a higher degree of segregation from other traffic. It has a single articulation and is 2.65 m wide and 27 m long overall. It accommodates 156 passengers of whom 70 are seated. The performance of a typical modern light rail vehicle is summarised in *Table 44.1*.

### 44.2.3.2 Dimensions

Light rail vehicles may be up to 30 m in length overall and the recommended widths are 2.2, 2.4 and 2.65 m. The largest width of 2.65 m permits seating to be arranged two seats either side of central gangway (2 + 2). Narrower

**Figure 44.24** (a) Duewag N6 light rail vehicle; (b) Duewag B80 light rail vehicle. Dimensions are in millimetres

**Table 44.1** Typical light rail vehicle performance

Maximum speed	80 km/h
Service speed	70 km/h
Initial acceleration	1.1 m/s <sup>2</sup>
Service braking	1.2 m/s <sup>2</sup>
Emergency braking	$\approx 3$ m/s <sup>2</sup>
Minimum curve radius in service	20 m
Minimum curve radius in depot	15 m
Maximum gradient	$\approx 6\%$
Maximum gradient (all axles motored)	$\approx 40\%$

widths limit the seating arrangement to 2 + 1. Although the greatest width of 2.65 m is larger than that normally permitted for buses (2.5 m), the fact that the light rail vehicle is guided means that the swept-path needed is no greater than for a bus.

The height from rail to roof ranges between 3.0 and 3.3 m, although in some designs roof-mounted equipment may increase this to over 3.6 m.

Empty weights range from under 30 t to between 40 and 50 t.

#### 44.2.3.3 Passenger capacity

Modern light rail vehicles have nominal capacities ranging from 100 to 250 passengers of whom about one-third would be seated. Traditional light rail vehicles have floor levels about 800 mm above the rail which require the use of high platforms or retractable steps to permit access from street level. High platforms can be difficult to incorporate in existing urban environments and steps present difficulties to the mobility impaired. In the Manchester system light rail vehicles stop with one door alongside a short length of raised platform to provide this access in the street running sections.

The interior of modern vehicles is laid out to accommodate the needs of the mobility impaired with provision for wheelchairs and carefully positioned handles and grab-rails.

Several manufacturers, including BN, Breda, Duewag and MAN, have developed low-floor vehicles with floor heights between 300 and 350 mm above the rail. These range from conventional vehicles with one section of floor dropped to those providing low floors over their entire length. The latter is generally only achieved at the expense of significant mechanical complication in the design of the bogies and positioning of traction motors, often requiring additional drive shafts and gears. *Figure 44.25* illustrates the prototype vehicle developed by MAN for Bremen.

#### 44.2.3.4 Structure

Traditionally, body shells are of light-weight welded steel design in which cable and air ducts, equipment boxes, longitudinal, articulation and end members are welded together to form an underframe. Roof and side-wall frames, fabricated of rolled and bent profiles, are welded together with side-wall sheeting and the underframe to form an integrated structure.

Light alloy construction is also used employing large size extruded sections with pressed on supports for equipment for the side walls, roofs and floors to form an integrated structural unit.

#### 44.2.3.5 Traction and braking equipment

Vehicles are propelled by electric motors which obtain power from an overhead conductor wire via a roof-mounted pantograph.

Most modern light rail vehicles employ d.c. traction motors with d.c.-chopper or a.c.-inverter control both with microprocessor control, although some installations use a.c. induction motors with three-phase inverters.

The motors may be self-ventilated or force ventilated with armatures and field windings insulated with class F or H materials.

Braking is achieved by a combination of rheostatic or regenerative braking by the traction motors combined with friction brakes. For street running, electromagnetic track brakes are fitted to provide an emergency braking rate of about 3 m/s<sup>2</sup>. Parking brakes are also fitted. Traction and braking systems are integrated to provide:

- (1) slip/slide protection;
- (2) blending of regenerative or rheostatic brake and friction brake;
- (3) control and protection of power electronics; and
- (4) the facility to operate coupled vehicles.

#### 44.2.3.6 Bogies

Two axle bogies are used. The bogie frames are usually fabricated from steel in a box section design. The frame is supported on the axle boxes by the primary suspension which may consist of chevron-type rubber springs which allow radial adjustment of the wheel sets or of leaf-guided helical or rubber spring elements. Secondary suspension, between the bogie frame and the vehicle body may be by helical, rubber or air springs or by a combination of these. Although the most complex, air springs offer a high ride quality and can maintain the vehicle floor at a constant height above rail level at stops which facilitates level access for mobility-impaired passengers.

**Figure 44.25** MAN low-floor light rail vehicle. Dimensions are in millimetres

There are two general arrangements for motor bogies. In the mono-motor layout a single motor is positioned in the fore-and-aft direction with drive shafts at both ends connected by right-angle gears to the axles. The traction motor and gears form a single unit which is suspended either on the bogie frame or, by means of rubber couplings, on the wheelsets. In the bimotor layout a separate motor is provided for each wheel set and is either hung from the axle or suspended from the bogie frame.

The mono-motor design offers the advantages of lower weight, simpler maintenance and lower cost because of its greater simplicity. A further advantage is that because both axles are connected together wheels cannot begin to spin or slide until all four wheels have lost adhesion. A disadvantage has been that because of restrictions on available space the size, and hence power, of the motor may be limited although recent advances in the design of compact motors has alleviated this to some extent. There is also a suspicion that mono-motor bogies may contribute the phenomenon of rail corrugation in certain circumstances because all wheels are mechanically connected, although the causes of rail corrugation are not well understood.

In addition to rheostatic or generative braking using the traction motor, mechanical brakes are fitted. These may take the form of clasp brakes operating on the wheel treads or disk brakes. Both types are of the spring-applied, power-released type.

Figure 44.26 shows the bogie design used on the MAN low-floor vehicle. The motor is body-mounted and connected to the bogie by a shaft drive with universal joints. Another shaft transmits the power to the two driven wheels because axles are omitted in order to lower the floor.

#### 44.2.3.7 Auxiliary equipment

Folding doors are commonly used which are operated electrically or pneumatically. Retractable steps provide access from street level. Their operation is interlinked with the doors and it is possible to arrange for the steps to operate in different combinations to deal with varying platform heights on different parts of a network. Heating and ventilation are normally fitted.

Automatic couplings can be fitted which will make all necessary mechanical and electrical connections automatic-

ally on buffering up two vehicles. Pneumatic uncoupling and central locking can be provided. Where vehicles are not normally operated coupled, provision is made for manual coupling to enable a failed vehicle to be towed or pushed away.

Pneumatic sanders can be fitted for street operation or where steep gradients are encountered.

Auxiliary electrical power supplies are normally fitted for controls, lighting, battery, charging and other purposes. In addition a 24 V d.c. supply is available for control circuits, public address and radio systems, etc. The battery is capable of maintaining emergency lights, public address and radio systems, and marker lights together with local control equipment for a period not less than 1 h.

Miscellaneous equipment normally fitted includes: a public address system to enable the driver to speak to passengers; passenger alarm to allow passengers to attract the driver's attention; radio equipment to enable the driver to communicate with the controller; route and destination displays; and ticket cancelling or validating machines.

External lighting is fitted generally in accordance with the 'Construction and Use of Public Service Vehicles', but taking account of the particular requirements of light rail vehicles. Additional lights may be fitted for operation on fully segregated sections.

#### 44.2.4 Trackwork

On fully segregated sections conventional railway track is generally used. This consists of rails and fixings, generally with sleepers laid on ballast, although it may be convenient in certain areas to fix the rails direct to the supporting structure.

On street-running sections grooved rail is used, set flush into the road surface. The extent of the swept path of the vehicles is indicated by using a different surface texture or colour, or by white lines to highlight the edges as necessary. There are several ways to install the rails in street-running sections. A recently developed method involves providing grooves in the surface. The rails are correctly located to line and level in the grooves before an elastomer material is poured around them. When set this material holds the rails in position yet provides a slight degree of resilience which helps reduce the noise and vibration generated as the vehicle wheels roll over the rail.

Figure 44.26 MAN low-floor bogie. Dimensions are in millimetres

Special care must be taken to minimise the effect of stray or leakage traction return current because of the use of d.c., especially in the urban areas. The rails themselves form the immediate return path from the vehicle and thus whatever method of fixing the rails is employed it must provide adequate electrical insulation. The rails themselves are often bonded at frequent intervals to a separate traction return cable. Reinforcing mesh or bars in any concrete slab under the track need to be bonded together and to the traction return cable. In some circumstances it is prudent to insert insulating sections in adjacent water or water pipes, especially those entering buildings, to prevent their being used by stray currents.

Where the line runs in a roadside or other reserve, grassed track can be used. In this, the rails are set flush with the level of the ground which is then grassed between the rails as well as outside them which greatly reduces the visual intrusion.

#### 44.2.5 Power supply

Electrical power is normally obtained from the local electricity supply company; in the UK this is normally at 11 kV a.c. Substations comprising transformer/rectifier units convert this to a lower voltage d.c. This is supplied to the overhead system at a voltage not exceeding 750 V d.c. on the street-running sections, although 1500 V d.c. may be used on segregated sections of the line.

The visual impact of the overhead-line equipment is greatly reduced by the use of insulated support wires made from Parafil which eliminates the need for obtrusive insulators. Wires can also be attached to existing buildings to obviate the need for separate poles. The minimum wire height on street-running sections in the UK is 5.5 m in order to provide safe clearance above other road traffic, but may be reduced to about 3.8 m on fully segregated sections.

#### 44.2.6 Signalling and control

Signalling and control systems permit safe and expeditious operation, while requiring the minimum of manual intervention in normal operation. In street-running sections separate heads are fitted to traffic signals to control the light rail vehicles. These are frequently used to give priority to the light rail vehicles as a means of encouraging the use of public transport. Apart from this, the vehicles are driven like any other road vehicle, with the driver being responsible for maintaining a safe speed.

A form of automatic identification system (such as the Phillips VETAG system) is often fitted to the vehicles. Information about the vehicle's route may be pre-set so that on approaching junctions the required route may be set automatically and the vehicle given a degree of priority over other traffic. Similarly, line-of-sight operation may be used on partially or fully segregated sections with drivers being responsible for maintaining a safe speed without the need for an elaborate signalling system. Where signalling is needed, at say termini, then a simple, local system can be used.

Mobile radio is normally fitted to the vehicles to enable drivers to remain in contact with a central control room. Staff in the central control room are responsible for the overall supervision of the operation and have good, direct communications to the police, fire and ambulance services for use in case of emergency.

#### 44.2.7 Stops

Stops are simple and unmanned. They basically consist of a raised platform to provide stepless, level entry to the vehicles. If low-floor vehicles are used then on street-running sections the platforms need only be raised some 200–250 mm above the level of the pavement when the height of the kerb is taken into account. Simple passenger shelters only are needed which can also be used to support passenger information notice boards and ticket vending machines selling adult and reduced rate single tickets. Passengers are generally encouraged to purchase multi-journey tickets (*carneys*), fare cards or reduced-rate tickets off the system.

#### 44.2.8 Depot

The depot provides maintenance facilities for the system and stabling siding for the vehicles. The depot would be equipped to carry out day-to-day servicing and maintenance of vehicles, power supply, signalling, trackwork, etc. Depending on the scale of operation, it may also be equipped to carry out more extensive maintenance work, although it may be found more economical to subcontract certain heavy maintenance of vehicles. One example is turning worn wheels. A wheel lathe for turning wheels *in situ* on the vehicles costs over £1 million. Facilities provided at the depot typically include: office building; control centre; staff facilities; tracked workshop; general workshop; storage areas for equipment, plant and spares; stabling sidings; washing plant; and external stores compounds.

#### 44.2.9 Economics and investment

In many other countries, public transport is funded by special taxes. In Germany there is a tax on petrol which is designated for roads and public transport, and in France local communities may decide to introduce a payroll tax on employers to fund public transport. In the USA there are a number of State-operated taxes (such as sales taxes) which are used to generate funds. In the UK grants towards construction costs are available from public funds under Section 56 of the Transport Act 1968—half coming from central government and half from local authorities. The grant is only available to fill any gap between the capital cost and the funds available from other sources and must be justified by the economic benefits the system offers to non-users. Primarily this is in terms of time and cost saving to road users who do *not* use the light rail system.

Light rail transit systems can claim decongestion, and social and environmental benefits which, if quantified, would make the schemes economically viable in cost-benefit terms. Nevertheless, no system recovers its full cost through fares, although *direct* operating costs which exclude any element of capital charges can be covered. The capital cost of light rail transit varies widely with the type of system, but typically it can vary between £2 million and £3 million per single track kilometre. Similarly, direct operating costs can also vary widely, but in the UK have been estimated to range between £2 and £4 per vehicle kilometre.

### 44.3 Battery vehicles

For many years, battery-powered vehicles have been used quite extensively in the UK for low-speed, low-range,

applications. These vehicles, which use well-proven technology, are described in Section 44.3.1.

Recently, there has been a surge of activity in the development of faster, longer range vehicles, with performance similar to combustion-engine-driven types, and capable of use in commercial fleets or for personal commuting. Such advanced vehicles are not yet fully developed for commercial production, but are expected to be so in the second half of the 1990s. Their current status is described in Section 44.3.2.

### 44.3.1 Low-speed battery vehicles

The main sphere of use is for local delivery work such as the door-to-door delivery of milk, bread, laundry, coal, mineral waters and other goods, and specialised work such as refuse collection, steel lighting maintenance and interworks transport. In such services a vehicle may be required to make 200–300 delivery stops, while the total distance is usually between 30 and 50 km daily, and rarely reaches the maximum range of about 70 km. Under these conditions the delivery speed and the road speed are almost unrelated, the chief considerations being acceleration, ease of exit and entry to the vehicle, simplicity of control and reduction of personal fatigue. Efficient service is generally obtained with maximum road speeds of the order of 30–35 km/h.

#### 44.3.1.1 Batteries

The lead-acid battery is customary. Choice of battery depends on vehicle duty. Thin-plate automotive starter batteries have high energy capacities but short life on deep-cycling duty. Traction batteries have thicker and firmly separated plates: their weight is kept down by using lightweight plastics cases and short intercell connections. 'Light traction' batteries are supposed to withstand 500 charge/discharge cycles, whereas true traction batteries are guaranteed for 1000–1500 cycles, and may last far more. These batteries are most economic (in £/kW-h throughput) if they are used almost daily and discharged to between 70 and 90% of their capacity.

#### 44.3.1.2 Motors

The basic design of d.c. traction motors has not been essentially changed, but the use of improved wires and strips for windings, and class H insulation, have greatly improved thermal transfer and reduced weight.

#### 44.3.1.3 Control

Until the introduction of semiconductors with high current capacity the accepted methods of speed and torque control were (a) series resistance, (b) series/parallel battery switching, (c) series/parallel motor switching and (d) field control. Almost all controllers provided a stepped variation or, at best, a smoothly variable control over limited ranges of torque and speed. The carbon pile variable resistor was also extensively applied, with compression by hydraulic master and slave cylinders.

**Series resistance** On small vehicles such as milk prams a single step of resistance usually suffices before the motor is switched on to the full battery, usually 24 V. On larger vehicles and works trucks several steps of series resistance may be used and these are cut out in sequence by a drum or cam controller. The one economical running connection is usually sufficient for low-speed vehicles of the pedestrian-controlled type. In some cases a second economical connection is obtained by field diversion.

**Parallel/series battery switching** By dividing the battery into halves, and putting them first in parallel to give half-voltage, then in series to give full voltage, and by using two or three resistance steps for each setting, the loss of energy in the resistors may be halved, compared with the previous system. In addition, an economic half-speed running circuit is obtained. The scheme is also less severe on batteries, since the first few current peaks are shared.

A conventional battery switching circuit employs a pair of contactors interlocked (usually mechanically) so that the double-pole contactor (*Figure 44.27(a)*) is closed for the parallel and the single pole for the series connection: they cannot be closed at the same time. In a circuit which involves no current breaking (*Figure 44.27(b)*) diodes make the parallel connections, and the contactor for the series connection reverse-biases the diodes so they do not conduct.

A patented diode/contactor arrangement elaborated from the above gives a multivoltage circuit in which, by contrast with the more obvious battery tapping systems, all batteries are used (not necessarily equally) all the time.

**Field control** Field control is fittingly used in addition to the two previous schemes. By use of a four-pole motor with its field windings in separate pairs, full excitation is obtained with the field windings in series, and half-excitation for increased speeds with the field winding pairs in parallel. Field diversion, for even weaker field and higher speed, may be given by shunting an appropriately low resistance across the paralleled field windings.

Figure 44.27 Parallel/series battery switching: (a) contactor; (b) contactor/diodes

**Solid state switching** With suitable commutation control equipment, thyristors can provide a substantially variable, loss-free motor power control, provided that the pulse rate is not too low. Several forms of pulsed thyristor control are available, differing only in circuit details. The variations are largely associated with the method of providing satisfactory turn-off characteristics for the main circuit thyristors, and correlation of mark/space, repetition frequency and current switching levels to obtain the required motor output characteristics.

Thyristor controllers consist of the following basic elements: (a) main power thyristors, (b) turn-off capacitor; (c) commutator thyristor, (d) function generator, (e) current limiting and fail-safe circuits, and (f) manual control device.

**Chopper control** In the simplified equivalent circuit shown in Figure 44.28, the switch (Sw) represents the main thyristor in an actual circuit arrangement. In (a) for normal motor operation, Sw is closed for a time  $t_1$  and opened for  $t_2$  (each time being of the order of a few milliseconds), the sequence being repeated with a switching time  $T = t_1 + t_2$ . During  $t_1$  the current rises at a rate proportional to the difference between the battery voltage  $V$  and the motor armature e.m.f.  $E$ , such that  $L(di/dt) = V - E$ , where  $L$  is the circuit inductance and resistance is neglected. With Sw now opened for time  $t_2$ , the motor current continues through the freewheel diode  $D_1$ , driven by the armature e.m.f.  $E$  and falling at a rate such that  $L(di/dt) = E$ . Under steady load conditions the rise  $\Delta i$  during the 'on' time is equal to the fall  $\Delta i$  during the 'off'. As the times are short, they are approximately

$$\Delta i = t_1(V - E)/L = t_2 \cdot (E/L) \Leftarrow$$

whence  $E/V = t_1/(t_1 + t_2) = t_1/T$ . The e.m.f. ratio is equal to the ratio between 'on' time and total switching period. For an average motor current  $i$  the mean battery supply current is  $I_s = i(t_1/T)$  and the mean motor current is  $I_m = I_s(T/t_1)$ . With  $E = V(t_1/T)$  it follows that

$$EI_m = V(t_1/T) \cdot I_s(T/t_1) = VI_s$$

whence the chopper acts like a 'd.c. transformer' in terms of the input and output voltage and current ratios, under

Figure 44.28 Essentials of a 'chopper' circuit: (a) for motoring; (b) for regeneration

steady-state conditions and with resistance and other losses neglected.

In operation,  $t_1/T$  is increased from zero towards unity to start the motor (with control by the current or voltage limiter). With  $t_1/T = 0.95$  or thereabouts,  $t_2$  may be too short to allow the thyristor current to quench. In many equipments a contactor is closed to bypass the thyristor and connect the battery direct to the motor, thus eliminating thyristor forward loss.

If sustained low-voltage high-current operation is required (and it is in such a case that the efficiency of the system is much higher than with resistance control), the mean square motor current is higher than the square of the mean current, which raises the motor  $I^2R$  loss. Enhanced cooling or reduced rating are then necessary in chopper control.

For *regeneration* the basic circuit is rearranged as in Figure 44.28(b). Diode  $D_r$  prevents feedback of the supply to the motor. When Sw is 'on', the machine generates, converting kinetic energy into magnetic energy in the inductance; in the 'off' time the machine is connected to the supply, and  $E$  together with  $L(di/dt)$  drives current through  $D_r$  into the battery. Then  $V/E = T/t_1$  and  $I_s = I_m(t_1/T)$ .

For *control* the function generator in the chopper system is combined with comparators to give current and voltage control, switching off when current or voltage attains a demand value. Both values are increased as the 'accelerator' pedal is depressed. Regeneration, if fitted, is usually current controlled by the initial movement of the brake pedal, which thereafter applies the friction brakes.

The flexibility of electronic control systems allows the use of a controlled field shunt motor, with electronically controlled field current. Full-field acceleration to the running voltage, with power thyristor control (as above) for the armature current, is followed by controlled field weakening to give, e.g. constant current motoring to a preset speed or the weakest allowable field. Regeneration by field strengthening is then easy to arrange. So far, schemes of this nature have been experimental.

As an example, Figure 44.29 shows in more detail the scheme for chopper control of a battery electric car.

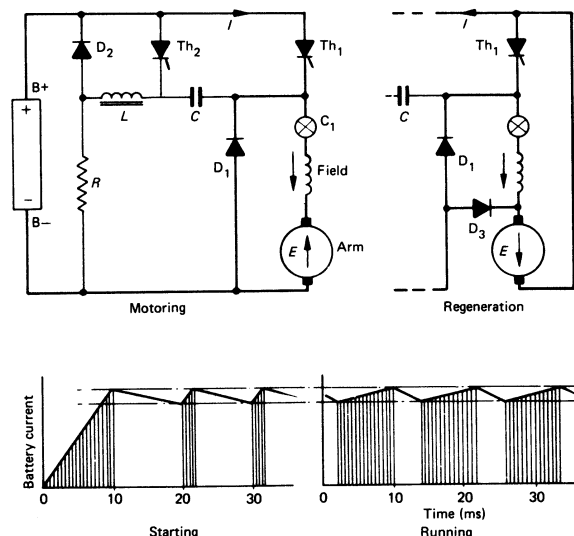

Figure 44.29 Thyristor control of an electric car

For *motoring* the battery motor circuit is completed by firing thyristor  $Th_1$ . The current rises, and at a predetermined value is cut off by the switching action of the current monitor  $C_1$ . The inductive energy maintains the motor current through the free-wheel diode  $D_1$ . The current decays, and at a predetermined minimum  $C_1$  switches on  $Th_1$ . The motor current fluctuates between the two limits, but battery current flows only while  $Th_1$  conducts. The rate of current fluctuation depends on the armature e.m.f. To switch off  $Th_1$  it is necessary to reduce its current momentarily to a very small value by means of  $Th_2$ ,  $C$ ,  $L$ ,  $R$  and  $D_2$ . Prior to any current demand,  $Th_2$  is switched on and charges capacitor  $C$  so that the potential of the left-hand side is raised to that of the positive battery terminal  $B+$  and the right-hand side to that of the negative  $B-$ ; then  $Th_2$  ceases to conduct owing to lack of 'holding' current. When  $Th_1$  is fired, the right-hand side of  $C$  is immediately raised to  $B+$  and the left-hand side to  $2B+$ . Current starts to flow from  $C$  through inductor  $L$  and diode  $D_2$ , reducing the voltage across  $C$  and increasing the inductive energy in  $L$ . When the left-hand side of  $C$  has fallen to  $B+$ , the current in  $L$  continues, which causes a continued fall in the voltage of  $C$ . When the current in  $L$  has ceased, the left-hand side of  $C$  will be at a potential  $B-$  and diode  $D_2$  becomes reverse-biased. The potentials on  $C$  are now  $B-$  (left hand) and  $B+$  (right hand), and remain so until  $Th_2$  again fires. A bleed path through  $R$  ensures that leakage currents through  $D_2$  and  $Th_2$  do not raise the left-hand voltage on  $C$  when  $Th_1$  conducts for long periods. When  $Th_2$  is fired again, the left-hand side of  $C$  is taken up to  $B+$  and the right-hand side to  $2B+$ . The cathode of  $Th_1$  is then positive to its anode and it therefore ceases to conduct. The motor current, which is thus transferred from  $Th_1$  to  $Th_2$ , flows through  $C$  and lowers the right-hand potential to  $B-$ . Then, as the motor current diverts through  $D_1$ , conduction through  $Th_2$  ceases for lack of holding current. The inductive energy of the motor maintains current through  $D_1$ . The circuit is now ready for  $Th_1$  to be fired again.

For *regeneration* the circuit is set up by changing the armature polarity with respect to the field and by adding diode  $D_3$ , accomplished by a simple changeover switch. When  $Th_1$  conducts, the motor is effectively short-circuited and the current builds up rapidly. At maximum current level  $Th_1$  is switched off and the motor current, maintained by the motor inductance, diverts through  $D_1$ , supplying a charging current to the battery. The cycle repeats to give a roughly constant average motor current and a constant resulting braking torque.

Conditions are complicated by the transition 'spikes' of voltage. They have a short duration but a large magnitude. The spikes have some effect on the battery, and increase motor core and  $I^2R$  losses. They may also impair commutation, particularly at low pulse rate frequency.

The cost of pulsed thyristor equipment is a disadvantage. The reduction of battery energy depends on the type of vehicle and its duty. The overall saving may be about 10% for typical delivery rounds, and rather more for industrial vehicles such as fork-lift trucks.

#### 44.3.1.4 Vehicle and operational details

**Charging** Taper chargers are now used extensively for the charging of traction batteries, and are normally provided with germanium or silicon rectifiers. Voltage sensitive thermal relays in conjunction with synchronous timing motors and contactors are used for charge termination. In one form

of charge control device a temperature sensitive non-linear resistor, preheated electrically, is cooled by hydrogen from pilot cells when gassing begins. The change in resistance through the cooling of the device causes transducers to regulate the output of the charger.

Improved conductor insulation and high-grade magnetic core material, together with forced cooling, have resulted in weight saving in charger equipments carried on vehicles. A typical charger for connection to a 13 A power outlet, and making full use of this current rating up to the start of the gassing period, has the performance shown in Figure 44.30 when charging a 48 V, 260 A-h lead-acid battery.

**Torque transmission** Most road and industrial battery vehicles are fitted with axles of conventional differential gear design, still the most convenient form of torque transmission to a pair of driving wheels. It has been shown by test that there is scope for improvement in performance by modifying the lubricant viscosity: the axles are normally fitted with extra gear reduction nose-pieces or external chain-and-sprocket reductions, and a fully run-in differential may absorb up to 1.5 kW at maximum road speed. Oils of lower viscosity have been used without excessive gear wear, although the noise is greater.

**Hydraulic transmission** has found only limited application. Even simple forms cannot compete as alternatives to thyristor motor control gear for driver-type vehicles, but may be suitable for some industrial applications where the infinitely variable characteristic makes elaborate motor control gear unnecessary.

**Motorised wheels** (i.e. motors built into the wheels) are extensively used in fork-lift trucks, sometimes with low-speed designs of reduced length and increased diameter. The powered wheels can be used for steering, thus improving manoeuvrability.

**Regeneration** In general, the small amount of energy recoverable does not warrant the cost and complexity of the control gear necessary for regeneration, although it reduces brake maintenance (a major operating requirement). Certain industrial vehicles such as fork-lift trucks might benefit from regeneration if enough load lowering duty were involved; this might be possible by use of recirculating ball screws in place of the normal hydraulic lifting rams, enabling the motor to generate on lowering.

Figure 44.30 Charging characteristics

**Tyres** Battery vehicles are affected to a greater extent than other vehicles by the rolling resistance of tyres. Radial ply tyres provide a more supple casing and as a result the loss due to flexing of the walls is less. A saving of 13% in energy consumption (or an increase of 15% in range) can be obtained. An advantage is that radial ply tyres are less sensitive to departures from optimum inflation pressure.

**Bodywork** Most recent rider-driver battery vehicles use glass-fibre-resin mouldings, which permit improved appearance with much lower tooling cost. Metal inserts are readily moulded into laminates to provide anchorage points or attachments for components. Translucent panels can be moulded into otherwise opaque surfaces.

#### 44.3.1.5 Applications

**Pedestrian controlled vehicles** Bakery and dairy delivery vans, 'led' by the driver, have capacities between 0.5 and 1 t and a range up to about 20 km. The steering handle carries running and brake controls and there is a separate parking brake. A typical specification includes a 2 kW motor, 24 V, 100 A-h battery, and chain or reduction gear differential drive.

**Rider-driver vehicles** Invalid carriages with 36 V, 75 A-h batteries have speeds up to 20 km/h and can negotiate any normal road. Municipal vehicles (refuse collection, tower wagons and tractors) are usually 4–6 t vehicles with batteries of up to 144 V, 600 A-h. The battery weight is useful in adding stability to the tower wagon. The most widely used industrial trucks are platform, elevating and fork-lift trucks, road and rail tractors, mobile cranes, and trucks for carrying hot forgings and molten metal buckets. The capacities range up to 1–2 t. Some lighter types are three-wheelers having the motor and front wheel mounted on a turntable, which makes them exceptionally manoeuvrable.

On elevating, tiering, crane and other types of trucks with power operation, it is usual to employ a separate motor to perform these tasks, power being drawn from the main battery. The location of the battery on the vehicle varies according to the design. On some they are mounted beneath the platform, but in many cases they are mounted on a separate platform or under the driving seat. It is common for these vehicles to work long hours and in such cases two or more sets of batteries are employed, a discharged battery being replaced when necessary. The voltage varies between 24 and 80 V.

When trucks are fitted with a platform for the driver to stand on, steering is usually by means of a tiller, while the controller is hand operated and interlocked with the brake pedal to give a 'dead man' effect. With this design the brakes are held off by brake pedal. When pressure on the pedal is released, the brakes are automatically applied and the electric circuit is broken.

**Locomotives** Battery shunting locomotives are used by many railways, factories and mines. A typical small locomotive develops a drawbar pull of 1.6 kN (360 lb-ft) at 6.5 km/h from a 4 kW, 48 V totally enclosed series motor with split field windings for control and worm drive on each of the two axles. Such a locomotive is designed for 0.46, 0.51 or 0.61 m gauge. Larger locomotives may weigh up to 8 t, operate at 120 V, and have two 12 kW series motors with series/parallel control, giving a 1 h tractive effort of 11.5 kN at 8.5 km/h.

#### 44.3.1.6 Electric buses

Two experimental vehicles of the early 1970s demonstrated the feasibility of battery buses. One was a 50-passenger single-deck vehicle, 16 t in weight (including a 4.8 t battery) with chopper control (with regeneration of a 72 kW, 330 V series motor, 64 km range, 64 km/h speed and 1.0 m/s<sup>2</sup> acceleration). The other was a 'minibus' for 34 passengers in a short single-deck body, with a 100 kW motor, 150 km cruising range, 80 km/h maximum speed, 0.9 m/s<sup>2</sup> average acceleration and weight 9.7 t.

From the mid-1970s, several experimental fleets of electric and duo-mode buses were established in Germany as part of a programme initiated by RWE, Germany's largest privately owned electric utility company. The projects included a fleet of MAN battery electric buses, operating in Münchenglöblich and Düsseldorf. The buses were originally designed for rapid battery exchange, to permit extended operation, but were later equipped with rapid recharge facilities at selected bus stops. Although the range on a single charge was only 60 km, these buses were able to achieve 360 km in a 16 h working shift due to 'opportunity charging'. Other experimental bus fleets were established in France by Renault.

More recently two prototype purpose-designed electric buses with 16-seat capacity have been built by a British company for clients in the USA and Hong Kong, and two 25-seat passenger vehicles have entered service in Santa Barbara, California, as part of an integrated pollution-free pedestrian/public transport scheme in the downtown area.

#### 44.3.1.7 Range and power assessment

The range is limited by the energy/mass storage capability. A 1000 kg lead-acid battery operating at a load of 10–15 kW/t stores about 20 kW-h, and as the transmission efficiency from motor terminals to wheel treads is about 70%, less than two-thirds of the capability is available at the wheels.

A vehicle of weight  $G$  with a (battery/total) weight ratio  $f$ , driven against a tractive resistance  $R$ , has a range  $S$  that is roughly estimated from

$$S = \frac{fG}{R}$$

Let a vehicle have the following particulars:

$G$	total weight (kg)	$k_r$	rolling resistance coefficient (N/kg)
$u$	speed (km/h)	$r_a$	air resistance (N)
$R$	tractive resistance (N)	$k_a$	drag coefficient
$A$	frontal area (m <sup>2</sup> )		
$r_r$	rolling resistance (N)		

The tractive resistance  $R$  comprises the rolling resistance  $r_r$  and the air resistance  $r_a$ . The former is  $r_r = k_r G$ , where  $k_r$  has a value in the range 0.1–0.2. The air resistance, proportional to the square of the speed, is

$$r_a = \frac{1}{2} \rho C_d A u^2$$

The drag coefficient  $k_a$  is 1.0 for bluff-fronted vehicles (e.g. vans), about 0.5 for cars and as low as 0.2 for fully streamlined bodies. The total tractive resistance is then  $R = (r_r + r_a)$ , and can be used to estimate the range  $S$  (in km).

Let  $G = 8000$  kg,  $f = 0.25$ ,  $u = 40$  km/h,  $A = 5.0$  m<sup>2</sup>,  $k_r = 0.15$  and  $k_a = 0.78$ . Then  $r_r = 1200$  N,  $r_a = 300$  N and  $R = 1500$  N. Then the range  $S = 67$  km.

The power at the wheels (in kW) is  $P = \frac{Fv}{3600}$ . For the parameters above,  $P = 47$  kW. The input to the motor is about  $17/0.7 = 24$  kW. Motor inputs of 8 kW/t may be required for a battery vehicle to emulate an internal combustion-engined vehicle.

If a vehicle is braked to rest from an appreciable speed, the range  $S$  is reduced by reason of the loss of kinetic energy in friction. Some allowance may be made by reducing  $S$  by about 0.3 km for each brake stop from 50 km/h, and less for lower speeds in proportion to the square of the speed.

#### 44.3.2 Advanced electric vehicles

At the beginning of the 1990s there was a surge of activity world-wide in the development of advanced electric vehicles. The driving force for this activity was mainly concern over atmospheric pollution, particularly in urban areas, and the concern in Western countries about the security of oil supplies, highlighted by the Gulf War of 1991. Increasingly stringent legislation was introduced to limit exhaust-pipe emissions, particularly in the USA where the introduction of zero emission vehicles before the end of century was mandated. As a result, practically all major vehicle manufacturers started development programmes for battery operated vehicles.

##### 44.3.2.1 Advanced batteries

**Lead-acid batteries** Modern lead-acid batteries specifically developed for electric vehicle application operate at defined conditions (temperature control, no acid stratification, battery management) and yield between 500 and 1500 duty cycles. Energy density is limited to about 30 W-h/kg, and at the 1–2 h rate this often falls below 25 W-h/kg. Valve-regulated lead-acid batteries employing gelled electrolyte allow total maintenance-free operation.

**Nickel-cadmium batteries** Nickel-cadmium batteries at the 1–2 h rate yield twice the energy density of lead-acid batteries, i.e. about 50 W-h/kg. They operate over a wide temperature range, give approximately 2000 cycles, and can be charged in less than 1 h. Nickel-cadmium batteries are used in various developmental electric vehicles. Unfortunately, the high cost of the electrode materials leads to prices 3–4 times higher than lead-acid, only partly offset by longer life.

The presence of cadmium poses a problem with disposal, and development work is in hand to replace the cadmium electrode with a hydrogen-storing electrode, to give the so-called nickel-metal hydride battery. Further developments will lead to a sealed, fully maintenance-free, version.

**Sodium-sulphur batteries** A host of other battery technologies are under development, including zinc-bromine, nickel-iron, and various lithium systems. However, it is the sodium sulphur system which is best developed and is now in pilot production by two major European groups. Sodium-sulphur batteries operate internally at temperatures above 300°C and require high-performance thermal insulation. However, they offer energy densities around 100 W-h/kg, fully maintenance-free operation, 100% coulombic efficiency, fast recharge times, good deep discharge performance, and the potential (yet to be proven) for long cycle life and costs similar to lead-acid batteries.

Together with a similar system, sodium-metal chloride, these batteries have been tested in a range of different

vehicles in Europe and the USA, and are expected to be in volume production by the mid-1990s.

##### 44.3.2.2 Advanced drive systems

Although d.c. traction motors are still widely used, some vehicle manufacturers are now developing their own a.c. systems which give higher power density. In some designs the motors drive the wheels directly, in others the motor is incorporated into the axle, or drives through a conventional differential.

Advanced electronic controllers are under development which interface with the battery electronics to provide overall system management.

##### 44.3.2.3 Applications

As the technology of electric vehicles improves, the emphasis is switching from commercial delivery vehicles towards personal transport. One US vehicle manufacturer has demonstrated a battery vehicle which achieves 0–60 mile/h in 8 s and has a top speed of 110 mile/h. Several European manufacturers have established small fleets of vehicles, often using conversions of existing models as a 'mule' vehicle to test out the drive system. Unless there are unforeseen problems, it can be expected that a new generation of electric vehicles will be on general sale by the middle of the 1990s.

## 44.4 Road traffic control and information systems

### 44.4.1 Traffic signalling

#### 44.4.1.1 Signals

Traffic signal heads usually have two aspects for pedestrians, or three for vehicles with additional aspects for turning movements. Standards exist for colour, light output (typically 400 cd over 30° for good daytime visibility), and sun phantom (the permitted re-emitted level of sunlight).

The aspects are switched on and off at the signal controller via multicore cables, usually at mains voltage. Low-voltage halogen lamps fed by transformers in the signal head are standard in the UK, but mains voltage tungsten lamps are also widely used. High-intensity signals are dimmed at night.

Possible developments include digitally controlled distributed switching having the necessary level of integrity, and solid-state light sources having acceptable colour and intensity.

Primary signals are located at the stop line, on each side of the approach if necessary. Secondary signals are located downstream of the stop line, either on the nearside or the far side of the intersection according to safety considerations.

#### 44.4.1.2 Phasing

Where signal heads control movements which can be started and stopped at the same time they are wired in parallel to a set of controller switches, and form a unit of control known as a 'phase group' or 'signal group'. Phases may be sequential or, providing they do not control conflicting movements, overlap.

To obtain the greatest capacity from the physical intersection space available as many non-conflicting movements are run together as possible, and the sequence of phases is optimised to minimise lost time between movements, taking account of any moves which are prohibited on safety grounds. A simple intersection may have about eight phases and a complex one 24, or more where trams have to be controlled for example.

Where an overall coordination plan is to be followed, for example from a central computer, it may not be necessary to control each phase individually, and phases are grouped into sequential stages such that a new stage is defined whenever a new combination of phases is needed. A normally complete sequence of stages is called a cycle, but stages may be omitted or their order varied according to traffic conditions. Several parallel stage streams (e.g. eight) may be defined in a modern single controller.

A simple three-stage four-phase intersection is shown in Figure 44.31.

Figure 44.31 Simple three-stage four-phase intersection

#### 44.4.1.3 Timing

Under vehicle or traffic actuated control, a phase is only called if a demand is received from a vehicle detector, unless it is a phase which must appear. For that phase to begin, conflicting phases must be safely terminated, usually via a leaving amber interval, followed by any all-red period needed to clear conflicting vehicles. In the UK a starting amber is shown before the green signal, which must then run for a minimum green period.

If traffic is still flowing over the detectors at the end of the minimum green interval, extensions of green time occur according to the speed of the vehicles. The phase is terminated when a gap in the extensions occurs or a pre-determined maximum green time is reached, provided a demand for a conflicting phase exists.

Under heavier traffic the maximum green times are usually reached. The optimum values must be calculated for the cycle time, and the amount of it which is allocated to each stage in order to minimise overall delay. Although controllers are becoming 'smarter', it is usual to pre-calculate the values from surveyed data.

Each approach has an actual flow ( $q$ ) which must be measured, and a saturation flow ( $s$ ) which is the maximum that could occur if continuously fed by a queue. Saturation flow is proportional to road width, corrected for gradient.

The ratio  $y = q/s$  tells us the claim that each stage will have on the available cycle time. (A narrow road with a large flow has a high  $y$  value.) Some of the cycle time is lost ( $L$  seconds) to traffic flow during the intergreen period between stages.

The optimum cycle time ( $c_o$ ) for minimum delay, e.g. by Webster's method,<sup>1</sup> is approximately

$$\frac{1.5L + 5}{1 - Y}$$

where

$$Y = y_1 + y_2 + \dots + y_n$$

As  $Y \rightarrow 1$ ,  $c_o \rightarrow \infty$  and a practical limit has to be set at about 120 s. Green times for the stages (the splits) can then be allocated,

$$g_1 = \frac{y_1}{Y}(c_o - L), \text{ etc.}$$

A single set of timings may not be appropriate for all peak and off-peak conditions throughout the week. Alternative timing plans (typically eight) are stored in the controller, and selected according to a time-table which is also stored and read in conjunction with a real-time clock. A controller can operate in several modes: fixed time, vehicle (traffic) actuated, police operated, emergency vehicle or rail priority (or pre-empt), or under central computer control.

#### 44.4.1.4 Controller equipment

Historically, a very simple and reliable controller consisted of cam-operated switches driven by a synchronous motor, with dials for alternative timing plans. A modern controller consists of a microprocessor printed circuit board with programmable read only memory (PROM) and battery backed random access memory (RAM) to hold the site configuration data; a user interface to a hand-held terminal or personal computer (PC); interfaces for vehicle detectors;

a central computer connection; lamp switching modules (usually triac); and, critically, a secure device to detect the possibility of conflicting green signals.

The whole unit must be be relatively cheap, and housed in a weatherproof cabinet with an internal temperature range of at least  $-15$  to  $+70^{\circ}\text{C}$ . Additional features include signal lamp monitoring, and autodialled fault reporting to a central point, strategies which seek to provide better distribution of capacity particularly under heavy traffic conditions.

Autoscheduling is used to help the traffic engineer prepare the considerable amount of data which may be necessary for each intersection, and many features vary from site to site. Controllers such as the GEC GX therefore allow specific values to be attached to the generic values.

#### 44.4.1.5 Vehicle detection

Vehicle detectors most commonly use shallow loops of wire in the roadway whose characteristics at frequencies of around  $100\text{ kHz}$  are altered by the presence of vehicles. These detectors are simple, unobtrusive and precise, but demand good installation standards and relatively frequent recutting of the detector loops.

Detection of variations in the earth magnetic field, and piezo/tribo devices to measure mechanical pressure are used less commonly.

Above-surface detectors include microwave, infra-red and ultrasonic measurement of reflected energy. Structures are needed near to the point of detection at a suitable height and position to avoid vehicle obscuration. Video-image processing is used for incident detection.

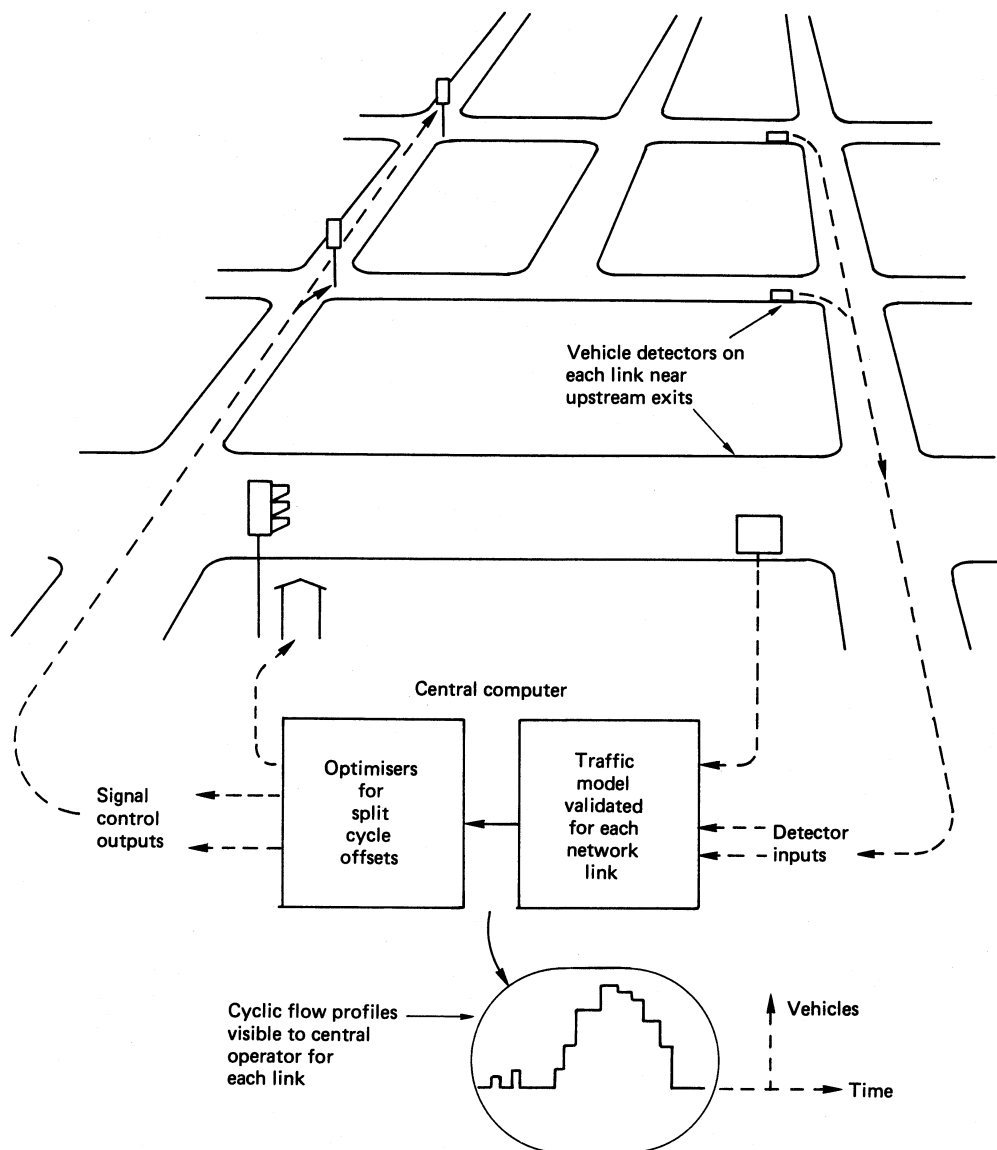

Figure 44.32 SCOOT adaptive traffic control system

#### 44.4.1.6 Signal coordination

Where the travel time between intersections is short enough for traffic platoons not to become unduly dispersed (e.g. about 30 s or less), it is beneficial to co-ordinate the time between the appearance of successive green signals, known as the 'offset'.

This can be done locally for small groups of intersections by synchronising the controller real-time clocks to the mains power frequency. The initial reference is set up manually, or using the dial-up remote monitoring equipment.

### 44.4.2 Traffic control systems

#### 44.4.2.1 Urban traffic control

Urban traffic control (UTC) systems use central computers to co-ordinate and monitor larger numbers of intersections, from typically 15 up to thousands of intersections in a complete metropolitan area.

Optimisation of signal settings for minimum overall delay in two-dimensional networks is traditionally done off-line using surveyed traffic flows and a method such as TRANSYT.<sup>2</sup> Fixed time plans are then loaded into the control computers together with a time-table as described for the controller. At least 15% overall reduction in journey times should be achieved.

The computer sends stage-by-stage change messages to each controller, with typically eight on one 1200 bits per second (bps) communication channel, and checks that the controllers have responded.

Plans may be changed by operators in a control room to suit abnormal traffic conditions, using closed-circuit television to monitor key intersections. It is difficult to quantify the benefits of manual intervention in terms of traffic measurements, but the cost of surveillance equipment is often justified in terms of the overall savings from the scheme.

Fixed time plans typically require updating after about 3 years if the initial benefits are not to deteriorate. Fully traffic adaptive systems such as SCOOT are now standard which, second by second, optimise splits, cycle time and offset from real-time traffic measurements. The principle is illustrated in Figure 44.32.

A standard system such as the GEC Traffic Management System combines SCOOT with car-park and diversion-sign control, emergency vehicle priority, and the ability to pre-program operator actions for holidays, etc. More central computing cells and operator PCs are simply added to the central local area network in order to control larger numbers of intersections.

#### 44.4.2.2 Motorway control

Roadside communication devices along a longitudinal cable, a central computer system and control centres are also used for motorway surveillance and control. The most basic requirement is for emergency telephones, which in some countries use solar power and radio.

Sign control is primarily for access and hazard warning. Ramp metering is a method of dynamic access control used to feed joining traffic onto the motorway. Signs may be

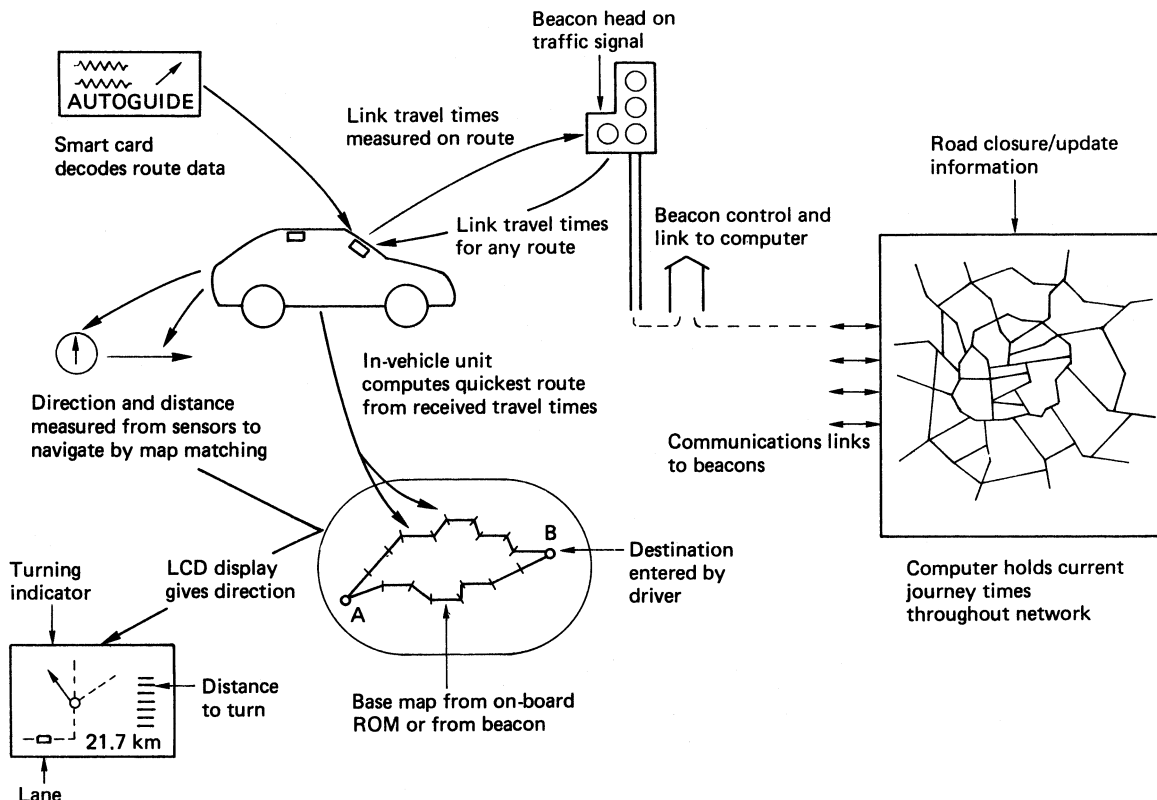

Figure 44.33 Autoguide driver-information system

used to close ramps in emergencies, and re-route traffic in conjunction with the UTC system in urban areas.

Hazard warnings on the motorway must be rapid and relevant, and are demanding in terms of closely spaced signs, vehicle and weather detection, and a reliable, fast and automatic incident detection algorithm. Their justification (by comparison with lighting, for example) must be set against relatively infrequent, but major, accidents.

#### 44.4.3 Driver information systems

##### 44.4.3.1 Route guidance

Traffic control schemes seek to make the best use of existing roadspace, but they can only respond to demand on the network resulting from drivers' route choice. This, in turn, is based on imprecise information about up-to-the-minute traffic conditions.

In a scheme such as GEC Autoguide, and its German equivalent Euroscout, drivers receive junction by junction routing information on a relatively cheap in-vehicle unit, based on up to the minute traffic data held in a central computer. Users help to gather this data, without revealing their identity, by giving their travel times for each network link back to the system. The principle is illustrated in *Figure 44.33*.

Other types of system provide traffic information without alternative routing advice, or provide in-car map-following navigation without live traffic data.

In Autoguide type systems information is exchanged with roadside beacons using infra-red or microwave transmission, or by cellular radio, preferably to digital standards with a broadcast channel. The vehicle is fitted with sensors to measure the direction and distance travelled, and uses map matching to correct its position. Beacon density follows network density, and is governed by the need to provide sufficiently frequent updates of journey times and map information.

##### 44.4.3.2 Added value information

Information is purchased in a commercial system by buying a smart card which enables the in-vehicle system to decode the received data. This can include parking availability or other added value information. The roadside/vehicle communication infrastructure can also be used for vehicle location, bus information, etc.

Relatively simple in-vehicle satellite terminals are also used for location and messaging, and are well suited to providing guidance information over longer distances.

##### 44.4.3.3 Tolls and road pricing

The combination of a vehicle-to-roadside link and smart-card technology also enables prepayment for the use of roadspace without stopping, e.g. for toll roads or road pricing in a city area.

Identification of non-paying users is achieved by detectors which can locate precisely the position of vehicles in the carriageway, and capturing video frames showing the registration numbers.

##### 44.4.3.4 Intelligent vehicle/highway systems

Intelligent vehicle/highway systems (IVHS) are enabling transport information and control systems to become fully integrated, to include pre-trip planning by phone or teletext, route guidance, hazard warning, passenger information, parking availability, etc.

## 45.1 Railway electrification

The benefits of using electrified lines for heavy traffic loadings are established and many countries now operate electric trains. About 180 000 route kilometres are electrified, with a variety of systems. The USSR contains about one-third of this total. Electric transmission is standard for high powered diesel locomotives.

### 45.1.1 Supply

Electrified-line systems fall into two broad divisions: (1) a.c. systems and (2) d.c. systems.

For city and suburban services, d.c. is most common; for main-line services there are many examples of both a.c. and d.c. systems. The use of a.c. has developed mainly in Europe and has become the standard for new schemes. In countries where the electrification of railways took place in the period 1920–1940, d.c. systems predominate and extensions maintain compatibility. For new high-power schemes, 25 or 50 kV a.c. is used for the distribution of power and sometimes as the voltage delivered to the locomotive. For lower power schemes such as new suburban lines, 25 kV a.c. is the usual voltage.

#### 45.1.1.1 A.c. systems

A.c. systems can be divided into (1) single-phase low-frequency (16 $\frac{2}{3}$  and 25 Hz) and (2) single-phase industrial frequency (50 or 60 Hz). Early three-phase systems have been replaced, although some special vehicles use three-phase collection.

*Single-phase low frequency* This system is widely used in Europe at 16 $\frac{2}{3}$  Hz and to a limited extent in the USA at 25 Hz. The low frequency was chosen to allow commutator motors to be used directly, with simple voltage control of power. Supply is taken from an overhead conductor at voltages up to 16 kV, with the rails used for return.

Figure 45.1 shows a typical power control circuit for a two-motor equipment. The supply is taken from the overhead line through a circuit-breaker to the primary of a step-down transformer, the secondary of which is tapped for low-voltage feed to the traction motors. Motor voltages of a few hundred volts are typical.

*Single-phase industrial frequency* The advantage here is the use of main national grid systems as the power source,

Figure 45.1 Main-circuit diagram for two-motor multiple-unit equipment with single-phase series motors

instead of special low-frequency generation or conversion stations. Pioneering work was done by the French in 1951, with several experimental locomotives subsequently being built. Although 50 Hz commutator motors were feasible, the use of d.c. motors from a rectified supply was preferred. Power control is either by control of the a.c. voltage prior to full-wave rectification, using a tap-changer, or control of the d.c. voltage by phase-angle control of a thyristor bridge. British Railways adopted the 25 kV, 50 Hz system in 1956; an early traction-control circuit in which a tap-changed voltage was used to buck or boost a fixed voltage in the feed to the rectifier is shown in Figure 45.2.

Industrial frequency is now used in many countries, with about 20 000 route kilometres in operation. Voltages of 50 kV are used, in some cases with locomotive equipment rated for this voltage, in other cases being used for feeding autotransformers to deliver 25 kV to the train. In the UK, 25 kV has been used for all schemes, but the Channel Tunnel route to London will use 50 kV with autotransformers. Figure 45.3 shows the principle of autotransformer feeding with these transformers connected between catenary, rail and the auxiliary feeder which is at  $-25$  kV. Current is forced to be equal in the two windings of these transformers and the 200 A train load is provided by addition of the components shown. The supply transformer is then feeding 100 A at 50 kV.

#### 45.1.1.2 D.c. systems

Systems operating at 600–1000 V are used extensively for urban and suburban electrification, usually with one live insulated rail and running rail return. Some four-rail systems exist, with positive and negative insulated electrical supply rails. Systems working at more than 1000 V use overhead catenary-supported conductors; typical voltages are 1500 and 3000 V. For heavily trafficked routes, 12 000 V has been considered.

D.c. motors are customary, although the trend is now towards the use of three-phase induction motors, driven from semiconductor inverters. The use of d.c. will reduce problems of electromagnetic compatibility, since voltages are not induced in track-side conductors. High power is more difficult to provide in d.c. systems than in a.c. systems since the voltage rating of d.c. train equipment cannot approach the 50 kV of the a.c. train. Currents are therefore high, requiring the use of heavy overhead conductors and closely spaced substations. With d.c. lines there are also possible problems of corrosion due to leakage currents.

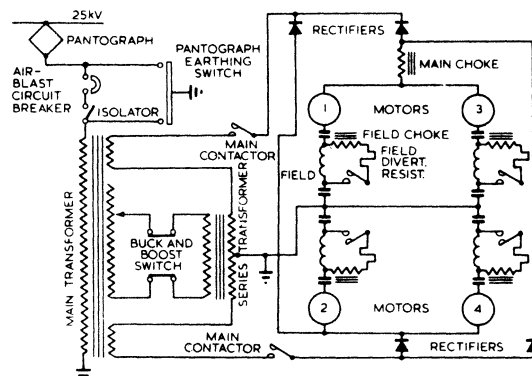

Figure 45.2 Main-circuit diagram for a 25 kV locomotive

Figure 45.3 Current distribution in an autotransformer system for 200 A train load

### 45.1.2 Fixed equipment

Provision of the live conductor for carrying power to the trains is complex and expensive, probably costing as much as the trains which will be used.

#### 45.1.2.1 D.c. conductor rail

The d.c. conductor rail is typically a flat-bottomed cast iron (99.75% Fe) rail of 50–75 kg/m mounted on porcelain insulators at the side of, and spaced about 40 cm from, one of the running rails. The negative return is via the running rails unless (as on London Underground lines) circumstances require an insulated return rail, usually mounted on insulators between the two track rails. A 45 kg/m rail has a resistance of about  $20 \mu\Omega/\text{m}$ .

A composite conductor rail is available with an aluminium body and a stainless steel contact surface. This has the advantages of reduced electrical resistance (typically half) and mass, but at a higher cost. This may be recouped if the substations can be placed further apart for the same voltage drop. Such rail is used on the Botley to Fareham line of British Railways, on the Docklands Light Railway, London (under-side contact), and the Singapore Mass Transit.

#### 45.1.2.2 D.c. overhead conductor

A hard-drawn copper contact wire is supported above the track by a catenary and dropper wires, in such a way that the contact wire sags by a small amount in mid-span. This sag results in an approximately level path for the pantograph at speed. On heavily loaded 1500 V lines, a twin contact wire may be used.

To maintain the wire tension in varying weather conditions, the catenary and contact wires are anchored via insulators to a structure at the mid-point of the wire length and are then stretched by weights at each outer end. The longitudinal force in catenary and contact wire is about 10 kN. The lateral position of the contact wire alternates from side to side of the track centre line, traversing the active width of the pantograph collector strip during running to equalise the wear of the contact materials.

#### 45.1.2.3 Feeder stations (d.c.)

Multipulse rectification is used with star/delta transformer connections and the basic ripple frequency on the d.c. output

is 6 or 12 times the a.c. frequency. Mercury rectifiers are still in service, but new stations use silicon rectifiers. The d.c. rail (or overhead conductor) is connected as a continuous circuit, energised at each feeder station.

#### 45.1.2.4 A.c. overhead conductor

This is similar to the d.c. system. For high-speed operation, a compound arrangement is used with an intermediate catenary. In another design, a partial second catenary some metres long is placed at the support, to reduce the change of mechanical impedance at the contact point. The tension may have to be increased for high-speed use and the Deutsches Bundesbahn use 15 kN for their 250 km/h design (70 mm<sup>2</sup> catenary and 120 mm<sup>2</sup> contact wires).

The Mark III design used by British Railways has a catenary of five strands of aluminium each 3.95 mm diameter with two equal strands of steel to give strength. This has an equivalent copper area of 42 mm<sup>2</sup>. A copper contact wire of 107 mm<sup>2</sup> is provided. Where overhead conductors are provided to give a preferential path for return current, these have 10 strands of aluminium, each 4.22 mm in diameter.

A consideration is the avoidance of conductor clashing in the event of short circuit. This places a minimum value on the vertical separation between the catenary and contact wires.

Where vertical space is at a premium such as in tunnels, a solid bar can be used instead of a contact wire. Such an arrangement can be used at speeds up to 140 km/h.

#### 45.1.2.5 Feeder stations (a.c.)

The 16 $\frac{2}{3}$  and 25 Hz systems use frequency converter stations at the points of connection to the national electrical network. Static frequency converters using thyristors are now in service at ratings of several megavolt-amperes, displacing the earlier synchronous converters.

Each feeder station at 25 kV supplies about 50 km of route and, to distribute the single-phase load on the main electrical network, different phases are used at succeeding feeder stations. The mid-point between feeders consists of an insulating neutral section through which the trains coast at zero power.

A wide spacing between feeder stations is a particular advantage in countries which do not have an extensive

industrial frequency network. In extreme cases, the electrical supply for the railway has to be taken along the railway route as a three-phase high-voltage system, sometimes using structures common with those which support the overhead contact wire. One alternative feeding method is to use a 25 kV supply from overhead wire to rail, feeding this through autotransformers fed from a 50 kV longitudinal feeder.

The traction current passing through the locomotive transformer returns to the feeder station via the rails. If no special arrangements are made, the current will enter the earth as well as the rails. This current distribution can induce voltages in parallel electrical conductors such as communication cables. These voltages can reach dangerous values and it is customary to provide a return conductor in parallel with the rails to reduce induction. A further improvement is obtained if current transformers are connected in the energised and in the return conductors, forcing the current into the latter and removing the current from the track rails and earth.

The feeder station includes protection switchgear to remove the supply in the event of a short circuit. Vacuum circuit-breakers are used, giving a small switch which can be mounted on a steel mast as part of the overhead construction. Motorised or hand-operated isolators are provided to ensure safety during maintenance work.

### 45.1.3 Power collection

#### 45.1.3.1 D.c. shoe

The collector shoes are of cast iron, and adequate contact between shoe and rail is effected by the mass of the shoe (10–25 kg). For high-speed running a spring-loaded shoe may be used with a contact force of about 300 N.

The use of an upwards-facing contact surface on the rail permits the use of a simple gravity shoe but the surface is vulnerable to contamination and ice formation. Alternative systems use side contact or bottom contact, with spring-loaded shoes.

#### 45.1.3.2 Current collectors (overhead)

A mechanism is required to maintain a current collector in contact with the overhead system. This, normally a pantograph, can be of several forms: a typical version comprises a folded arm which is raised by an air cylinder, carrying a contact head on separate springs. The collector material which slides along the overhead conductor can be of various materials, but metallised carbon is used in the UK. The pantograph frame ensures that the head moves on an approximately vertical path and maintains a constant contact force of about 90 N between head and conductor.

### 45.1.4 Power control

#### 45.1.4.1 A.c. supply to train

*Transformer design features for traction* The prime objectives in transformer design are low mass and high reliability. A modern 1.5 MVA naturally cooled transformer weighs about 3100 kg. A 7.7 MVA unit weighs about 8200 kg.

*Tap-changer* Older designs used mechanical switches to change the taps on a transformer, this stepped voltage being fed to rectifiers and then to the d.c. motors. On

16 $\frac{2}{3}$  Hz the traction motors are capable of working with the a.c. voltage source.

*Thyristor phase angle* Recent designs use thyristors to regulate the voltage. Figure 45.4 shows the basic elements of the armature power control circuit of a phase-angle-controlled locomotive. The output winding of the transformer is divided into a number of parts (usually two but more can be used), which feed asymmetrically controlled thyristor/diode bridges. Each bridge is sequentially advanced to full conduction as increased power is required.

Thyristor current normally extinguishes by natural commutation as the voltage reverses. Figure 45.5(a) shows the voltage and current waveforms for partial conduction of a single bridge; Figure 45.5(b) shows full conduction. The latter shape is that which applies for tap-changer/diode circuits.

The power factor can be improved if the current is forcibly reduced to zero during the half-cycle, a system known as sector control. The drawback is an increase in harmonic content. Figure 45.6(a) shows part power and Figure 45.6(b) full power for a single sector-controlled bridge.

An improved harmonic performance is available if the firing angles of both bridges are controlled simultaneously, with different angles for each bridge. This can reduce the selected harmonic content of the primary current.

Figure 45.4 Two sequential half-controlled bridges

Figure 45.5 Voltage and current waveforms of a phase-angle-controlled bridge: (a) partial power; (b) full power

**Figure 45.6** Voltage and current waveforms of a sector-controlled thyristor bridge: (a) partial power; (b) full power

The use of several secondary windings with sequential control can improve the harmonic content and power factor, but at the expense of weight and cost.

The fields of the traction motors are supplied from a separate thyristor bridge, with arrangements to link the armature and field-control circuits to maintain a satisfactory operating balance between currents in the motor.

**Gate turn off** The advent of the power gate turn off (g.t.o.) thyristor has changed power circuits in a dramatic way. As well as assisting the design of inverters it has allowed the use of power conditioning of the single-phase input in novel ways. Individual g.t.o.s of 4000 V and 2500 V are available, allowing single device per arm circuits to be built for traction ratings.

**Four-quadrant chopper** This circuit, shown in *Figure 45.7*, converts single-phase a.c. into d.c. (or vice versa) with a high power factor and low harmonic content. The essential process is the creation of energy in the inductor  $L$  and transfer of this energy to the link capacitor  $C$ . The g.t.o. thyristors  $T1$  to  $T4$  are switched to provide three voltages across the inductor; either ( $V$  a.c.) or ( $V$  a.c. +  $V$  d.c.) or ( $V$  a.c. -  $V$  d.c.). For positive a.c. current, the ( $V$  a.c.) condition is provided via ( $T2 + D4$ ) or ( $T3 + D1$ ), ( $V$  a.c. +  $V$  d.c.) via ( $T1 + T3$ ), and ( $V$  a.c. -  $V$  d.c.) via ( $D1 + D4$ ).

**Figure 45.7** Four-quadrant chopper circuit

Other circuit paths are switched to cope with negative a.c. current. The four-quadrant chopper circuit can operate in all four quadrants of the voltage/current vector diagram and permits inversion from d.c. to a.c. In traction use the circuit is usually controlled to give a constant d.c. link voltage. Switching operations take place at 300–500 Hz and pairs of four-quadrant circuits can be interleaved to give a.c.-side harmonics at 600 or 1000 Hz. On/off control can be regulated to give a unity power factor fundamental current with no harmonics below switching frequency. The switching produces an output component at twice the supply frequency and the filter LF and CF is provided to absorb this current.

Although using more components than phase-angle control and requiring a complex firing control, the benefits of unity power factor, low harmonic content, and simple regeneration make this the preferred control circuit for single-phase traction.

*Figure 45.8(a)* shows part power and *Figure 45.8(b)* full power voltage and current waveforms for a four-quadrant chopper circuit. The in-phase nature of the current is apparent, as is the low harmonic content.

**Three-phase inverter** Early inverters required the use of many components and were complex, heavy and subject to failure. Developments in controlled semiconductors and

**Figure 45.8** Voltage and current waveforms of a four-quadrant chopper circuit: (a) partial power; (b) full power

drawn from the traction supply. A fixed frequency also avoids the generation of current at track circuit frequency.

This form of control avoids the energy losses associated with rheostatic control and is particularly valuable where frequent starting is required. It is therefore used widely for urban rapid-transit systems. By reconnecting the elements of the circuit it can use the motor as a generator and convert the mechanical energy of the train during braking into electrical energy and return it to the traction supply. If the supply is not receptive, braking rheostats on the vehicle can be used.

Recent equipments have used gate turn-off thyristors which avoid the need to provide a separate thyristor-switched turnoff circuit. The chopping frequency can be varied, usually in multiple steps, to allow the wide range of output voltage to be provided. Starting is at low frequency since, at high frequency, the minimum on-time of the thyristor would deliver too high a voltage to the motor.

*Inverter* As with a.c. supply, inverters are used for power control. A simple inductor/capacitor input filter is used to isolate the inverter from transients on the power supply and to prevent switching frequency currents from flowing from the inverter into the supply.

#### 45.1.4.3 Operation of multiple unit trains, train lines

Operation of several power units from one driving cab can be provided by the use of a multi-core cable which runs the length of the train. Known systems use 27 or 36 cores to control the essential functions and return indications of response.

#### 45.1.4.4 Train line multiplex for locomotive push or pull

Where a train is to be driven from both ends but train lines have not been installed, or are expensive to provide in new vehicles, power control can be achieved using two wires only. A series of coded signals can be sent to intelligent decoders, using techniques such as time division multiplex. Actuators can be addressed individually and sent binary messages which give the necessary commands. Frequency shift keying, typically at 90/120 kHz can be used for binary codes.

#### 45.1.4.5 Driving cab

Where possible, it is desirable to use standard cab layouts for all forms and ratings of traction. Power and brake handles should be in similar places and the flexibility with which electric controls can be positioned is then an advantage.

Display of information to the driver is essential for safe and reliable operation of the train. Unambiguous displays with good lighting are required, whilst ensuring that the driver is not distracted from outside signals. Train status can be displayed on touch-sensitive screens, with selectable menus for different functions.

The increasing use of track-based signalling systems, which deliver permitted speed values to the cab, are reducing the need to observe track-side signals. They demand, however, an increase in the amount of information which has to be presented to the driver and the ergonomic design of cabs is receiving increased attention.

Closed-circuit television with visual display units can be used to monitor the surroundings, such as passenger behaviour on platforms.

### 45.1.5 Drives

The mechanical means by which the drive is taken from the motor to the axle are worthy of mention since they have

important implications for the type of motor which can be used and the environment in which the motor has to operate. A simple drive places half of the motor mass on the axle, with high consequential mechanical loading on the motor. Complex drives can isolate the motor from track stresses.

*Axle-hung geared motor* The motor is suspended partly by bearings around the driving axle and partly by a bracket resting on the bogie frame. The motor output is taken to the driving axle via a single reduction gear. This is a simple form of construction but the non-spring-borne part of the motor mass results in increased dynamic loads on the track. If high-speed motors are used an idler gear can be interposed, or a double reduction train used.

*Axle-hung direct drive* The axle can form a driven part of the motor with the electrical armature placed inside (held through the axle bearings) or outside the axle. In one version, a three-phase induction motor is formed from a wound stator held within a large-diameter tubular axle, the cage winding of the motor being fixed to the inner surface of the axle tube.

*Frame-mounted geared motor* For express locomotives and for other cases in which riding qualities are important, drives have been devised to reduce the non-spring-borne mass, to raise the mass centre and to allow for relative movement between frame-borne and axle-borne parts.

*Spring drive* This consists of a hollow shaft surrounding the driving axle and having sufficient clearance therefrom to permit the necessary relative movement between the spring-borne quill and the axle. The quill carries the gear-wheel (or a gearwheel at each end) engaging with a pinion on the motor shaft. A twin- or double-armature motor is frequently employed, and to secure flexibility the pinions may be spring cushioned. The chief feature of the drive is the method of connecting the quill to the driving axle, which is accomplished by an arrangement of circumferential springs acting between a spider on the quill and a special spoke arrangement on the driving wheel.

*Link drive* To avoid the use of springs, forms of quill drive using links (such as the Buchli drive) have been designed. The locomotive frames are within the wheel space and the motor shaft extends over the frame to a pinion engaging with a gearwheel carried in a frame-mounted bearing. The gearwheel is arranged nearly concentric with the driving wheel and outside it; the connection between the two is made by an ingenious gear-link arrangement working on to pins fixed to the driving wheel.

*Flexible-disc drive* Here the motor is mounted on the bogie frame. The armature shaft is hollow and the drive is taken through a flexible disc coupling at one end by means of a shaft passing through the armature and connecting through another flexible disc to the pinion which is carried in bearings in the gearcase.

*Alsthom drive* The drive to the wheels is by means of a hollow quill shaft and flexible links, using a 'dancing member' and rubber-bushed bearings in the links. The quill is carried in the motor frame by large diameter taper roller bearings.

*Longitudinal monomotor* The motor is arranged along the longitudinal axis of the bogie frame, driving both axles from gear outputs at both ends of the motor shaft. Bevel gears are provided on each axle, with an intermediate flexible coupling. This is used on the GEC drives for the

London Docklands light railway, with flexible couplings to allow angular movement of the axles.

***Bogie frame direct*** The motor is supported from the bogie frame, with a hollow output shaft. This shaft has a sufficient internal clear diameter to accommodate the axle and the relative axle to bogie movements. Drive is taken to both the wheel discs via links. An example of this arrangement is the 650 kW, 600 rev/min induction motor drive of the Skoda prototype 85 EO locomotive.

***Bogie frame monomotor*** A large single motor is mounted on the bogie frame, occupying part of the body space. Drive to the axles is via gear trains. This couples the axles together for traction purposes. It gives a low yaw inertia to the bogie. French National Railways are the main users of this system.

***Body mounted motors*** Where the bogie design has to meet special targets, for example giving high speed with low track loading, the motor can be attached to the body of the vehicle. This requires a drive which can tolerate the substantial vertical and lateral relative movements between body and axle. The motor can be arranged with the drive shaft parallel to, or at right angles to, the axle. In the former case the output can be taken back across the vehicle; in the latter a splined cardan shaft can be used with universal end couplings, to drive via a bevel gear box.

***Individual wheel drives*** Suspension designs have been reviewed and separate wheels, not linked via common axles, are used for special cases. The Italian AVRIL train uses a pair of 200 kW motors mounted longitudinally side by side on the body, to drive two wheels on one bogie via a cardan and bevel gear transmission. Each vehicle has two pairs of motors.

#### 45.1.6 Train resistance—motor inertia

When calculating train resistance for run timings, note that the inertia of the motors is to be added to that of the other rotating parts, and that the windage losses of the motors may be significant.

#### 45.1.7 Electric braking

The ability to use motors for braking allows a reduction in brake wear and offers the possibility of converting brake energy into useful traction energy for use by other vehicles. Electric braking has to be blended with the mechanical braking system of the train and the mechanical brake must be arranged to take over the full braking duty if the electrical mode fails.

##### 45.1.7.1 Regenerative braking

The braking of heavy trains on long down gradients is materially facilitated by the use of regenerative braking, whereby some of the mechanical energy released by the train in its downward progress can be reconverted into electrical energy and returned to the supply system. For this purpose it must be possible to reconnect the traction motors as generators and control the speed by the braking torque developed. Regeneration is possible with any form of electric traction at the expense of additional weight, cost and complication. Regeneration has been most successfully employed on locomotives which have to negotiate heavy grades. Regenerative braking is also feasible in heavily loaded urban railways. If the railway system is not receptive (detected typically by a rise of voltage above a given limit), the excess energy can

either be returned to the national electrical supply or dissipated in rheostats at the railway substations. Regenerative braking can give significant reduction in overall energy consumption on urban railways, and typical figures of 15–20% are achieved on densely loaded systems. Cost savings due to reduced brake wear can be equal to energy savings.

##### 45.1.7.2 Rheostatic braking

An alternative form of electric braking, referred to as rheostatic or electrodynamic braking, is available for electric locomotives and is particularly useful for a.c. locomotives, which cannot be designed for regenerative braking as readily as those operated on d.c. systems. With this type of braking, the energy generated by the motors is dissipated in resistors. Control is usually exercised by separately exciting the motor fields, but some systems use self-excitation of the motors with main resistance switching. Owing to the large amount of energy which may have to be dissipated for considerable periods if descending a steep incline, the braking resistor is usually forced-air cooled, and special types of strip resistor units have been developed for this purpose. Where substantial rheostatic braking is required, the roof of the vehicle can sometimes be used to accommodate the rheostats.

##### 45.1.7.3 Braking using the rail

Use of the rail for braking has attractions since the thermal mass is large and new rail enters the brake zone as the train proceeds. Care needs to be taken if frequent braking takes place on the same rail since thermal stresses may become excessive, increasing the tendency of the track to buckle.

***Eddy on rail*** Non-contact braking can be provided by the use of an eddy current brake acting on the rail head. A multipole array is suspended close to the rail head and a 2 m long device, with a 7 mm air gap, has developed a brake force of 14 kN at 250 km/h. The excitation power was 42 kW.

***Contact on rail*** Alternatively, magnets can be arranged to make contact with the rail head when energised. Brake force depends on the coefficient of friction and forces of 5–15 kN have been found from a 2 m long unit. Power consumption is about 2 kW. Permanent magnet (neodymium) excitation is also used.

Both these methods involve substantial vertical forces.

##### 45.1.7.4 Electric actuator for mechanical brakes, motor/screw

Although brakes are normally operated by air cylinders, a motor-driven screw can be used to apply and release the brakes. This gives a substantial reduction in mass by removing air pipes and reservoirs.

#### 45.1.8 Traction vehicles

##### 45.1.8.1 D.c. locomotives

On d.c. locomotives there is almost invariably an even number of traction motors. With two motors (there are usually at least four) the simple well-known series/parallel control can be used.

In this, the motors are first connected in series with starting rheostats across the contact line and rails; the rheostats are then cut out in steps, keeping roughly constant current, until the motors are running in full series; next the motors are rearranged in parallel, again with rheostats; the rheostats are cut out in steps, leaving the motors in full parallel. Some

stages of field weakening are generally included. The power input remains roughly constant during the series notching, then jumps to twice this value during the parallel notching. With a four-motor equipment, a series/series-parallel/parallel connection can be used, giving three economical speeds (i.e. running without resistance) unless the line voltage is too high to be applied direct to a motor. In modern locomotives, chopper control of motor power is used and some locomotives have three-phase inverter/motor systems.

Italian Railways use high power 3000 V locomotives and the E 632 uses a three-bogie design to provide six driven axles. Intended for passenger service, with a top speed of 160 km/h, it weighs 105 t, is 17.8 m long, 4.3 m high and 3 m wide. Three large motors, each weighing 5400 kg and of 2000 V, 1635 kW, 1700 rev/min maximum rating, are frame mounted and drive two axles each via link drives.

Power control is by d.c. chopper, with the basic chopping frequency of 390 Hz converted to 2340 Hz at the supply by interleaving the six choppers. Harmonic current taken from the supply does not exceed 0.3 A up to 1300 Hz.

The main circuit contactors performing the functions of motor grouping, field weakening, and cutting out rheostats are operated either electromagnetically (e.g. by solenoid) or electropneumatically (electrically controlled compressed air cylinders); further, they may be grouped together and interlocked by a camshaft, or separated and individually controlled.

When a locomotive is fed from a third rail system, the inevitable gaps in the conductor rail at points and crossings (up to 150 m) cause momentary interruptions to the supply, resulting in snatching and surging of the vehicles, particularly with goods trains. This difficulty has been overcome by the Southern Region of British Rail, which has put into service 1100 kW, 600 V d.c. locomotives using a booster motor-generator in the traction motor circuit; a flywheel on the motor-generator set provides sufficient stored energy to enable the locomotive to run over a gap without perceptible reduction in torque.

Proper distribution of the weight of the apparatus in the locomotive body is an important design feature and strongly affects running qualities.

#### 45.1.8.2 A.c. locomotives

**Low frequency** Systems operating at 16 $\frac{2}{3}$  or 25 Hz normally use one-phase commutator motors. These require low armature voltages to achieve good efficiency and high power factor. The motors are generally connected in parallel and, except for smaller locomotives, primary tap-changing on the main transformer is used to provide a variable voltage supply to the motors. With this type of control, each accelerating notch is an economical running point. This is in contrast to the d.c. locomotive, which cannot run continuously on the resistance starting notches. To avoid jolts and momentary short circuits, preventive coils connected across successive tappings are used. Various elaborations of the simple transformer tapping system have been devised to reduce the number of tappings without reducing the number of available motor voltages. Thus, by use of a small auxiliary transformer a tapping voltage can be increased or reduced by a required amount, so that six tappings will give 18 running voltages.

**Industrial frequency** D.c. series motors are fed through a rectifier (or controlled rectifier) which is, in turn, supplied by variable voltage from a tap-changer (or fixed voltage) on the main transformer. Semiconductor rectifiers are normally

used and give reliable service when suitable protection is provided against the voltage transients which occur due to switching and other causes. Primary protection is provided by an air-blast circuit-breaker mounted on the roof, and in the case of solid state rectifiers, it is usual to protect each string of rectifiers by a fuse. A smoothing inductor is incorporated in the rectifier circuit in order to limit the ripple in the d.c. supply to the motors.

*Figure 45.11* shows the layout of a tap-changer control a.c. locomotive. Modern locomotives for 160 km/h have similar layouts but for higher speeds the motors are normally body-mounted.

A specially prepared short train of French Railways stock (two traction vehicles and three coaches of the TGV-A) attained a speed of 515 km/h in May 1990.

#### 45.1.8.3 Multiple unit trains

For suburban and stopping services, passenger coaches are equipped with traction apparatus placed below the floor. This leaves the body free for passengers. Both d.c. and a.c. traction supplies are used, with the 25 kV cable passing sometimes vertically through the passenger compartment from roof to transformer. Rheostat, chopper d.c. and inverter drives are used with d.c. supply and tap-changer/rectifier, controlled phase angle and inverter drives with a.c. supply. Power ratings of up to 400 kW per coach are used. These trains form the greater number of electric traction vehicles on railways.

#### 45.1.9 Battery locomotives

These are still built and recent examples are those for the Hong Kong Mass Transit Corporation. They can operate from the 1500 V d.c. overhead or from the 750 V battery. Two 140 kW motors are installed, with three-thyristor resonant chopper control. The battery capacity is 360 A-h at the 5 h rate. Such locomotives are valuable for night-time use when the power supply is switched off for maintenance, and for shunting duties in yards which can then be left without overhead conductors.

#### 45.1.10 Underground railways

In city centres where a high-capacity transport system is required but where surface routes are not available, railways can be built underground to provide a rapid passenger transport. The cost of tunnelling is very high and this method is only economic for large concentrated passenger flows. The electrical supply is normally by third-rail system at about 750 V d.c.; but where tunnelling costs permit, overhead electrification at higher voltages is provided. Underground railways use the same range of electrical propulsion and control techniques as on surface railways. The acceleration of underground trains is rapid and the separation between stations is small, perhaps 800 m. Under these conditions, if rheostatic camshaft control is used, the starting sequence may be completed before the train leaves the station. Subsequent running is on the natural characteristic of the motors, with weak-field operation to extend the speed range.

In France some underground lines use rubber tyres for propulsion and guidance, running on concrete tracks. This provides high acceleration and braking, contributing to passenger capacity. The rubber tyres have a higher energy loss than steel wheels, and additional ventilation may be necessary if a line is converted to rubber-tired operation.

**Figure 45.11** British Rail 2500 kW, 25 kV a.c. electric locomotive: A, main transformer; B, tap-changer; C, rectifier; D, smoothing inductors; E, control equipment; F, low-voltage fuses; G, fault indicator; H, main compressor; J, exhausters; K, auxiliary compressor; L, high-voltage compartment door; M, transformer coolers; N, hole storage capacitor; O, motor contactors; P, braking exciters; Q, braking resistors; R, rectifier coolers; S, motor coolers; T, auxiliary transformer; U, battery charger; V, battery; W, train heating panel; X, field divert resistor; Y, main reservoir; Z, tap-change inductor

## 45.2 Diesel-electric traction

Petrol and diesel engines have been used for traction purposes, both road and rail, for a number of years, but the extensive application of diesel-electric locomotives to railway service has only occurred since about 1935.

### 45.2.1 Locomotives

Diesel-electric locomotives may be divided into two main groups: main line and shunting. Railcars form a third group which is quite small, and in which, on the lighter cars which predominate, mechanical or hydraulic drive is more often employed.

Main-line locomotives may again be subdivided: the smaller units ranging from 450 to 750 kW, used for mixed traffic duty; and the larger units ranging from 1000 to 4000 kW for main-line service. The larger locomotives are usually arranged for multiple-unit operation and several units can be used together to haul a large train. The units are sometimes distributed throughout the train to reduce drawbar stresses and braking transients, and radio control is sometimes used to give balanced power distribution.

Diesel-electric shunting locomotives have been used for a number of years on British Rail and are mostly in the 250–350 kW range and weigh about 50 t.

### 45.2.2 Design

The diesel engine is primarily a constant-speed, constant-power unit, and it is necessary to convert this to a

variable speed, constant power at the wheels of the locomotive. The characteristic of the series d.c. motor is ideal for traction, since it provides a falling torque with increasing speed; by varying the voltage applied to the motor the torque-speed product can be made to match the constant power of the engine. The generator, which becomes in effect a flexible power link between the engine and the motors, provides the necessary current at varying voltage.

The essence of the problem of diesel-electric equipment design is to match the generator output curve to the engine power curve. The typical generator characteristic at constant (maximum) engine speed in *Figure 45.12(a)* is shown by the curve ABCDE.

The voltage-current curve for constant input power at this speed is BGD. Between B and D the two do not match and engine speed falls to give the relation BFD, with loss of power. In a shunting locomotive the speed drop produces output-input balance. Alternatively, the voltage-current characteristic of the generator may be made to follow the curve AGE, but full engine power can then only be developed at G, with loss of tractive effort for other operating conditions (*Figure 45.12(b)*).

For main line locomotives it is desirable that full engine power be maintained over a wide range of train speeds. The diesel engine has an optimum operating zone in which the fuel efficiency is highest. For any desired output power there is therefore an optimum diesel engine rotational speed. The load regulation system normally responds to the setting by the driver of a desired engine speed. The excitation of the generator is then adjusted so that the optimum output power is taken from the diesel engine. If the train load

**Figure 45.12** Diesel-electric characteristics: (a) voltage–current characteristics for: ABCDE, generator at constant maximum speed; BDG, constant generator input power at constant maximum speed; BFD, reduced speed. (b) Performance of 300 kW, 50 ton shunting locomotive (traction 280 kW, auxiliaries 20 kW, two motors with double reduction gearing)

reduces, the generator will run at a high-voltage, low-current condition delivering part power.

### 45.2.3 Electrical equipment

Electrical equipment consists essentially of a main traction generator, one or two auxiliary machines, a number of traction motors and the control equipment necessary for both main and auxiliary circuits. On large main line locomotives the auxiliary supply has to provide for compressors, traction motor blowers, lighting, heating, control and similar requirements. A battery is usually included to provide stand-by power and starting.

#### 45.2.3.1 Generator or alternator

The generator armature is usually coupled direct to the engine crankshaft with a single bearing in the generator end housing. The auxiliary generator may be overhung from the main generator or in some cases driven together with an exciter by belts. Since the generator is a variable-voltage machine, the maximum voltage is arranged so as to obtain the most economical use of materials and the lowest  $I^2R$  losses. The maximum voltage is usually limited to 1000 V and normal operation is around 600 V.

#### 45.2.3.2 Motors

Motors are of series type and are generally similar to those used on d.c. electric trains and locomotives. They are usually built for operation at the full generator voltage but in some cases may be connected permanently two in series. The size of motor is determined largely by the maximum tractive effort required and bears little relation to the power capacity of the diesel engine.

#### 45.2.3.3 Control

The control equipment on a diesel-electric locomotive is concerned mainly with the following functions.

**Engine-speed control** The varying requirements of railway service make it necessary for the engine to have some speed

control so that it can operate when required at reduced speed and power. In its simplest form a hand-operated lever, which alters the governor setting, provides a range of speeds between idling and full speed. No more is required on locomotives of the shunting type.

**Generator-field control** On large locomotives a speed-sensitive device is used to adjust the generator field to match the engine power.

**Motor control** Motors are normally connected in parallel and this provides the simplest arrangement. In certain cases, however, series/parallel control may be necessary to give the required locomotive characteristics and provision must be made for changing over the motor connections. A reverser is required for changing direction of running, and diverter contactors may be provided if the fields have to be shunted to give top-speed running.

**Driver's controls** On a typical shunting locomotive three control levels are provided on each side of the cab so that the driver has alternative driving positions. A time delay in the operation of the dead-man pedal is introduced so that the driver can change over from one operating position to the other without shutting off power. The engine, or master, control is used to start and stop the engine, and provides for engine testing with the locomotive at rest. A reversing lever with an off position determines the direction of movement of the locomotive. Finally, a power controller gives the driver complete control over all locomotive movement. Initial movement of this control lever prepares the power circuits and brings on generator excitation with the engine running at minimum operating speed. Further movement strengthens the generator field and finally brings the engine up to full speed.

The arrangement for main line locomotives is similar, except that a single driving position at each end of the locomotives is provided, with facilities for multiple-unit operation when double heading is required.

#### 45.2.3.4 Starting

The usual method is to start the engine from the battery by motoring the main generator, using a special starting winding. Compressed air starting is occasionally employed, but it involves the use of a compressor for charging the air cylinders. Bendix starters, similar to the type used on motor-car engines and operated from a 24 V battery, are used on some American locomotives. In the case of most shunting locomotives it is usual to make provision for tow starting in an emergency if the battery is too far discharged to motor the generator for normal starting. This involves connecting one or more of the motors so that they act as generators to motor the main generator and thus start the engine. Although emergency starting is seldom required, it is a useful provision, since another locomotive is usually available and starting can be effected with very little delay.

#### 45.2.3.5 Mechanical design

The design of diesel-electric locomotives follows very much the same lines as that of normal electric locomotives; main line locomotives, particularly, use axle-hung motors and bogies which are generally similar.

## 45.3 Systems, EMC and standards

### 45.3.1 Novel systems

#### 45.3.1.1 Magnetic levitation

Research work on high-speed maglev trains has continued for several years but no public service is in operation. Two types have been taken to full-scale tests, one using controlled magnets working in attraction, the other using fixed magnets working in repulsion. Attraction systems such as the TransRapid 07, built in Germany, use a series of steel-cored magnets placed below a laminated suspension rail. The TR07 has a three-phase winding embedded in the track rail and this interacts with the vehicle magnets to provide propulsion and braking. Separate magnets give lateral guidance. The vehicle sits on a T-shaped beam. No sliding contacts are used, the traction power being supplied to the track and the vehicle auxiliaries being powered via induction pick-up from the track.

The MLU 002 of Japan National Railways uses superconducting magnets interacting in repulsion with wound coils fixed to the U-shaped track, to provide lift, guidance and traction/braking. The vehicle has wheels since levitation in repulsion is not available at low speed. No sliding contacts are required.

One maglev system is in public service at Birmingham International Airport, UK, offering a 600m link from airport to railway station. The 6t vehicle uses attraction magnets (which also provide guidance) with linear motor propulsion and braking. Power is supplied via sliding contacts to on-board power control for this 50 km/h vehicle.

An M-Bahn system is in use, in which permanent magnets exert an upwards force greater than the mass of the vehicle, the surplus force being taken on rollers. Other rollers provide guidance and others carry the vehicle across gaps in the magnets. Windings in the track give three-phase synchronous motor drive and braking.

The US Government has launched a maglev Initiative to produce a 480 km/h vehicle using American technology. The first full sized components are due for testing in late 1993.

#### 45.3.1.2 Monorail

Systems using a single beam for the track, termed monorails, are in use. The Alweg design is most common, with rubber tyres used for support and guidance. Power is collected by sliding contact and the support wheels are powered.

### 45.3.2 Coaching stock

Modern passenger coaches use significant amounts of electrical energy. Environmental comfort requires heating and air conditioning, and many other amenities and essential services have to be provided. Power is supplied via train lines from the locomotive or from the local multiple-unit power source. Train-line voltages are typically 1000 V single phase 16 $\frac{2}{3}$  or 50 Hz, or 750 V d.c. On multisystem vehicles, d.c. voltages of 1500 or 3000 V are used. Depending on whether a.c. or d.c. supply is used, a transformer and/or inverter is used to supply those auxiliaries which require a.c. feeds.

**Heating** Resistor heating banks are provided, with thermostat control of air temperature. A coach may have 40 kW installed for this duty.

**Air conditioning and pressure ventilation** Power for the refrigerant compressor is required and an inverter is usually

used to convert the train-line supply to three phase for this motor. A rating of 26 kVA may be required. The fans for air circulation could consume 6 kVA.

**Lighting** Fluorescent lighting is standard, supplied from inverters which produce high-frequency a.c. to reduce mass and avoid flicker effects.

**Toilet wash water and hand dryer** Hot water is required for toilets and a 1.5 kW heater is usual. If a hot air hand dryer is installed, the electrical load may be 4 kW.

**Shavers, public address, telephone and audio visual service** A number of small amenity loads may need to be supplied.

**Battery and battery charger** To ensure lighting in emergencies and sustain ventilation under fault conditions, a vehicle battery is fitted. This is typically 24 V, 440 A-h, and requires a battery charger. This charger is usually fed from a high voltage train line.

**Power doors** It is advantageous for train operation if doors are power operated. Electric or air motors can be used for doors. Audible warning of door closure should be provided.

**Passenger information** Display panels may be provided within the vehicle to announce the next station and provide route information. Train services can be publicised. Liquid crystal displays (l.c.d.), light-emitting diodes or visual-display units are available options. External displays of route information can be generated by two-state dot arrays of electro-mechanical discs which have black and coloured sides.

**Servicing information** Vehicle status can be monitored by transducers and fault condition data can be stored in a micro-processor memory, for interrogation by maintenance staff. An l.c.d. can be used to indicate areas requiring attention.

### 45.3.3 Electromagnetic compatibility

Electrified railways must be bonded to earth so that dangerous voltages are not produced during short-circuit conditions. The spacing and type of bond depends on the rating of the system and the distance from the feeding point.

Traction currents must not induce dangerous voltages in nearby conductors and conductor geometries are arranged as required. Leakage of d.c. current can cause corrosion to pipes and cables and bonding must be adequate to keep voltages below safe levels. In practice, when the railway has designed its systems to prevent damage to itself, nearby apparatus is normally safe. Regular inspection of safety measures is required.

Sliding current collection of power normally involves the generation of some radiofrequency noise and filters may have to be added if disturbance is caused.

### 45.3.4 System simulation

With the advent of fast computers, simulation of train movements on actual track layouts is feasible and can be used to study the electrical aspects of introducing a new service or rolling stock. Colour graphics are used to observe train movement and energy use.

### 45.3.5 Standards

Although railways tend to use their own standards and specifications when purchasing equipment, a number of standards exist. These include those listed below.

45.3.5.1 *British standards*

BS 173	Specification of rotating electric machines for traction
BS 2618	Electric traction equipment
BS 3403	Tachometer and speedometer apparatus
BS 4999	Rotating machines

*Railway Industry Association* 6 Buckingham Gate, London SW1 6JP, UK. Technical Specifications have been prepared in collaboration between railways and manufacturers. These include:

BRB/LUL/RIA 12	Protection of traction electronic equipment from transients in d.c. control systems
BRB/LUL/RIA 13	General specification for electrical equipment used on traction and rolling stock
BRB/LUL/RIA 18	Interference testing for electronic equipment used on traction and rolling stock
BRB/LUL/TG 22	Technical guide on e.m.c. for electronic equipment used on traction and rolling stock

45.3.5.2 *International electrotechnical commission*

A number of leaflets have been issued, giving guidance for the design of traction apparatus. These specify limits such as working voltages and permitted harmonic currents.

IEC 77	Rules for electric traction equipment
IEC 165	Rules for testing electric rolling stock
IEC 310	Traction transformers and reactors
IEC 322	Ohmic resistors
IEC 349	Rotating electrical machines
IEC 411	Power converters for electric traction
IEC 494	Pantographs of electric rolling stock
IEC 563	Limiting temperatures of electrical equipment
IEC 571	Electronic equipment on rail vehicles
IEC 631	Characteristics and tests of electrodynamic and electromagnetic braking systems
IEC 638	Criteria for assessing commutation of traction machines
IEC 737	Measures for limiting disturbance of light current installations by electric traction
IEC 801	Immunity to electromagnetic disturbance

## 45.4 Railway signalling and control

The purpose of railway signalling is to control the passage of trains such that they may run at speed by maintaining a safe adequate distance between following trains and safeguarding their movement at junctions. Inherent in any system, therefore, must be the ability to detect the presence of all trains and vehicles and a means to ensure separation between them.

The basis of modern signalling is the electrical track circuit to detect the presence not only of trains but also of single vehicles. A track-circuit equipment must detect the presence of a vehicle presenting a maximum resistance of  $0.5\ \Omega$  between rails, a figure taking account of contact effects due to rusty rail surfaces and other features. There are several forms of track circuit, and their principles are considered first in relation to the simplest d.c. track circuit.

The fundamental philosophy of all signalling systems is that they should *fail safe*, i.e. fail to a more restrictive condition. Solid-state devices are used extensively for supervisory and information purposes, and are being introduced

Figure 45.13 D.c. track circuit

for safety functions such as track circuits, the transmission of vital controls and interlocking.

### 45.4.1 D.c. track circuit

The track circuit (*Figure 45.13*) is formed by a section of the track normally isolated electrically from adjacent sections by insulated rail joints. Ordinary joints within the section are bridged by metallic bonds. Feed-end and relay-end connections are made to the rails close to the insulated joints. The rail resistance is small enough for the rails to be considered as equipotential bus-bars between which is a distributed ballast resistance  $R_B$ . The ballast resistance is the critical variable in the track-circuit performance: it varies from day to day, being low in wet conditions, high in dry and totally frozen conditions. It varies also with the type of track. Modern track is laid on reinforced-concrete sleepers, and it is necessary to ensure that the rail is isolated electrically from the sleeper. The fixings for the rail are metallic and thus the rail has to rest on an insulating pad and the clips holding down the rail are separated from the rail by insulating material. Insulation break down can cause a failure, the source of which is difficult to locate. The type of ballast may be significant. Stone ballast (preferably granite) has good resistivity; but in some areas ash ballast is found, and this can make reliable track-circuit conditions difficult to achieve. Low-resistance ballast conditions occur where the track is adjacent to the sea or is carried through under-sea tunnels. A good track under the worst conditions may have a ballast resistance of  $14\text{--}20\ \Omega$  per 1000 m; but on poor track it may be as low as  $0.5\ \Omega$  per 1000 m.

Track-circuit adjustment must take account of variation in the battery voltage. The cell shown in *Figure 45.13* can be a trickle-charged cell which, if of the lead-acid type, has a voltage range of  $1.8\text{--}2.5\text{ V}$ . If a guaranteed mains supply is available, the battery can be replaced by a transformer and rectifier.

#### 45.4.1.1 Track relay

Standard d.c. track relays have a resistance of  $4\ \Omega$  (although there are many of  $2.25$  or  $9\ \Omega$  in service). The significant characteristics are: (a) *drop-away voltage*, at which the energised contacts 'break', when, after the relay has been energised, the voltage is reduced; and (b) *pick-up voltage*, at which the energised contacts 'make' when, after the relay has been de-energised, the voltage is increased. The drop-away voltage is a minimum of 68% of the pick-up voltage. Associated with these voltages is the train-shunt resistance  $R_S$ : (1) the *drop shunt* is the maximum resistance that produces track-relay drop-away conditions; and (2) the *pick-up shunt* is the minimum resistance such that the relay just picks up.

In practice the pick-up shunt is greater than the drop shunt and as long as this is a practical resistance the track circuit will work. If not, the track circuit will fail to re-energise.

In setting up the track circuit, the regulating resistance is adjusted for maximum battery voltage and maximum ballast

resistance such that with a drop shunt of, say,  $0.5\ \Omega$  the track relay is de-energised. Then it is necessary to check that the track relay will re-energise with minimum battery voltage and minimum ballast resistance. If the pick-up shunt is relatively high, say  $10\ \Omega$ , then the conditions only need to become a little more critical for the track circuit to fail to re-energise. In this case, assuming that no fault exists, the selected length of track circuit is too great. On the other hand, if the pick-up shunt is relatively low under these conditions, increasing the regulating resistance will give economies of power, which is important where primary cells are used, as it gives them longer operating life.

It is normally possible to work track circuits successfully with ballast resistances down to  $2\ \Omega$ . The length of track to which this corresponds depends on the ballast conductivity: on good ballast a length of 1–2 km is typical.

#### 45.4.1.2 Fail-safe conditions

To prove the track clear, the track relay must be energised. It will de-energise if: (a) the power supply fails; (b) a disconnection occurs in the feed-end or relay-end connections, or in the rails (e.g. a rail removed); or (c) a short-circuit occurs on the track. As the de-energised state is taken to mean that a train is present, the fail-safe principle is achieved.

A wrong-side fail condition could occur if the voltage were excessive. The possibility that this condition could occur owing to a voltage from an adjacent track is eliminated where possible by reversing the supply polarity at each pair of insulated rail joints; then, should the joint insulation fail, both track circuits will fail safe. The staggered-polarity principle is applied to pointwork, where the requirements can be complicated.

#### 45.4.1.3 Operation

The d.c. track-circuit system is reliable and economical. In certain circumstances relay timings of successive track circuits may become critical. When the supply voltage is high, the track relay may pick up faster than it drops away (which may take as long as 2 s), and in consequence a short train or single locomotive may be 'lost' for a brief time.

The d.c. track circuit will work satisfactorily in a.c. traction areas. It is necessary to ensure that the track relay is a.c. immune, to guard against false energisation from traction currents. For the same reason it is not possible to use d.c. track circuits in d.c. electrified areas and, hence, a.c. track circuits are used.

### 45.4.2 A.c. track circuit

The track circuit is fed by a transformer which isolates the power supply from the track. The track relay, a double-element device, has a 'local' winding connection to the same supply as the feed-end equipment (normally at 110 V), and a 'control' winding fed through the track circuit. This makes possible reliable operation with less track power.

#### 45.4.2.1 Track relay

The two-position a.c. relay is an induction device, which is in principle the same as an induction-disc wattmeter. An aluminium vane lies in the magnetic fields produced by two electromagnets (Figure 45.14); one, the 'local' magnet (Q), is energised at voltage  $V_q$  from the main transformer, and the other, the 'control' magnet (R), at voltage  $V_r$  from the track circuit. The torque is proportional to  $V_q V_r \sin \theta$ , where  $\theta$  is the angle between the voltage phasors. If  $V_q$  is large, a

Figure 45.14 Principle of a.c. track relay

relatively small  $V_r$  can ensure operation of the relay, the angle  $\theta$  being adjusted by a variation in the current-limiting devices.

#### 45.4.2.2 Capacitor feed

In a capacitor-fed track circuit a 1:1 isolating transformer feeds the track through a variable capacitor (Figure 45.15). The advantage is that there is little loss in the feed and no path for d.c. traction currents.

#### 45.4.2.3 Impedance bonds

On electrified lines where both rails are used for traction return currents, impedance bonds are used to provide a low-resistance path for the traction current (d.c.) but a high impedance to track-circuit currents (a.c.). A simple bond is shown in Figure 45.16(a): it consists of a few turns, centre-tapped, on a laminated ferromagnetic core. Balanced traction currents give zero effective magnetomotive force (m.m.f.); but unbalance up to 20% is mitigated by the provision of an air gap in the core. The d.c. resistance of an impedance bond may be about  $0.4\ \text{m}\Omega$  and its impedance of the order of  $0.5\ \Omega$  at 50 Hz.

### 45.4.3 Jointless track circuit

In modern rail track designed with continuous welded rail, there are no joints: concrete sleepers and careful installation allow thermal expansion and contraction stresses to be accommodated.

Figure 45.15 Capacitor-fed track circuit

Figure 45.16 Impedance bond and tuned sectionalisation

#### 45.4.3.1 Audio-frequency circuits

One method of achieving electrical separation between adjacent track circuits on jointless track relies upon tuning a short length of track using two series-resonant tuning circuits. The short circuit and rails have inductance that can produce a resonant circuit with a parallel-connected capacitor, as shown in *Figure 45.16(b)*. With this arrangement no power from the source on the left can reach the receiver on the right. If two adjacent track circuits are required, it is possible to tune from both sides as in (c). A tuned length of typically 20 m results with this arrangement. The obvious disadvantage is that vehicles near to the short circuit may not be detected.

One form (*Figure 45.17*) uses a series circuit in resonance at a given frequency. Adjacent track circuits operate at different frequencies, and their limits are achieved as follows. At a frequency  $f_1$ , components  $C_2$  and  $L_6$  are in series resonance, short circuiting  $C_3$  and presenting (ideally) zero impedance across EF, while  $C_1$  is such that the whole circuit is in parallel resonance and of high impedance: thus, the end of track circuit  $f_1$  is defined. At a different frequency  $f_2$  (with  $C_2$  and  $L_6$  now off-resonance and of high impedance),  $C_1$  and  $L_5$  are series resonant short circuiting AB, and  $C_3$  is such that the whole circuit is antiresonant, so defining the limit of track circuit  $f_2$ . The rails contribute inductances  $L_1$  to  $L_4$  to the network. Transmitter and receiver units are connected to the network through the track transformers.

Operating frequencies are a compromise between capacitor size and maximum track circuit length. With one transmitter and one receiver at opposite ends, track circuits between 50 and 1000 m in length can be operated at frequencies in the range 1.5–2.6 kHz. If a track transformer coupled with a transmitter is placed at the centre and a receiver at each end, the length of the track circuit can be doubled. Adjacent track circuits are allocated different frequencies, as are parallel track circuits on multitracked lines.

### 45.4.4 Other forms of track circuit

#### 45.4.4.1 Coded circuits

Coded pulses (on–off or frequency–shift) may be superimposed on track circuits designed for the purpose, and detected by the receivers or by pick-up coils at the front of a train. The system can be used for train control.

#### 45.4.4.2 Impulse circuits

Where wheel contact is bad, as on rusted rails or on gradients and curves where locomotives use sanding to improve adhesion, non-detection can be overcome by using high-voltage pulses detectable by the receiver.

#### 45.4.4.3 Reed circuits

Mechanically coupled reed filters at each end of the track circuit ensure that only the desired frequency is fed to the

Figure 45.17 Jointless track circuits for adjacent sections

track circuit and that the relay responds only to the correct frequency. The range of frequencies used is 360–400 Hz (but avoiding multiples of 50 Hz) allowing the circuit to be suitable for use in areas where both a.c. and d.c. traction are employed. By using different frequencies for successive tracks and for each parallel track on multiple lines, false operation due to failure of insulated rail joints and diverse feed paths through the traction system is avoided.

#### 45.4.4.4 Overlay circuits

In all cases the relay is de-energised in the presence of a train. Sometimes interlocking controls require a train to be detected at a given spot to operate some function. This may be done by providing an ‘overlay’ circuit which energises when a train is present, additional to the normal track circuit. Frequencies in the range 20–40 kHz can be used, but the attenuation is such that detection is possible only for distances up to about 50 m.

### 45.4.5 Other means of vehicle detection

In addition to track circuits, various methods are available to detect the presence of a vehicle. The mechanical action of a wheel flange on the arm of a treadle is used to close electrical contacts and register that a train has passed a particular location. This method is used in association with track circuits as a diverse means of safely operating automatic level crossings. To save track-circuiting long stretches of lightly used line a system of axle counting is used. The passing of a vehicle is detected by the change in magnetic flux around a transducer caused by a vehicle wheel as it passes. When connected to an evaluator unit two such transducers can be used to count axles in and out of a section of line. Besides long stretches of single line, axle counters find use in special circumstances where track circuits are not suited, such as on lines prone to flooding and slab track formations.

### 45.4.6 Multiple-aspect signalling

Colour light signals are used to display a simple and logical set of indications to drivers. The displays are the same by day and night and the lens system is designed to give long-range viewing and good penetration in fog. Two groups of signal exist; main signals which are used for main line and high-speed moves and position light signals designed for controlling shunting and low-speed moves (*Figure 45.18*).

#### 45.4.6.1 Main signals

Main signals are arranged to show four basic indications or aspects:

Red: stop, danger

Yellow: caution, be prepared to stop at next signal

Double yellow: preliminary caution, be prepared to find next signal exhibiting a single yellow light

Green: clear, next signal exhibiting a proceed aspect

These various aspects are used according to the density of traffic and are arranged to form two-, three- or four-aspect systems.

#### 45.4.6.2 Terminology

**Braking distance** The service braking distance is the minimum spacing between the first caution signal that a driver sees and the red aspect to which it refers. From this distance

Figure 45.18 Signals

trains running at their maximum permissible speed can stop by normal service (not emergency) braking before reaching a signal at danger. The distance is derived according to maximum line speed, gradient and deceleration rate of the trains.

**Sighting distance** A driver on approaching a caution signal will act to reduce the speed of his train at a sighting distance from that signal.

**Overlap** It is practice in Britain to provide a short length of line beyond a signal to act as an 'overlap' in the event of a train overrunning a signal at danger. Normally a distance of 183 m is provided at multiple-aspect signals.

**Headway** This is the separation (in time or distance) between successive trains travelling at the same speed such that the following train can maintain speed.

#### 45.4.6.3 Two-aspect signalling

Used on lines with low traffic density the two-aspect system divides the line into sections (Figure 45.19), each of which is protected by a red/green stop signal (B and D). At braking distance to the rear of each stop signal is a yellow/green repeater (A and C) to advise drivers in advance of the state of the stop signal to which it refers. Before a stop signal is

Figure 45.19 Two-aspect signalling

allowed to show clear (B) the line ahead must be clear to the overlap beyond the next stop signal (D). The repeater (A) changes from yellow to green at the same time.

#### 45.4.6.4 Three-aspect signalling

Where greater traffic density is required the line must be divided into smaller sections. A stage is reached where the repeater for one stop signal falls close to the stop signal in rear. The two functions are then combined to give one signal capable of displaying stop, caution and clear (Figure 45.20). Each signal is at least full service braking distance from the next. Signal B changes from red to yellow when the rear of the leading train passes the overlap of signal C. Signal A changes from yellow to green at the same time. The headway can now be defined: if the following train is to run at normal speed it must not approach closer to A than its sighting distance before A clears to green. For a train of length  $L$  running at speed  $V$ , the headway distance  $H$  and time  $T$  are

$$H = S + 2D + O + L \quad \text{and} \quad T = H/V \quad (45.1)$$

where  $S$  is the sighting distance,  $D$  the braking distance and  $O$  the overlap. Three-aspect signalling is usual on lines carrying medium-density traffic and can cope with trains at 5 min intervals.

#### 45.4.6.5 Four-aspect signalling

When a three-aspect system is unable to give adequate headways in an area of dense traffic, a fourth aspect (double yellow) is introduced (Figure 45.21). This allows signals to be placed at half braking distance, a driver being warned initially of a red signal ahead by the double yellow aspect. The headway can now be defined as:

$$H = S + 1\frac{1}{2}D + O + L \quad \text{or} \quad T = H/V \quad (45.2)$$

In practice, a four-aspect system gives around 30% greater capacity than a three-aspect system. As  $D \propto V^2$  approximately, then a train travelling at 0.7 of the maximum line speed requires only one-half of the braking distance afforded by the system, thereby allowing the driver to effectively ignore the double yellow. This means that

$$H = (S + D + O + L) \quad (45.3)$$

and, therefore, greater capacity.

If one lamp of a double yellow fails, it leaves the greater restriction of single yellow, failing safe.

Figure 45.20 Three-aspect signalling

Figure 45.21 Four-aspect signalling

#### 45.4.6.6 Position light signals

These signals are used to control movements into and out of sidings, between running lines and into occupied platforms. The 'stop' indication is given by a red and white light displayed horizontally, the 'proceed' by two white lights inclined at 45°. Where a position light signal is associated with a main signal it is positioned either beneath or to the side of the main aspects. When at 'stop' it displays no indication, the main red performing this function. When showing 'proceed' the two inclined white lights illuminate and the red of the main signal remains lit.

#### 45.4.7 Signalling for junctions

British railway practice is to employ a route style of signalling whereby a driver is informed of the direction in which the route is set ahead. Where speeds are in excess of 64 km/h the routing is given by a junction indicator mounted above the main aspects.

The indicator shows a row of five white lights in the general direction of the route to be taken. Where multiple routes exist, up to six indicator positions are available (*Figure 45.22*). An indicator must be proved alight (at least three lights) before the main signal may show a 'proceed' aspect. The main (highest speed) route is not provided with an indication.

Most diverging junctions have speed restrictions lower than for the main route, and the usual practice is to prevent the junction indicator and signal from clearing until the train has passed the previous signal, thereby enforcing the driver to begin braking. This is known as 'approach release from red'.

In many situations this is over-restrictive and so a system known as 'approach release from yellow' is applied (*Figure 45.23*). In this instance the signal beyond the junction (D) is held at red allowing the junction signal itself to show a single

yellow with junction indicator (C). The signal in rear of the junction signal (B) is then arranged to show flashing single yellow to inform the driver that the junction signal is showing a 'proceed' aspect for the divergence. The driver may then slow his train for the turnout. Once the train has passed the flashing yellow signal, signal D is allowed to show a 'proceed' aspect (provided the line ahead is clear) enabling C to improve to double yellow or green. In four-aspect territory, signal A will be fitted with a flashing double yellow.

In and around stations and other locations where the line speed is 64 km/h or less, letter or number indicators are used to identify the route with the characters formed by a selection of optical fibres lit from a single source.

#### 45.4.8 Coloured light signals

Each aspect is provided with its own lamp and lens unit. A double-lens optical system giving an 8° beam angle is employed. The 212 mm diameter outer lens is of clear glass, and has a downward-deflecting sector for close-up visibility. The 139 mm inner lens is coloured according to the aspect to be displayed. The units are set 279 mm apart in the vertical plane, are provided with hoods to screen off sunlight, and backed by matt black plates to give a dark background.

Double-filament tripole lamps are used rated at 12 V 24/24 W normally operated at 11.5 V to prolong filament life without undue loss of light flux. The main filament (with a guaranteed normal life of 1000 h) is detected by a current-sensing relay which switches the supply to the auxiliary filament if failure of the main is detected. The changeover is indicated to the control centre in order that the lamp can be replaced before complete failure.

A transformer is associated with each lamp, the feed circuit being 110 V a.c. allowing signals to be controlled from a distance. In 25 kV a.c. traction areas this is limited to 200 m to guard against false illumination brought about by induction into the cable from the traction system.

Figure 45.22 Junction indicators

Figure 45.23 Approach release from yellow

#### 45.4.9 Signal-aspect controls

Before a signal is allowed to show a 'proceed' aspect the line ahead must be clear, including the overlap at the next signal and the next signal must be alight. The actual aspect displayed is reliant upon the aspect being shown by the next signal such that the correct sequence is always shown approaching a red signal. Therefore in four-aspect territory the sequence is green, double yellow, yellow, red.

On open track the passage of a train will replace signals to danger behind it and allow them to clear again as it progresses. At least one red indication will protect the train and be preceded by the relevant caution aspects. In areas where pointwork and diverging routes exist the signals are still replaced to danger automatically behind each train but movement of the points and selection of routes is performed by a control centre.

#### 45.4.10 Point operation

In modern power signalling, points are moved by equipment on the ground controlled electrically. There are two forms of operation in widespread use: electric and hydraulic.

##### 45.4.10.1 Electric

The drive machine is a d.c. split-field motor to reduce the possibility of false operation due to electromagnetic interference. The control circuits are preferably four wire.

Control is through a contactor designed to pass a control current up to 10 A at 120 V. There are separate contactor relays for the two operations: when the signalling controls require a point to be moved, then the appropriate contactor is energised first, proving that its complementary contactor is de-energised. The power is then applied to the motor. For passenger train movements it is necessary to ensure both that the point is detected in its correct position and that it is also mechanically locked. The first operation of the point machine is to unbolt this lock, then to move the point switches in the required direction and rebolt the lock. As this is completed, the point machine windings are cut off by special contacts within the machine and a special electrical snubbing circuit is brought into use by another set of contacts to prevent the motor from over-running. Also operated by the point machine contacts is a detection circuit which uses a three-position a.c. relay or two neutral polar relays: this circuit detects the point machine normal or reverse setting, including the detection of the mechanical bolt in its locked position. When the detection is in correspondence with the point machine calling, the point contactor is de-energised.

Normal operation takes about 3 s. A clutch is provided to slip if, owing to poor adjustment or an obstruction, the point machine is unable to make its full travel; and to protect the motor, a timing circuit will disconnect the machine.

#### 45.4.10.2 Hydraulic clamp lock

The purpose of point (switch) mechanisms is to ensure that the switch mates with the stock rail without gap. A positive and definite method is to clamp the two together by an electrically controlled hydraulically operated unit. Each unit has its own electrohydraulic power pack, and control from the hydraulic unit is by means of valves which actuate two pistons, one for movement to the normal and the second for movement to the reverse position. When the movement is completed, the control circuit is de-energised. The locking of the points is achieved by the clamping mechanism, which will only make in its correct position if the switch is properly against its stock rail. Thus, in operation the clamp is unlocked, and the switches are moved and then clamped. The units include detection contacts which operate a detection circuit similar to that for a point machine.

#### 45.4.11 The modern control centre

The control of railway signalling is today brought together into large centres responsible for the supervision of many miles of line over a wide area. The latest of these exploit microprocessor technology to its best advantage. Known as 'integrated electronic control centres' (i.e.c.c.s) they contain not only the means to manually monitor and control the railway system but also features such as automatic route setting and interfaces to adjacent control centres and information systems.

The i.e.c.c. consists basically of a number of processor modules configured on two local area networks. The networks and modules are duplicated for availability. The segregation of the system into separate networks (signalling and information) provides control over the amount of data flowing in the signalling network, in order to ensure quick response times. The response times in the information network are less critical. All of the modules are based on versa module eurocard (VME) bus architecture.

The man-machine interface is provided by the signalman's display system (s.d.s.). One is provided for each

signalman up to a maximum of three per i.e.c.c. Each is housed in a workstation comprising a number of high-resolution graphic monitors, keyboard and trackerball. The graphic monitors depict the relevant control area using a special character set to display the track layout, points, signals, etc. Overview and detail screens are available plus a general-purpose display. Command input lines, output messages and alarms are handled by the general-purpose display which can also show simplified real-time movements on map displays of adjacent workstation or control areas.

Other modules include solid-state interlocking (s.s.i.) (see Section 45.4.12.1), automatic route setting (a.r.s.), timetable processor (t.t.p.), external communication system (e.c.s.), gateway system (g.w.s.), and system monitor (i.s.m.) (Figure 45.24).

The a.r.s. package is designed to set routes automatically in response to the approach of trains based on data available from the timetable processor. Out of sequence and late running are catered for with operating strategies designed to minimise delays and deviation whenever a conflict occurs. The signalman remains in control at all times and may set routes ahead of a.r.s. or restrict its sphere of operation. Certain shunt routes and unscheduled movements require manual route setting. This is achieved using the trackerball and associated control buttons.

The signalman uses the trackerball to position a cursor over the symbol of the signal from which the route is to be set, then presses a 'set' button. He then moves the cursor so that it is positioned over the signal at the end of the route and again presses the 'set' button. A correctly set route is shown by the normally grey track layout changing to white. The progress of the train is shown by occupation of each track circuit which is indicated by turning the relevant portion of track display red. The four-digit train description number is also displayed in line with the 'red track occupied' indication.

Actual signal indications are displayed on the graphic screens as are point positions, level-crossing and other ancillary functions. Signal, point and track-circuit names are displayed optionally upon request by the signalman.

Trackerball control is exercised over individual points and is used for many of the routine commands, aided by a set of icons depicted at the bottom of each graphic display. The keyboard is used to set up train descriptions and to interrogate the system. Additionally it is available as a fall-back mode of operation should the trackerball fail.

The timetable processor holds the various timetables appropriate to particular days of the week, downloaded from the national train service data base. Local details and short-term alterations are handled by input at a local level to ensure that the information passed to the a.r.s. processor is current. The t.t.p. also makes its contents available to the information network to assist in the running of passenger-information displays.

The gateway system is tasked with handling the interface between the signalling and information networks. It regulates the exchange of traffic between the two networks, isolating the response-critical signalling network from heavy demands of information. Incoming information from outside the i.e.c.c. area that is required by the s.d.s.s is passed into the network by the g.w.s.

System monitoring, status and fault reporting are handled by the i.s.m. which provides for a technician's interrogation facility. Time synchronisation is performed by the i.s.m. in conjunction with the Rugby radio clock.

In order to interface to other control areas or subsystems, an external communications system is provided to translate message formats to and from these connected systems.

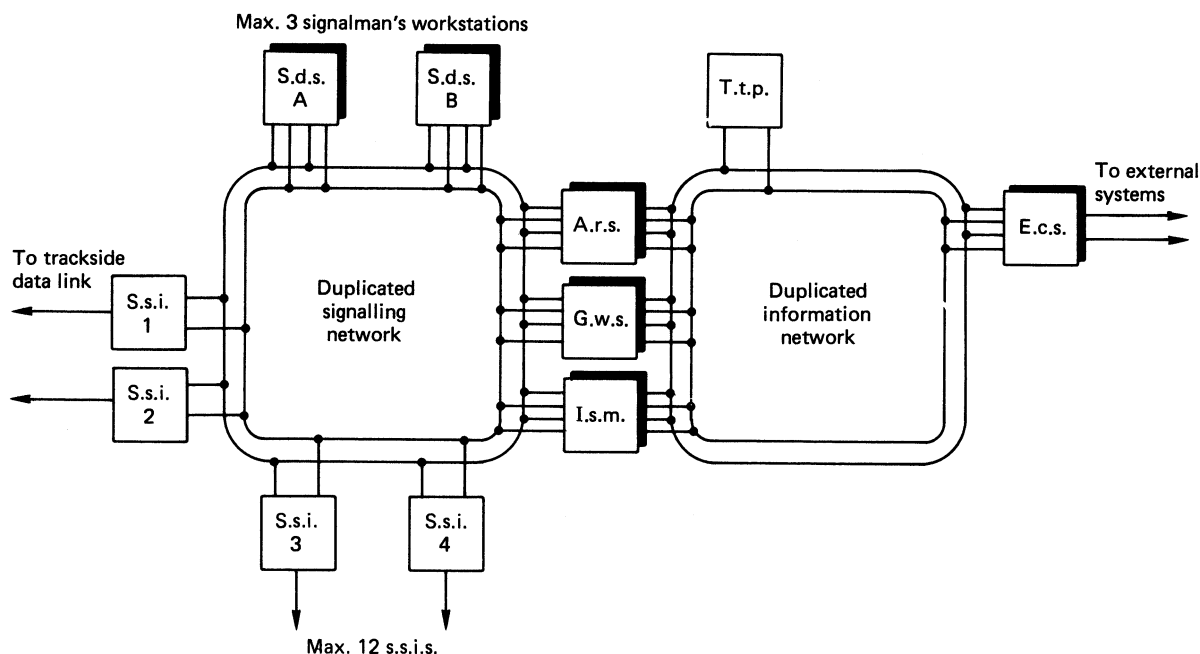

Figure 45.24 I.e.c.c. network

#### 45.4.12 Interlocking equipment

It is necessary to ensure, before a signal clears, that the route has its points in the correct position and that there is no possibility of a train being signalled in an opposing direction. Equally, once a train has been signalled, there must be no possibility of a point in that signalled route being moved or another movement being signalled against the first-signalled move.

A signalled route generally extends from one signal to the next. In it there will probably be a number of track circuits, and a point in one of the middle track circuits. The control of that point is fundamental to the safe passage of trains: (1) the point will be locked in position by occupation of the track circuit that includes it; (2) when the signal has been operated and cleared, it must be locked; (3) if after (2) the signal has to be restored to 'danger' (e.g. in emergency), then the point must be kept locked for a time sufficient for an approaching train to stop—the time normally allowed is 2 min minimum and 4 min maximum, depending on the spacing of the signals to the rear; and (4) when a train has passed a signal which had cleared, on occupation of the first track circuit and subsequently others, the signal would revert to 'danger' and it would be necessary to ensure that the points are still locked for these movements. But there might be movements in opposite or other directions through these track circuits, in which case point locking may not be necessary. Thus, locking by these track circuits is conditional: it is called 'route locking' and is often designed to incorporate the other features listed above; and it is essentially a part of any electrical interlocking system. Another important feature is that of sectional release whereby, as a train clears each track circuit and the sections ahead are still locked, the locking of points in those track circuits that have been occupied and cleared can be released.

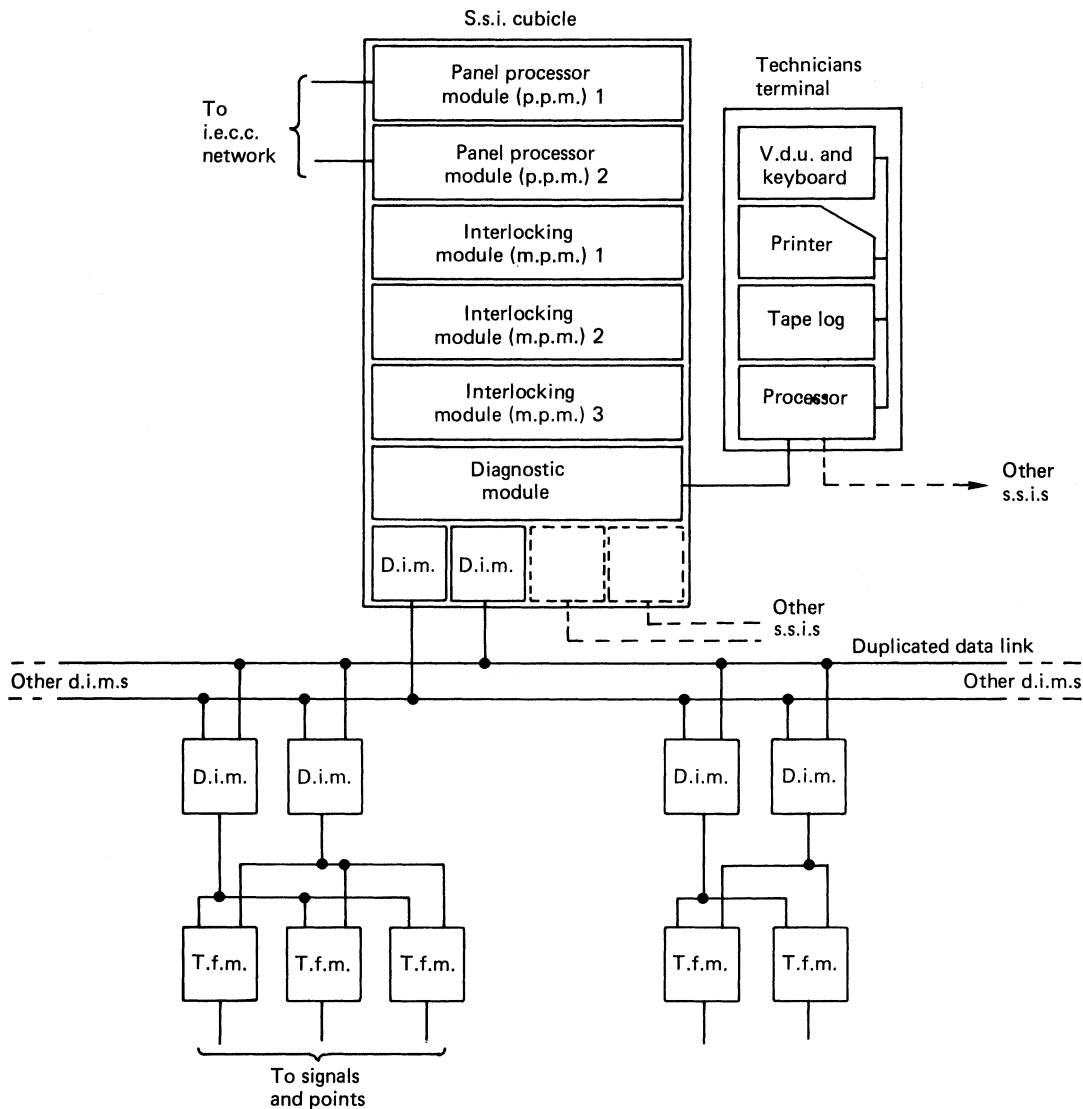

##### 45.4.12.1 Solid state interlocking

Whilst a number of older systems remain in use, nowadays safety logic required by railway signalling is performed by solid state interlocking (s.s.i.), which is a purpose-built microprocessor-based system. Safety is provided by redundancy, the s.s.i. employing a two-out-of-three voting arrangement.

The interlocking is usually sited at the control centre and communicates with trackside equipment via a data link and trackside functional modules (Figure 45.25). The area of control is limited by the density of trackside equipment but single s.s.i. modules can be connected to form multiple interlockings to control larger layouts. Interface to the signalman's control and display system is via a standard RS422 link driver from panel processor modules which are duplicated to provide fault tolerance.

The interlocking program is data driven and comprises two parts. There is a fixed program written in assembler which has a modular structure to enable clear validation, and geographic data which configure the interlocking for its specific location. Each of the panel processors and the triplicated multiprocessor interlocking modules are fitted with an interchangeable memory module which contains the fixed program and geographic data in erasable programmable read only memory (EPROM).

The three multiprocessor modules which perform the interlocking logic tasks are identical and run the same program. They form a two-out-of-three majority voting system and each contains a redundancy management device which monitors output states, system states and program memory comparing with the other two units. A faulty module can be disconnected by its own or either of the other two management devices allowing the remaining two modules to continue operating as a two-out-of-two redundant system.

**Figure 45.25** Scheme of solid-state interlocking. D.i.m., data link module; t.f.m., trackside functional module

without a reduction in safety. If a further fault occurs in either of these remaining modules a complete system shut-down is invoked and signals are retained at red.

Connection to the lineside equipment is made through trackside functional modules (t.f.m.s) connected to a duplicated data cable via data link modules which handle the communications. The integrity of the complete system relies upon the safe transmission of data between the interlocking and t.f.m.s and on each t.f.m. performing in a fail-safe manner. Data are transmitted at a rate of 10 kbaud in each direction in the form of telegrams addressed to and from each t.f.m. Up to 63 t.f.m.s can be addressed by one interlocking, each being polled and reply received in turn. Telegrams take the form of Manchester II code containing direction, addresses, identity, status, signalling controls and parity.

The t.f.m.s contain two processors working in a two-out-of-two voting arrangement for safety, availability being less stringent than for the central interlocking.

The modules act as a serial/parallel multiplexer taking control commands from the interlocking and turning these into outputs to directly drive signal lamps and electro-hydraulic clamp locks or point machines via contactors. Other equipment is interfaced via relays driven from outputs of the t.f.m.s. Likewise, inputs from lineside equipment such as track circuits, point detection and lamp proving are converted to serial data and transmitted back to the s.s.i. (Figure 45.26).

Finally, a diagnostic processor is connected to a technician's terminal to provide comprehensive fault reporting and maintenance support.

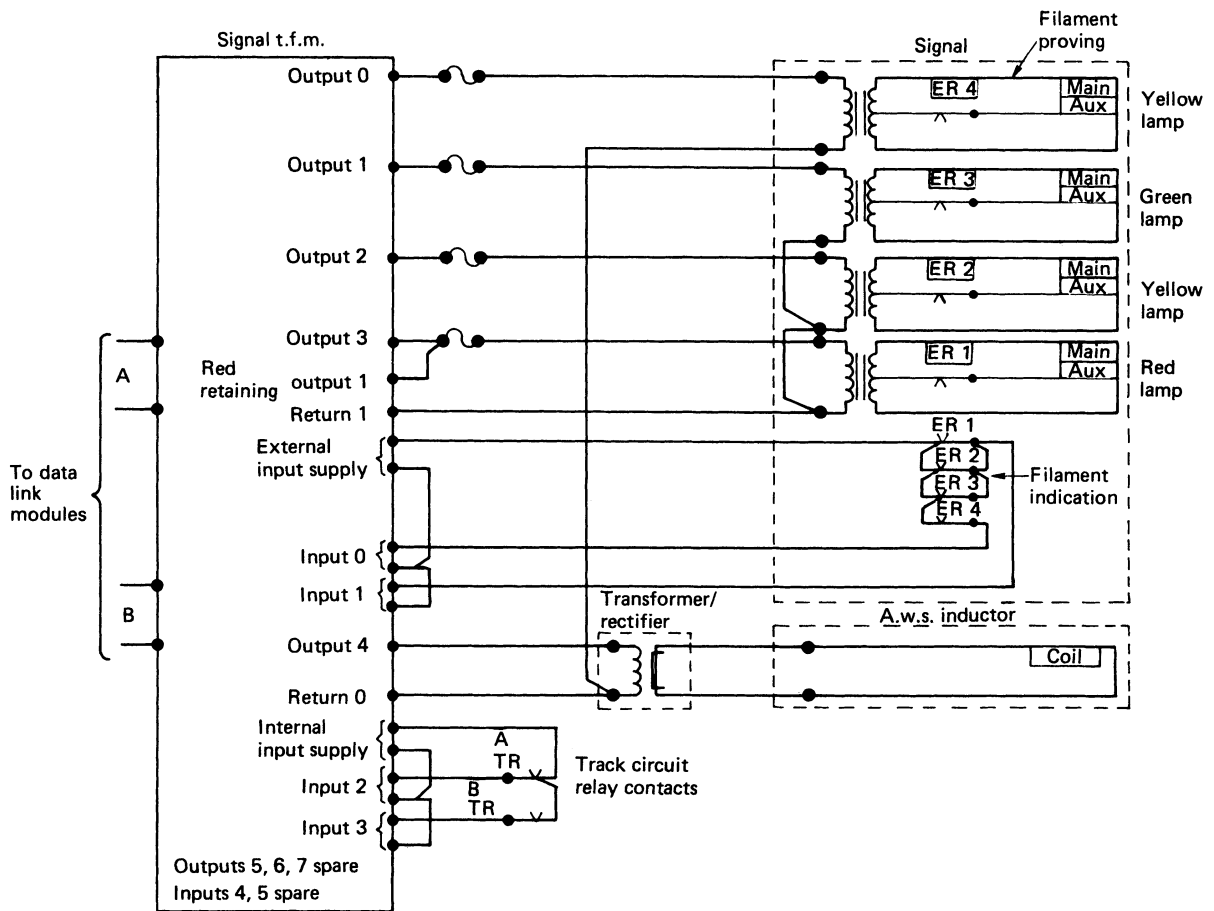

Figure 45.26 Typical trackside functional module connections

#### 45.4.13 Automatic warning system

The standard British Rail form of in-cab signal, fitted to around 70% of the network, is intermittent in operation and gives only two indications, 'caution' and 'clear'.

Two different audible sounds can be given to the driver. If the signal ahead is showing green, an electric bell rings for approximately 1 s; but if the signal displays any other aspect a horn sounds continuously until the driver makes an acknowledgement. If the driver fails to acknowledge, a full brake application is automatically initiated. When the driver makes an acknowledgement, a visual indicator operates to remind him of the fact that he has received and acknowledged this warning, and the indication remains displayed until it is cancelled on approaching the next fitted signal.

##### 45.4.13.1 Track equipment

The link between the track and locomotive or vehicle is magnetic, the track being fitted with two inductors, the first one to be passed over being a permanent magnet and the second an electromagnet. The magnet centres of these

two inductors are 787 mm apart. The magnets have a vertical axis, the permanent magnet having its south pole uppermost and the electromagnet, when energised, having its north pole uppermost. The electromagnet is only energised when the signal ahead is clear (green). The inductors are usually fitted about 183 m on the approach side of the signal with their upper surface at rail level. They are sufficiently powerful to operate the equipment on the locomotive or vehicle through a 165 mm air gap at speeds up to 240 km/h. The permanent inductor has a magnet of Alcomax II, fitted with mild-steel spreader plates, top and bottom, to give a projected flux curve that is of sufficient intensity to operate the vehicle equipment over a horizontal distance of 250 mm measured at a height of 165 mm above the top of the inductor casing. The electro-inductor coil has two windings, and the core is similarly fitted with spreader plates to give a flux curve like that of the permanent inductor. The two coils can be connected in series or parallel for 24 or 12 V d.c., the nominal coil consumption being 9 W.

Permanent magnets are also fitted on the approach to permanent and temporary speed restrictions to give a warning and to provoke a response from drivers.

#### 45.4.13.2 Rolling-stock equipment

Rolling-stock equipment has various forms for diesel and electric locomotives hauling vacuum-braked trains, diesel multiple-unit trains with vacuum brakes, and diesel or electric multiple-unit trains with air brakes.

On the underside of the locomotive or vehicle is a receiver responding to the magnetic flux from the track inductors. It consists of a permanent-magnet armature, centrally pivoted and lying between soft-iron poles. The armature carries a flexible beryllium-copper contact strip to act as a single-pole changeover switch when the armature moves under the influence of the south and north poles of the inductors. Its own magnetism holds it in one or other of the two positions against the vibration of the vehicle. A coil wound round one of the poles is energised by the driver when acknowledging a warning indication, the magnetic field causing the armature to return to the normal position from which it had been moved by the flux from the permanent inductor. If the signal has been clear, the receiver armature after being thrown by the south pole of the permanent inductor will be automatically restored by the north pole of the now energised electro-inductor, no acknowledgement by the driver being required.

Power for the automatic warning system (a.w.s.) apparatus is provided from the vehicle battery through a static voltage converter, which serves to isolate the a.w.s. equipment electrically from the driving control and lighting circuits and to provide the correct voltages (12 V for the main circuits and 40 V for the acknowledging or re-setting circuits). Normal power consumption is about 4 W with a peak of 12 W for a few seconds on receiving a signal from the track.

The 'caution' indication is either a vacuum or compressed-air operated horn controlled by an electropneumatic (e.p.) valve normally energised. A second e.p. valve, similarly energised and mounted in the same unit, is used to control the a.w.s. brake valve. On passing over a permanent-way inductor with the electro-inductor de-energised, the breaking of the normal receiver contact de-energises the e.p. relay, which, in turn, energises both e.p. valves. The horn immediately sounds and the brake valve begins to release in the air/vacuum system. Within about 3 s the valve releases fully and a brake application is made to bring the train to a stand.

The driver can acknowledge and re-set the equipment by pressing a re-set plunger within the 3 s period and maintain control of the train. The visual indicator changes to a black and yellow display to act as a reminder that a 'caution' signal has been passed.

#### 45.4.13.3 Mechanical safeguards

On double-ended locomotives and multiple-unit trains, means have to be provided to isolate the a.w.s. equipment in all drivers' cabs except that from which the train is being driven. For vacuum braked stock, a combined electrical and vacuum switch is provided with a loose handle which is carried by the driver. When the driver enters a cab, he inserts the handle into the switch and turns it to close the necessary electrical contacts, which puts supply to the a.w.s. apparatus and opens the a.w.s. brake valve to the train pipe. The handle cannot be removed without first switching off to isolate. To ensure that the driver inserts the loose handle and switches in the a.w.s., additional contacts are provided through which the supply to the main driving controls is taken. The train cannot be moved unless these contacts are made. This switch also carries a second fixed handle, which is sealed in the running position. In case of a failure of the a.w.s. apparatus which would apply a permanent brake, this

seal can be broken and the handle moved to isolate the a.w.s. equipment and yet allow the train to be moved.

On air-braked trains the same principles apply, but the independent a.w.s. loose handle is dispensed with and the switching effected by operation of the driver's brake control key.

#### 45.4.13.4 Bi-directional lines

Where a line is used for signalled moves in both directions steps have to be taken to suppress the permanent magnets which are passed over in the wrong direction. This is achieved by switching on a suppressor unit comprising an inductance forming part of the permanent magnet. When switched on a magnetic field is produced that is equal and opposite to that of the permanent magnet. Having said this many lines now fitted with a simplified form of bi-directional signalling do not have this feature built into the a.w.s. track equipment. In these cases the driver must cancel and ignore the warnings received that do not apply to his direction of travel.

#### 45.4.14 Automatic train protection

Although the a.w.s. has made an important contribution to increasing the safety record of British Rail, it cannot ensure that drivers respond correctly to a caution signal or warning of a speed restriction. A programme of fitting automatic train protection (a.t.p.) has therefore been embarked upon. Like a.w.s. the a.t.p. system is intermittent, in that information is passed to the train at fixed locations. However, the amount of information passed between track and train is sufficient to allow complete speed supervision at all times.

The trackside equipment comprises beacons, usually fitted adjacent to signals, into which are encoded data relevant to the route ahead. These data comprise such items as: present position, distance to 'danger' signal, overlap at signal, gradient, maximum line speed, distance to next speed restriction, value of next speed restriction and its length. Variable information such as signal aspect and route information is determined by selection from the signal controls. The data are encoded into a telegram and presented to the track beacon which comprises either a cable loop laid between the rails or a transponder mounted on a sleeper. On passing over a beacon the train-borne receiver passes the telegram to the on-board processor.

##### 45.4.14.1 Speed supervision

The on-board processor is responsible for taking the trackside messages and other train-carried inputs such as speed and direction and generating supervision curves to ensure that the train does not exceed speed limits or pass a signal at 'danger'. A certain amount of fixed train-carried data is required to enable the processor to make the right calculations. This includes: length of train, maximum permitted speed, and braking capability. These are entered by the driver at the start of the journey. When all signals are at 'clear' and no speed restrictions exist in the immediate route ahead the processor will supervise the train speed to ensure that the driver does not attempt to exceed the maximum line speed or maximum permitted speed of the train, whichever is the lower. When approaching a speed restriction or signal at 'danger' the processor calculates a series of braking curves down to the target speed at the signal or restriction. There are four curves (*Figure 45.27*).

The basic curve is derived from the distance required to slow the train  $D_b$  from its present speed  $V$  to the target

Figure 45.27 Automatic-train-protection generated curves

speed  $V_t$  where  $B$  is the deceleration on level track brought about by service braking and  $I$  is the deceleration resulting from the gradient:

$$D_b = (V^2 - V_t^2) / 2(B + I) \quad (45.4) \Leftarrow$$

In order that the on-board processor can intervene in the event that a train is not being braked sufficiently early, account must be taken of the time required for full service brake force to build up. A second (intervention) curve is therefore derived from the basic speed displaced by the distance travelled at constant speed during the time it would take for the brakes to be fully applied. This distance  $D_i$  is derived from the formula

$$D_i = D_b + VT_b \quad (45.5) \Leftarrow$$

where  $T_b$  is the time taken to build up full service brake force. In the normal course of events the system should not be called upon to intervene as the driver will control braking well before any overspeed is detected. To advise the driver should he come close to invoking intervention a third (warning) curve is generated. The warning is based upon giving a constant warning time  $T_w$  and, therefore, the displacement of this curve from the intervention curve is the sum of  $T_w$  and the time taken for the brakes to fully apply  $T_b$ . The warning curve is thus derived from the formula

$$D_w = D_b + V(2T_b + T_w) \quad (45.6) \Leftarrow$$

The driver requires his indication of target speed to be updated such that he is able to react before receiving a warning from the system and so a fourth (indication) curve

is used to update the cab display. Again a constant time  $T_{id}$  is allowed for the driver to react to the change of indication and so the distance from target at which the curve begins  $D_{id}$  is defined as

$$D_{id} = D_b + V(2T_b + T_w + T_{id}) \quad (45.7) \Leftarrow$$

The warning and intervention curves result in being 4.75 and 9.5 km/h above the indication curve, respectively.

In order to allow trains to draw up to a signal at red or to pass a previously red signal which has improved to proceed, trains are not supervised to an absolute stop. The release speed is determined by the length of the overlap  $D_o$  such that should a train pass a red signal it can still be brought to rest in the overlap. If the release speed is known as  $V_{max}$  and the time taken for the emergency brakes to be applied  $T_{be}$  then

$$V_{max} = \sqrt{[2(B + I)D_o] - 2(B + I)T_{be}} \quad (45.8) \Leftarrow$$

#### 45.4.14.2 Driver's interface

The driver's interface comprises green and yellow lights around the dial of a conventional analogue speedometer. The green lights indicate permitted speed and the yellow lights release speed. A three-character alpha-numeric display gives details of status and actions of the system. Four push buttons are supplied to cater for switching on, shunting, passing signals at danger, and regaining control after intervention. A separate keypad and display are used for entering train data. Various audible tones alert the driver to changes of state.

#### 45.4.15 Signal power supply

As industrial power supply reliability cannot be guaranteed, all signal systems have stand-by arrangements. For isolated signals and light loads, the stand-by is in the form of trickle-charged batteries. Where a.c. is essential, inverters have been used. The normal provision for major power signalling systems is a stand-by diesel-engine/generator set. It is accepted that the set may take up to 7 s to be ready for load. Transfer back to normal supply is done manually. An acceptable main power variation is  $\pm 10\%$  in voltage and  $\pm 2$  Hz in frequency. The stand-by equipment is designed to detect wider variations and take over the load in such a case.

A normal power distribution system is based on 650 V a.c. In densely signalled areas ring mains are used, and in all other areas spur mains are used. Power supplies are sited at suitable points according to loads but, on average, power supplies are required, with associated stand-by equipment, every 16 km.

The basic signalling equipment operates at voltages of 110 V a.c. for signals and track-circuit equipment, 50 V, 24 V and 12 V d.c. for relays, and 120 V d.c. for point machines. Transformers are provided at suitable intervals to give 110 V from the 650 V main, and the other voltages used are obtained from the 110 V a.c. Batteries are normally used on telecommunications equipment and at automatic level crossings, the latter to ensure continued operation on safety grounds. In certain track layouts it is possible to operate 12 point machines at once and this would require a large transformer rectifier. As it is only an intermittent load a small transformer rectifier and heavy-duty battery are used to overcome this heavy peaking.

All signalling circuits other than track circuits are insulated from earth.

#### 45.4.16 Protecting signalling against traction currents

A.c. traction systems are unbalanced, and as much as 50% of the return current may reach the substations through the earth, and signalling circuits are subject to induction. In order that induced voltages will not exceed the International Consultative Committee for Telephone & Telegraph (CCITT) limits of 60 V normal and 430 V under fault conditions, circuits are restricted to a length of 2 km, and in the presence of a.c. traction use a.c.-immune d.c. relays.

Connection to colour light signals is restricted to 200 m in electrified areas. Point machines are d.c. operated with a.c.-immune motors and contactors, the latter being located near the machines. For track circuits, a.c. feed is used on d.c. electrified lines and d.c. on a.c. lines. A.c. track circuits operating at frequencies of  $83\frac{1}{3}$  Hz or at frequencies which are not a multiple of 50 Hz are acceptable for both forms of traction electrification.

#### 45.4.17 Level crossings

The railway has an obligation to protect road users at level crossings on public highways. Traditionally this was done with gates, but currently there are six main ways of achieving modernised protection. These comprise automatic half barrier (a.h.b.), automatic open crossing (locally monitored) (a.o.c.l.), automatic barrier crossing (locally monitored) (a.b.c.l.), manually controlled barrier crossing (m.c.b.), trainman-operated barrier (t.o.b.) and miniature warning lights (m.w.l.).

All these crossing types, with the exception of m.w.l., are fitted with road-traffic signals. These comprise one yellow and twin red flashing lights located in each of the four corners of the crossing facing oncoming traffic. Additional units are provided for side roads as necessary. Other fixed

road signs and audible warnings are provided according to the particular type of crossing and the number of lines crossed.

The road signals are lit on initiation of the crossing and show a yellow light for 3 s followed by alternate red flashing lights at a rate of 80 flashes per minute. The red signals continue to flash throughout the operation of the crossing until the train is clear and, if there are barriers, until these have begun to rise.

##### 45.4.17.1 Automatic half barrier

These are controlled automatically by the approach of trains through track circuits and treadles. Barriers are provided on each nearside road approach only with red and white booms which carry two red lights.

A minimum of 27 s warning is given before the fastest train arrives. At initiation the yellow aspects show for 3 s followed by the flashing red for 7 s before the barriers lower. With the lowering taking 5 s the barriers are down for a minimum of 12 s. No indication of the crossing is given to the train driver but operation and power status together with emergency telephones are monitored from a supervising control centre.

The maximum line speed where a.h.b.s are installed must not exceed 160 km/h and on multiple lines the barriers must remain up for at least 5 s before a second train initiates operation. If this period cannot be achieved the barriers remain down until the second train clears the crossing.

##### 45.4.17.2 Automatic open crossing (locally monitored)

These are controlled in a similar manner to a.h.b.s but no barriers are provided. A minimum of 27 s of warning time is given and the lights must remain extinguished for at least 10 s before a second train initiates operation on an adjoining line. In this instance a separate road signal on each side of the crossing flashes red with the words 'another train coming'. The equipment and power supply are monitored by the train driver through a rail signal. This normally exhibits a flashing red indication which changes to flashing white once the red road signals are correctly lit. Should the red lamps in one road signal fail, or a failure of the main power supply occur, the rail signal will not show the proceed aspect. The driver is then authorised to pass over the crossing at caution once he is sure it is safe to do so.

Each a.o.c.l. is restricted to a speed dependent upon local sighting conditions but always within the maximum of 88 km/h. Before reaching the crossing and sighting the rail signal the driver will pass an 'advanced warning board' at braking distance followed by a crossing speed board advising of the speed restriction.

##### 45.4.17.3 Automatic barrier crossing (locally monitored)

This system is similar in operation to an a.o.c.l. with the addition of road barriers but without emergency telephones. It is similarly subject to a speed restriction based on local conditions. The train driver receives the same trackside approach boards and monitors the operation of the crossing via the red and white flashing rail signal. During a failure situation the barriers remain raised. A plunger is provided for the driver to lower the barriers in this situation before entering the crossing.

##### 45.4.17.4 Manually controlled barrier crossing

This type of installation is provided with full barrier protection which closes off the whole road. The barriers are normally fitted with skirts and the usual yellow and flashing

red signals are shown to road users. Whilst in the lowered position the barriers are locked down.

There are several variations on the style of control but each essentially requires an operator to ensure that the barriers are lowered and that the crossing is clear before a train is allowed to approach. Controlled signals are, therefore, provided on each rail approach interlocked with the level crossing.

There are no restrictions on train speed, traffic levels or the number of lines passing over the crossing. Typically operation will be performed by a signalman or crossing keeper adjacent or near to the crossing or remotely by the aid of closed-circuit television. Automatic raising is often fitted and in many instances automatic lowering, whereby an approaching train initiates operation. Before the signals can be cleared for a rail movement, however, the operator must always confirm that the crossing is clear.

#### 45.4.17.5 *Trainman operated barrier*

Used on rural lines, the train driver is responsible for operating the crossing from a switch or push button which he can reach from the driving cab. A flashing red and white rail signal indicates the status of the road signals and barriers before the driver ensures that the crossing is clear and then proceeds. A special signal is located beyond the crossing to indicate to the driver that the barriers have raised automatically behind the train. If they fail to rise the train must stop and the crew raise them manually.

#### 45.4.17.6 *Miniature warning lights*

This type of installation is used for footpath crossings or minor level crossings where user operated gates or barriers are fitted. Red and green lights are provided for users on each side of the crossing, operated by the approach of trains. Users may only cross when the green light is showing. No indications are given to the train driver.

#### 45.4.18 **Train to signal box radio**

To facilitate driver-only operation of suburban passenger trains a system of 'train to signal box radio' is implemented on appropriate routes. This allows for secure direct voice communication between the signalman and driver and for the exchange of fixed data messages.

Each signal box or control centre is equipped with a management processor and one or more signalman's processors each with interfaces comprising a visual display unit (v.d.u.), keyboard and audio equipment. Radio coverage is provided by a number of fixed radio stations along the length of the railway under control. These are connected back to the signalman's processor by four-wire circuits. Coverage through tunnels is maintained by using leaky co-axial cables or directional antennae. The signalman has control of the system at all times, his v.d.u. advising of all incoming calls and alarms and echoing his inputs from the keyboard. The fixed stations transmit on two frequencies, a nationwide signalling (or control) channel used to establish calls and a discrete traffic channel assigned to the area. The system is allocated 19 traffic channels in the ultra-high frequency (u.h.f.) band. To prevent cross-talk between areas continuous tone controlled signalling system (c.t.c.s.s.) is employed. Each base station is allotted a time slot in which to transmit. Synchronisation of time is handled by the management processor from reference to the Rugby radio clock. The train-carried equipment comprises a transmitter, receiver and control equipment. The cab interface includes a keypad and alpha-numeric display.

The system aids safety and operating by giving direct communication during all times without the need for drivers to leave their train and contact the control centre via signal post telephones. When stopped at a signal a driver can for instance send a 'waiting at signal' data message by operation of a function key. The signalman can respond to this with the instruction 'wait' by pressing a function key. This message is then displayed on the driver's display in his cab.

The management processor is kept informed of train whereabouts by the signalling system and is thus able to identify each caller by the train running identity and pinpoint the location of the train.

## 46.1 Introduction

Prior to 1950, electrical installations in ships (other than tankers) were predominantly d.c. This predominance has been reversed because of the higher power requirements of modern ships, for which a.c. systems have lower capital and maintenance costs. The main problems of this change-over have concerned the requirement, based on tradition, for variable-speed deck auxiliaries (winches, capstans and windlasses), pumps and fans. For the latter, makers have accepted single-speed or change-pole two- or three-speed induction motor drives, with additional throttle control in appropriate cases. For deck auxiliaries it was similarly found that for certain trades the change-pole induction machine was adequate, and that Ward-Leonard or other sophisticated systems could meet more demanding duty.

The development of North Sea exploration since 1970 led to the introduction of Mobile Offshore Installations generating large electrical power; their systems are invariably a.c., with d.c. conversion for operation of drilling machinery.

The concept of centralised control stations has been fully developed, with control gear, alarms and instrumentation grouped in enclosed, air conditioned and soundproofed rooms. With advances in the automatic control of steam raising plant, including the re-emergence of coal burning, engine rooms unmanned at night and with reduced manning by day have become the norm.

## 46.2 Regulations

With very few exceptions, every seagoing ship must comply with national, international and classification society rules and regulations. The leading classification societies (to which the administration of international requirements is sometimes delegated by the government concerned) include Lloyds Register of Shipping, Bureau Veritas, American Bureau of Shipping, Germanischer Lloyd, Nippon Kaiji Kyokai, Norske Veritas and Registro Italiano Navale. Lloyds Register of Shipping's Rules and Regulations for the Classification of Ships, which are reviewed regularly, lays down the necessary guidelines to ensure that all registered vessels are safely operated within the laws of the relevant nations. In addition to the well known larger societies, other smaller ones have emerged and unified requirements are promulgated by the International Association of the Classification of Ships.

Ships are to comply with the 1974 United Nations Resolution for the Convention for the Safety of Life at Sea (SOLAS), the 1986 consolidation and its 1988, 1990, and 1991 protocols. They must also comply with 1991 Marine Pollution (MARPOL) Consolidation which incorporates the International Maritime Organisation's (IMO) 1973 Convention on Marine Pollution and its subsequent protocols and with the acts of the various maritime nations. For British ships this includes the Merchant Shipping Act 1988. Passenger ships (carrying more than 12 passengers) must have a valid Passenger Safety Certificate and cargo vessels a valid safety Construction Certificate. Validity for communications including terrestrial radio and telex is encompassed by the Global Maritime Distress and Safety Systems which is covered in the 1988 amendments to SOLAS. The IMO is responsible for reviewing Conventions and Codes relating to the safety and operation of vessels at sea and any revisions must be accepted and acted on by the leading maritime nations.

Electrical construction and performance standards are set by each of the classification societies, SOLAS, government

regulations, International Electrotechnical Committee (IEC) and, in the UK, by the British Standards Institution (BSI) and Institute of Electrical Engineers (IEE). The electrical regulations for offshore oil and gas rigs are incorporated in the IMO Code for the Construction and Equipment of Mobile Offshore Drilling Units 1991. The main IEE publication is the regulations for the Electrical and Electronic Equipment of Ships with Recommended Practice for their Implementation 1990. BSI publications include BS 2949:1960 which covers the construction and performance of rotating machinery and BS 3399:1961 which covers the regulations for transformers. The main IEC regulations are IEC 92 PT101 which cover the general requirements for electrical installation in ships, IEC 92 PT502 for electrical installations in tankers, and IEC 92 PT503 which is applicable to electrical installations with voltages in the range 1 kV to (and including) 11 kV.

## 46.3 Conditions of service

IEC Publication 92-101 specifies for ships on unrestricted service an ambient air temperature of 45°C for all equipment other than rotating machines in machinery spaces, in galleys and on weather decks. For rotating machines in machinery spaces it is 50°C. In all other spaces and for vessels on restricted service (i.e. coasters, tugs and harbour craft operating solely in temperate climate) 40°C is recognised. For electronic devices, semiconductor diodes, etc., much higher ambient temperature conditions may have to be withstood.

Other onerous conditions are vibration, and inclination up to 15° transversely and with rolling up to 22½°. Voltage variation may be +6 to -10%, with simultaneous frequency variation of ±2.5%. With a.c. generation a momentary voltage dip of up to 15% at the generator is permissible when large motors or groups of motors are switched direct-on-line.

From the point of view of electrical equipment, very severe conditions prevail while a ship is under construction. Welding and painting will be in progress in the vicinity, accompanied by dirt and exposure to the weather.

Skilled maintenance and repairs can be carried out only in ports where suitable facilities exist. This applies particularly to machine windings. Installations must therefore be of a high standard of reliability and suitable for operation over prolonged periods with a minimum of attention. Unlike industrial conditions, in which there are shut-down or reduced-load periods, apparatus on essential ship's services may operate continuously for several days.

## 46.4 D.c. installations

Standard practice is to use parallel-operated level-compounded generators with equaliser connections and reverse-current protection. For small installations 110 V may be used, but 220 V is the general norm. Installations of up to 3000 kW with individual machine ratings up to 1000 kW were formerly common, but the present preference for a.c. means that d.c. systems do not now exceed 1000 kW total with smaller generating units.

The hull return system of distribution is not permitted for any tanker vessel or for any ships of greater than 1600 t gross tonnage, unless an exception is granted by the appropriate classification society. Exceptions to this rule are:

- (1) impressed current cathodic protection, and
- (2) insulation monitoring devices.

## 46.5 A.c. installations

Tankers and passenger ships of recent construction are almost all equipped with a.c. systems—about 40% with a frequency of 50 Hz; the remainder of 60 Hz. As most marine generators and motors are special to this service, the choice of frequency does not have to be related to particular national supply systems. The frequency of 60 Hz gives the advantage of higher operating speed and lower weight. Motors built for 440 V, 60 Hz can operate from 380 V, 50 Hz shore supplies and (if some additional heat can be tolerated) on 415 V, 50 Hz. However, contactors and voltage operated relays may not always be amenable to such conditions; and 50 Hz motors may not operate satisfactorily on 60 Hz, particularly with centrifugal fan and pump loads.

In some tankers and passenger ships, high-voltage generation has been adopted, particularly in those vessels that are electrically propelled. IEC Publication 92, *Electrical Installation in Ships*, Part 503, and BS 3659 (replaced by BS 5311:1991:Parts 1–7) apply to vessels with high-voltage generation.

## 46.6 Earthing

Regulations permit isolated or earthed neutral systems, except for tankers, in which earthed systems are forbidden. The choice (where there is one) is almost always for isolation, the risk of overvoltage being accepted to avoid the loss of a vital service, e.g. steering, should one earth fault occur. A single earth fault on an insulated system can be detected, and does not result in an outage unless a second fault occurs; and in any case overvoltages are rare compared with the incidence of earth faults. Every insulated distribution system, whether primary or secondary, is required to be provided with means to continuously indicate the state of insulation from earth and is to be arranged in such a way as to give warning of abnormally low levels of insulation. However, care must be taken when designing the installation to protect electronic circuits, particularly those containing semiconductor diodes, from overvoltage 'spikes', direct or induced.

## 46.7 Machines and transformers

The construction, installation and performance of rotating machinery on ships is dealt with in BS 2949:1960, BS 4999:1992, and IEC 92 PT202. Transformers for high voltage discharge lighting should comply with BS 3535:1990. Other transformers are covered in BS 3399:1961, BS 3535:1990 and by IEC Publication 92–303. It is recommended, except for those used for motor starting, that they should be doubly wound, i.e. with separate windings and that dry types should be used in preference to 'wet' types.

Because relatively large motors and groups of motors are started direct-on-line, the consequent voltage dip is important because of its effect on the system as a whole and, in particular, on lights, contactors and voltage operated relays. Stipulations are:

- (1) A limit of 15% voltage dip at the generator terminals and a recovery to within 3% of rated voltage within 1.5 s, when the generator is subjected to a suddenly applied symmetrical load of 60% rated current at a power factor between zero and 0.4 lagging; the recovery may be increased to 4% within 5 s for emergency generators.

Figure 46.1 A typical voltage response

- (2) A limit of 20% excess voltage following initial recovery.
- (3) Under steady-state conditions the system, which may include an automatic voltage regulator, must be maintained within 2½% rated bus-bar voltage (3½% for emergency sets). The conditions are shown in Figure 46.1.

These requirements are for normal installations. Special conditions apply if the impact load exceeds 60%, or if the deck machinery consists of groups of multi-speed cargo winches liable to be switched simultaneously, or in any other special conditions.

It is common practice in modern ships to use self-excited compounded a.c. generators, or brushless machines with a.c. exciters and shaft mounted rectifiers (Figure 46.2). In order not to nullify short-circuit protective gear, such generators must maintain adequate voltage under short-circuit fault conditions. BS 2949:1960 specifies a current of at least three times rated value for 2 s unless provision is made for a shorter duration without impairing safety.

### 46.7.1 A.c. generators

Self-excited self-regulating a.c. generators are now available in all sizes for marine service, with excitation obtained from a three-phase exciter through semiconductor rectifiers. The principles are the same whether a slip-ring or a brushless form is applied. Voltage and current transformers connected to the generator output feed field excitation through a three-phase rectifier to give a compounding effect. A typical arrangement (Figure 46.3) combines compounding with closed-loop control: the effect on the excitation due to the compounding is supplemented by a fine control, the response of which is determined by the divergence of the generator voltage from a pre-set reference. A transient dip of generator voltage during the first period following a

Figure 46.2 Cross-section of a brushless a.c. generator

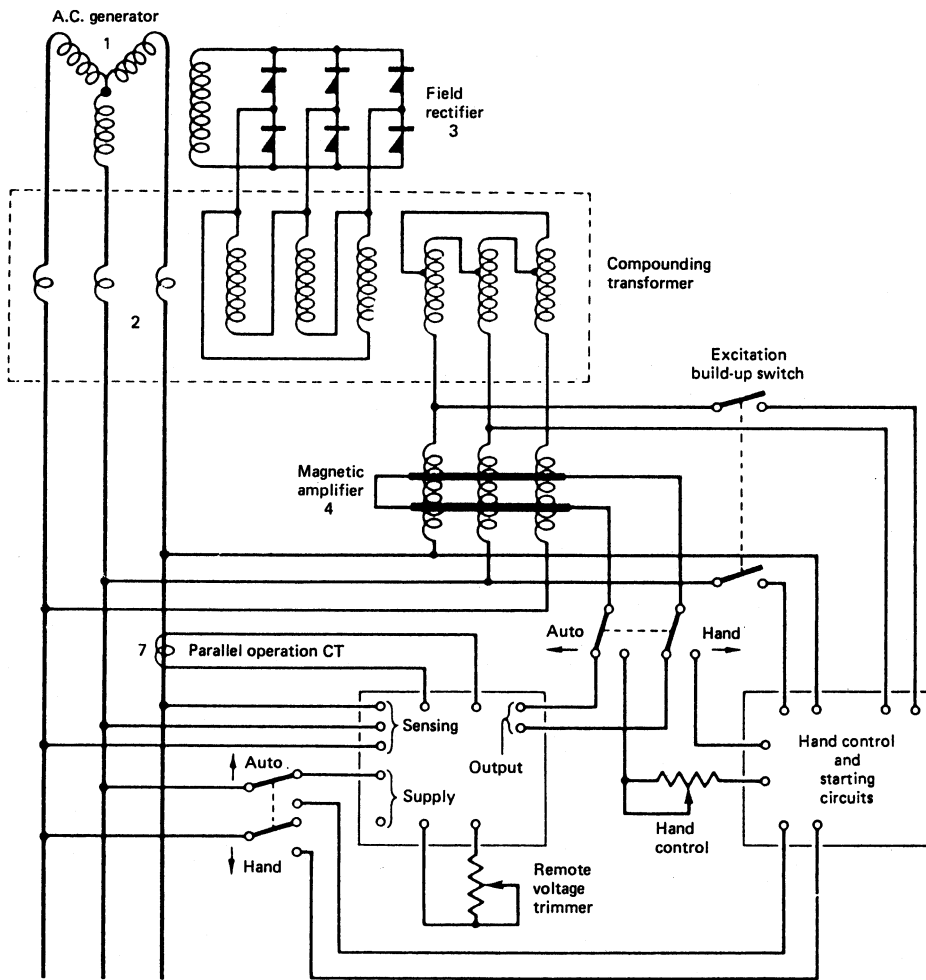

Figure 46.3 Schematic diagram of a static-excited a.c. generator

disturbance is inevitable, but no further change due to armature reaction occurs, because the excitation is rapidly corrected by field forcing through the action of the series windings of transformer 2.

Under short-circuit conditions saturation of the static excitation components limits the excitation to about 1.5 times full-load value, and the sustained short-circuit current is about three times rated value. Variations in field resistance are swamped by the series impedance of the magnetic amplifier. The circuit self-compensates for speed changes, as the amplifier current rises as the frequency falls. The automatic control circuit incorporates a Zener diode which controls a silicon transistor driving a thyristor. The three-phase rectifier is connected to the generator main field through slip-rings.

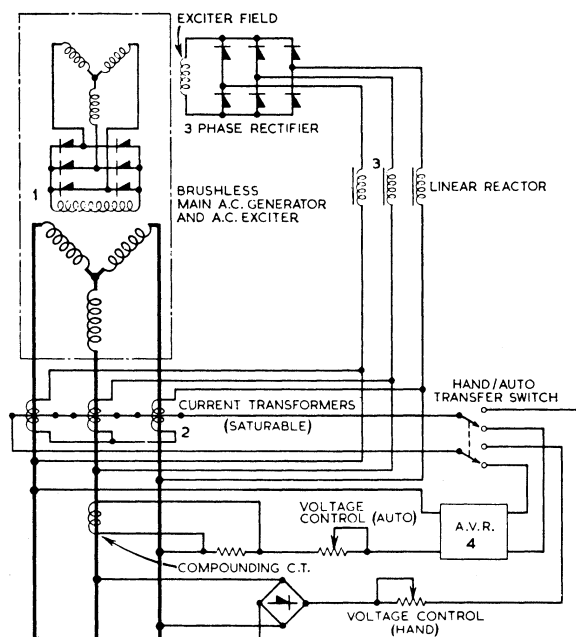

An example of a brushless system is given in Figure 46.4. Excitation is provided partly by saturable current transformers and partly by a three-phase linear inductor, all of small rating and easily accommodated on the switchboard. There is sufficient magnetic remanence in the a.c. exciter to ensure starting. By means of the automatic voltage regulator (a.v.r.) a steady voltage regulation of  $\pm 1\%$  is obtained with high-speed response, typically within 0.5 s.

Governors on prime-movers are required to automatically maintain rated speed within a momentary maximum variation of 10% and a maximum steady state variation, i.e. droop not exceeding 5%. These figures are to be met during tests whereby a fully loaded generator is subjected to a step 50% load reduction for a short period before full load is restored.

#### 46.7.2 Voltage build up

In Figure 46.3 the no-load terminal voltage is applied to magnetic amplifier 4; its current lags this voltage by nearly a quarter-period, passes through the compounding current transformer 2 and the field rectifier, and supplies the no-load excitation. When the generator is on load, the load current passes through the series coils of current transformer 2; the secondary current is then the phasor sum of the inductor current and a current proportional to the load current. By correct proportioning the static excitation is appropriate for all normal loads, even at low lagging power factors.

With brushless generators two rectifiers in parallel are provided in each phase of the rotating element to provide

**Figure 46.4** Schematic diagram of a brushless a.c. generator. C.T., current transformer; A.V.R., automatic voltage regulator

back-up should one fail. The commonest diode failure is a short circuit, so that each diode must be fused. A failed diode produces an unbalance and a ripple in the exciter field current. This can be used to detect failure.

### 46.7.3 Reverse-power protection

Loss of power from the prime-mover may be accidental or intentional. If the generator was left connected in parallel with other generators, it would act as a motor and continue rotating, with possible damage to the prime-mover. With d.c. generators this is taken care of with a reverse-current tripping relay, but with a.c. a reverse-power relay is necessary. To prevent inadvertent operation of reverse-power relays due to power surges, particularly when synchronising, a time-delay feature is incorporated. With diesel engines a fairly coarse setting of the order of 10–15% of full power is suitable, but steam turbines absorb very little power when motored and a fine setting of 2½–3% is necessary.

The alternative to reverse-power relay protection is to provide electrical interlocks or contacts which will respond to predetermined occurrences, such as failure of lubrication, closing of fuel or steam admission valve, operation of over-speed governor or excessive back pressure.

### 46.7.4 Single phasing

A common cause of motor burn-out is single-phasing, which can arise from broken or faulty connections or, more commonly, the blowing of one of the three-phase fuses. For this reason the IEE Regulations for the Electrical and Electronic Equipment of Ships with Recommended Practice for Their Implementation 1990, stipulate that matching cartridge fuses be used. In addition, overload relays with alarms and indication of motor failure to start must be

fitted. This is particularly important if automatic starts are employed or if the machinery spaces are operated unmanned.

Undervoltage releases do not provide protection. Should the open circuit occur on the motor side of the circuit-breaker, the coil will continue to be fed from the supply, and if the open circuit is on the supply side, the coil will be fed by voltage induced in the motor.

A three-phase motor will not restart with an open-phase connection: out of sight and sound it may remain stalled, and if the overload protection is set too high or with too long a time delay, the motor may burn out. Pilot lights across one phase will give a false indication if the fault is on another phase. The remedy is to set overload protective devices closely, with suitable time lags, or to adopt some form of single-phase protection.

## 46.8 Switchgear

### 46.8.1 D.c. switchgear

Open switchboards have all essential switchgear exposed on the front. Some owners prefer dead-front construction. For the open type all parts, front and back, are readily accessible for maintenance, an important consideration when it is remembered that these operations have to be performed on a live board.

Regulations state that for each d.c. generator installed which does not run in parallel, a double-pole circuit-breaker or a fuse for each pole and a double-pole switch is required. For generators that run in parallel in a two-wire-insulated system a double-pole circuit-breaker is required for each machine. With compound generators the equaliser switch is required to be interlocked with the circuit-breaker of each machine so that it is made before the circuit-breaker can be closed and not opened until the circuit-breaker is opened.

Regulations require preferential tripping in large installations so that non-essential loads can be automatically switched off when the generators become overloaded. This can be done in either one stage in a simple installation or in two or three stages in larger systems. A typical arrangement is shown in *Figure 46.5*.

### 46.8.2 A.c. switchgear

Because of the greater risk of shock in a.c. systems, the open construction is not permitted and switchboards must be 'dead-front'. In the usual construction the switchboard is divided into cubicles. Circuit-breakers can be withdrawn and isolated from the bus-bars for maintenance and adjustment. Access doors are interlocked to prevent access to live parts. A similar construction is used for control gear.

Preferential tripping as described for d.c. systems is also required. Instrumentation must include a synchroscope (see *Figure 46.6*). Automatic synchronising is now becoming necessary in installations comprising prime movers which start automatically, and SOLAS and its protocols require automatic start-up and circuit-breaker closure within 45 s to ensure continuity of supply with unmanned installations.

Circuit-breakers are required to comply with the requirements of BS 4752 (replaced by BSEN 60947:1990). Air-breakers and miniature circuit-breakers are common at 440 V; high fault levels have led to the introduction of current-limiting breakers. At 3.3 kV and above, vacuum

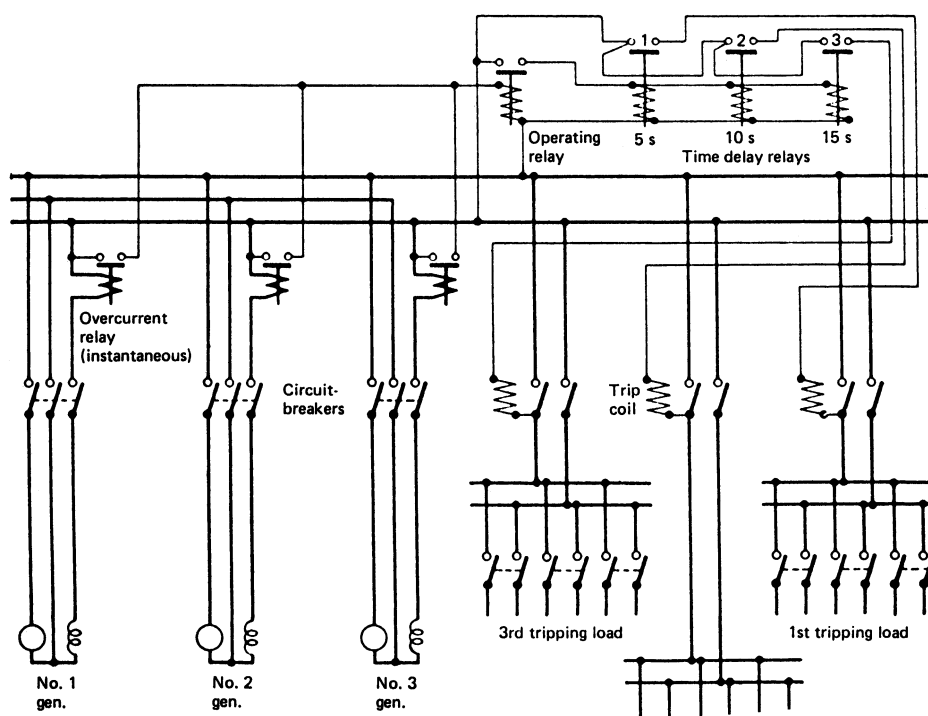

Figure 46.5 Diagram of typical preferential tripping circuits

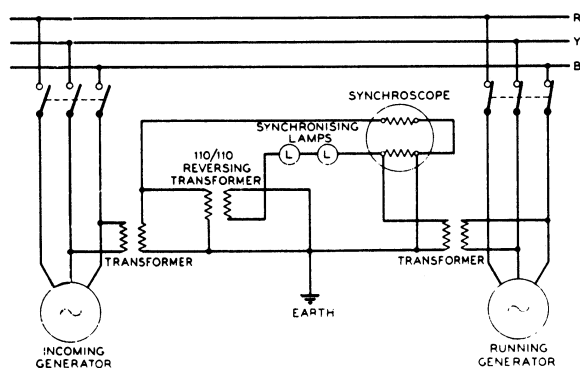

Figure 46.6 Schematic diagram of a synchroscope and synchronising lamps for a 'lamps bright' system

contactors are often used; active consideration is given to SF<sub>6</sub>.

## 46.9 Cables

EPRCSP, PVC and XLPE, all with metallic sheath and PVC overall, are most common, being flame retardant as required by SOLAS. MICC and silicone rubber withstand high temperatures and have appropriate applications.

Cables which are required to be flame proof, for example those in tankers and gas carriers, are required to retain insulating properties after severe fire damage. The regulations governing these types of cable are covered by IEC 331 and by BS 6387:1991.

## 46.10 Emergency power

SOLAS and its protocols have extended for all ships the services to be supplied; for cargo ships the period for which this power must be available is stated.

*Passenger ships* are to have emergency power from a generator or battery adequate for 36 h duration. With a generator there must be a transitional battery to supply specified services for 30 min to come into operation automatically.

*Cargo ships* have similar requirements for 18 h duration, but do not need a transitional battery if the emergency source can start and be connected automatically.

*Mobile offshore installations* are covered in the MODU Code.

Both nickel-cadmium and lead-acid batteries are used for emergency or stand-by services to vital circuits such as computer communication, fire detection, etc., without 'excessive volt drop', a term interpreted by the British authority as a drop, at the end of the specified emergency period, not exceeding 12½% of nominal system voltage. The voltage should be within the limits -10% to -12½% from the fully charged condition to that at the completion of the prescribed duty.

Battery installation, ventilation and maintenance correspond to the best practice ashore.

## 46.11 Steering gear

Electric steering can be either all-electric or electrohydraulic. Its function is to control the position of the rudder through an angle of 35° each side of the central position. Regulations require that the time taken to put the rudder from 35° on

**Figure 46.7** Schematic diagram of a rudder follow-up system and the synchro transmitter and receiver (Sperry system)

one side to  $30^\circ$  on the other is not to exceed 28 s at maximum service speed. The steering gear must be provided with running indicators, one on the bridge at the main steering position and one in the engine room. A usual arrangement is that one quarter-turn of the steering wheel corresponds to one degree of rudder movement. Automatic steering on a set course controlled by a gyro-compass can be superimposed on a power-operated system.

One such system is shown in *Figure 46.7*. Mounted in the bridge control unit is a follow-up ring assembly consisting of two pairs of silver rings mounted on insulating formers. Carbon brushes on the outer rings are connected to rectifiers which, in turn, are connected to contactor coils. Follow-up rollers make contact with the inner surfaces of the rings, one half-ring of each inner ring being connected to the complete outer ring. The carbon brushes are fixed, but the rings and the bracket carrying the inner contact rollers are free to rotate. The inner roller assembly is rotated by a synchro receiver; the contact rings by the pilot wheel when under hand control or by the gyro-compass transmitter when under automatic control. In this system the transmitter is geared to the rudder so that it adopts a corresponding angular position. When the rudder has reached the angle set by the pilot wheel (or by the compass), the rollers will have caught up with the gap in the ring and the contactors will open.

Electrohydraulic systems usually depend on a continuously running motor coupled to a variable-delivery pump supplying oil pressure to one or other of a pair of hydraulic cylinders. Operation from the bridge is by telemotor control, in which the rudder motion continues until its position coincides with that of the bridge setting.

All-electric systems depend either on a direct-coupled reversing motor or on Ward-Leonard control. In the latter the generator voltage may be controlled by a voltage divider or by field windings of opposite polarity. In push-button systems the rudder movement continues so long as the push-button is held closed.

Steering is a vital service. SOLAS now requires duplication of power supplies and control circuits, the latter to be supplied specifically from the associated power circuits. Alarms and transfer switching are to be sited on the navigating bridge. Large ships require steering power to be available, automatically within 45 s, from the emergency source on loss of main power.

## 46.12 Refrigerated cargo spaces

The system now commonly used consists of batteries of brine cooled pipes over which air is circulated by fans and

distributed uniformly to all parts of the hold. The fans vary in size and number according to the holds, and a ship may require up to about 40 fans of 1–8 kW rating. Compressor motors up to about 200 kW at constant speed are commonly required. The fans are located in the holds and their lubrication presents a problem, as the ambient air temperature can vary between tropical conditions at the loading port and approximately  $-20^\circ\text{C}$  when fully refrigerated.

Temperature control of the holds within narrow limits is essential for some cargoes (e.g. bananas), so that provision must be made for accurate and sensitive sensing and control at numerous points. Electrical thermometers have been specially developed to read to  $0.1^\circ\text{C}$  over a range of approximately  $-20^\circ\text{C}$  to  $+15^\circ\text{C}$ . A tolerance of  $\pm 0.1^\circ\text{C}$  at the freezing point of water is attainable under working conditions.

Container ships with typical installed power of 6 MW, 450 V, 60 Hz and considerable instrumentation are now common. Up to 3000 containers of rating 3.5 kW may be supplied through flexible connections.

## 46.13 Lighting

### 46.13.1 General

For general lighting both tungsten and fluorescent lamps are used. For deck lighting halogen floodlights or high-pressure mercury lamps may be installed. Where colour rendering is not important, sodium lamps, which have high efficiency and long life, are suitable for high-level general lighting. The lighting load for large public rooms can be appreciable, and fluorescent lighting can reduce power and heat, which, in turn, assists air conditioning.

Under the Merchant Shipping Act, the Department of Trade requires artificial lighting in crew accommodation to be well diffused, avoiding glare and deep shadows. Bunk lights must be provided, and 25 W or 40 W tungsten or 15 W fluorescent lamps are considered satisfactory. In cold stores separate light fittings of robust construction, with a switch outside the compartment and a pilot light, are required.

For general lighting the level of lighting measured at a height of 0.85 m above floor level and midway between adjacent lamps, and between any lamp and a boundary of the space, is prescribed in precise terms. Good lighting in galleys is important, and brings faster working, fewer mistakes and accidents, and better hygiene.

Statutory regulations (when applicable) require emergency lighting supplied from the emergency source of power to be embodied in the lighting system. All boat stations, lifeboat launching gear and all public and crew areas, alleyways, service spaces, stairways and exits must be provided with emergency lighting.

Voltage variation affects the light flux output and life of both filament and fluorescent lamps.

### 46.13.2 Navigation lights

The requirements are prescribed in the International Regulations for Preventing Collisions at Sea 1972, as amended. All ships are to be provided with 'steaming lights', masthead, side, stern and anchor. Each navigation light should be provided with primary and alternative lanterns. Classification rules require that navigation lights shall be connected to a distribution board reserved solely for this service, and connected directly or through transformers to

**Figure 46.8** Schematic diagram of a typical navigation light indicator

the main or emergency switchboard. Each light must have aural and/or visual indication of failure. If only an aural device is fitted, it must be battery operated. If a visual signal is connected in series with the navigation light, there must be means to prevent extinction of the navigation light through failure of the signal lamp. Typical arrangements are shown in *Figure 46.8*. The volt drop across series connected indicators must not exceed 3% of the system voltage. The use of double-filament navigation lights is not permitted.

## 46.14 Heating

SOLAS prescribes that electric heaters, where used, must be fixed in position and must not have an element so exposed that clothing, curtains, etc., can be scorched or set on fire.

Except in ships employed solely in the tropics, crew accommodation has to be provided with a heating system of prescribed minimum performance. With certain exceptions a temperature of 19°C must be maintained in a ship regularly employed otherwise than as a 'home-trade ship', and 15°C in the case of any other ship, when the outside air temperature is  $-1^{\circ}\text{C}$ .

## 46.15 Watertight doors

Watertight doors, under certain conditions prescribed by regulations, have to be power operated and to conform to specific requirements, including testing at maker's works in the presence of a surveyor.

They may be either electrically or electrohydraulically operated and controlled, either in groups or individually from a central control position, usually the navigating bridge. In addition, hand operated gear must be provided which can be worked at each door or from a position above the bulk-head deck. At each control position an indicator must show whether the door is open or closed. An audible warning device situated near the door and operated by a time switch giving about 10 s notice functions before it starts to close.

The central control station has overriding features which decide whether the doors are to close; they can be opened locally but re-close automatically. They can also be closed locally independently of the central control.

An essential feature of the powering system is that it should exert an initial high effort to withdraw the door from the grip of door wedges which come into effect in the fully closed position. Thereafter this force diminishes and the rate of opening increases.

## 46.16 Ventilating fans

When trunking carries ventilating air to accommodation and cabins, any noise arising from fans or fan motors must

be avoided. For this reason sleeve bearings are generally preferred. A variable speed or a choice of speed is usually necessary for control purposes.

Regulations require means to be provided for stopping fans from remote positions in the event of fire.

## 46.17 Radio interference and electromagnetic compatibility

Radio communication is vital and must as far as practicable be interference-free. 'Noise' may originate in the ship's electrical installation, in the rigging, from other radio frequency apparatus (e.g. public address systems) and from electromedical appliances. The radio installation can also cause interference with other electronic circuits; hence the concept of electromagnetic compatibility.

Suppression of unwanted noise is an economic problem to be shared by the supplier of the radio equipment, the shipbuilder, the electrical contractor and the manufacturers. Usually interference cannot be entirely eliminated, so permissible levels are prescribed. Interference can be alleviated by careful planning of radio installations and aerial systems, by applying certain techniques to the rigging, and by fitting suppression devices to electrical equipment and wiring. Interference arising from the electrical installation can be of two kinds—i.e. radiated and picked up by the aerial or conducted by cables entering the radio cabin. BS 1597:1985 deals with remedies generally considered necessary for the electrical installation and prescribes the permissible level of interfering emissions in the various wavebands. Precautions to be taken in the construction of the rigging and in the installation of cables are included.

This subject is detailed in an Appendix to the IEE Regulations for the Electrical and Electronic Equipment of Ships 1990.

## 46.18 Deck auxiliaries

Deck auxiliaries include cargo winches, cranes, capstans, warping winches, windlasses and hatch cover winches. For some classes of ship a variable speed for deck auxiliaries is still preferred, but, in general, two- or three-speed change-pole induction motors are suitable. For cranes a high-speed facility is needed for rapid return of the empty hook.

### 46.18.1 Variable speed

Where variable speed is essential in a.c. systems, slip-ring motors or Ward-Leonard control may be provided, the latter with a motor generator for each winch or for a group. In recent years there has been a trend to employ a.c. variable-speed drives. With d.c. systems, a variety of methods has been used: e.g. series resistance, Ward-Leonard, boost and buck, and lowering by dynamic braking or regeneration. Dynamic braking is generally achieved by means of diverters in shunt with the armature giving a potentiometer connection. In nearly all cases load discriminators may be necessary to control speed in relation to load, i.e. to permit of higher speeds with empty or lightly loaded hooks.

### 46.18.2 Deck auxiliary services

Some of the additional factors concerned with particular applications are given below.

46.18.2.1 Cargo winches

Emergency centrifugal brakes are fitted, where necessary to prevent excessive speeds when heavy loads are being lowered. Provision must also be made to prevent the load from running back in the event of a power failure. Light-hook speeds are 3–4½ times normal full-load speed.

Serious generator loading problems may be introduced where several winch motors with direct-on-line starting are in use. Large currents at low power factor cause generator and cable heating. *Table 46.1* gives empirical data for the effective current (in per-unit of the full-load current per winch) of a group of  $n$  winches ( $n > 2$ ). Load-assessment curves are given in the IEE Regulations for the Electrical and Electronic Equipment of Ships.

46.18.2.2 Warping

Warping is frequently done with an additional barrel on care winches or windlasses. A flange prevents the hawser from running over the rim, and at the inner end of the frame a projection prevents it from becoming jammed between frame and warp end. If a foot-brake is fitted, its effect should be limited to the full-load torque of the winch, or torque-limiting relays should be fitted.

46.18.2.3 Capstans

Capstan barrels are normally mounted on a vertical shaft and the motor mounted below deck to leave the deck free.

46.18.2.4 Windlasses

Anchor windlasses are vital to the safety of the ship and have no stand-by. They are subject to classification and governmental requirements. The cable lifter is shaped to fit the links of the cable, and will normally accommodate four or five links around its circumference, although only two links are actually engaged at one time. The lifter can be declutched so that it runs freely for lowering, the speed being controlled electrically or by band brake. A slipping clutch is fitted to prevent excessive stress which could otherwise occur when heaving or when entering the anchor into the hawsepipe. A crawl speed is necessary to enable the anchor to be housed safely and to allow the motor to stall when it is fully home. It is also necessary while the anchor is still holding.

The overall efficiency of a windlass is about 60% and as much as 30% can be lost in friction unless, in accordance with modern practice, rollers are fitted. Windlasses can perform warping duties and extra control refinements are sometimes incorporated for these. They provide for a pull of about one-third of that of the cable lifters but at a greater speed. This speed is also required for recovering lines cast off from the quayside.

46.18.2.5 Mooring winches

Mooring winches are similar to warping winches except that one end of the line is fixed to the barrel.

The St Lawrence Seaway regulations require short-period stalling while docks are navigated, also constant tensioning against rising and falling tides or lock waters and during rapid loading or unloading.

46.19 Remote and automatic control systems

Since 1960 automation of ship's machinery spaces has increased considerably to the point where it is now generally recognised as an indispensable part of modern propulsion plant. In 1981 about 55% of the ships classed with Lloyd's Register of Shipping were designed to be operated with an unattended machinery space (UMS), and approaching 80% of the ships, including those with a UMS notation, had machinery spaces operated from a centralised control station.

Automation has also become indispensable in such areas as cargo handling, disposal by incineration of obnoxious waste, and pollution prevention. With high discharge rates, critical incinerator temperatures and specified limits of contamination, control systems are required to anticipate demand and give rapid response if catastrophes are to be avoided on board or at the terminal.

The proper functioning of control systems demands careful planning, since their viability may be governed by the nature of the ship's trading, the type of machinery to be controlled and the shipowner's manning and maintenance policies. A full specification is required of the extent of control facilities to be provided to ensure compatibility of controls with machinery, the marine environment and the operating personnel.

46.19.1 Operational modes of machinery spaces

Modern applications of control engineering systems permit two basic operational modes of the machinery space: (1) continuously attended, but with a high degree of remote and automatic controls to allow operation from a centralised control station; (2) periodically unattended machinery spaces so that engineers need not be tied to traditional watch-keeping routines and, for example, may leave the machinery space unattended during the night.

On vessels where centralised control is adopted, it is usual to incorporate all controls, alarms and instrumentation in an enclosed control room which is sound and vibration proofed and air conditioned. With the withdrawal of the engineer from the machinery space, it is essential that the controls and instrumentation provided be such that supervision of the machinery plant from the control room is as effective as it would be under direct supervision. The arrangements must give provision for corrective actions to

**Table 46.1** Effective group current (in p.u. of the full-load current of  $n$  similar winch motors in a group, for  $n > 2$ ) of winches

Part of system	D.c. motors (series resistance)	A.c. cage motors	A.c. slip-ring motors	A.c. Ward-Leonard
Cables and switchgear	$0.33n$	$3.3 + 0.3n$	$1.6 + 0.2n$	$1.2 + 0.15n$
Generators	$2.2 + 0.2n$	$5.0 + 0.4n$	$2.0 + 0.25n$	$2.2 + 0.2n$

be taken at the control station in the event of faults such as stopping of machinery, starting of stand-by machinery, adjustment of operating parameters, etc. These actions may be effected by either remote or automatic control.

With the advent of microprocessor-based control systems the concept of centralised control has been extended to incorporate techniques known as 'totally distributed control'. This enables all machinery within specified areas to be controlled and monitored by one integrated system. To implement this, individual microprocessor-based interface units are placed at various locations throughout the machinery space and are interconnected to the central control station by a data link.

Figure 46.9 shows diagrammatically a totally distributed control system. The outstations, interface units, have two functions: (1) to receive data from the various sensors, and (2) to output information to the control actuators. The system is arranged so that information is transmitted to the central station only as and when requested, or when a fault condition develops. If the data link between the central station and the outstation is broken, the outstation is capable of continuing operation.

In order to transmit information from the central station to the outstations, and vice versa, a multiplex system has to be used. This arrangement eliminates the need for inter-connecting individual signals from each outstation to the central station. Multiplexing is a technique whereby each individual signal is given a specific address which can be transferred from one station to another along the cable in a very short time. The address is recognised only by the unit it is intended for, i.e. it will search many 'go-no go' gates until it finds the one 'go'. The information will then be used by the unit for action. Figure 46.10 shows diagrammatically how multiplexing functions.

At the control station the complete operation of the system is organised; it consists of the central computers along with visual display units, keyboards, printers, analogue recorders, etc. In early distributed-control systems conventional analogue controllers were used at the outstations with the facility for the set points to be changed from the central station. However, as microprocessor systems have become more reliable, analogue controllers have been replaced by software generated digital control algorithms. Thus, the desired requirement for each control loop is retained in software rather than hardware. These systems are called direct digital control (DDC) systems. All the facilities that were available with the analogue controllers are built into these DDC systems.

#### 46.19.2 Alarms and safeguards

For periodical unattended operation of a machinery space, all controls and safeguards necessary for centralised control are required, but safety actions must be automatic. In addition, it is necessary to extend the machinery space alarm system to the bridge and accommodation areas so that engineering personnel are made aware when a fault occurs. Control of propulsion must also be extended to the bridge to enable the navigating officers to carry out manoeuvres if the need arises. It is important, when an engineer responds to an alarm and enters the machinery space alone, that other personnel are aware of his well-being. It is usual to configure the alarm system so that the navigating officer is also made aware of a machinery fault, when it is being attended to and when it is corrected. Figure 46.11 shows the functioning of an alarm system to meet these requirements.

**Figure 46.9** A totally distributed control system. A, Operator station alarm; B, operator station control; C, multiplexer and control unit; D, trend recorders; E, magnetic storage unit and general-purpose computer; F, extension alarm system; G, process interface analogue/control and alarms; H, process interface digital/alarms; I, multiplexer unit

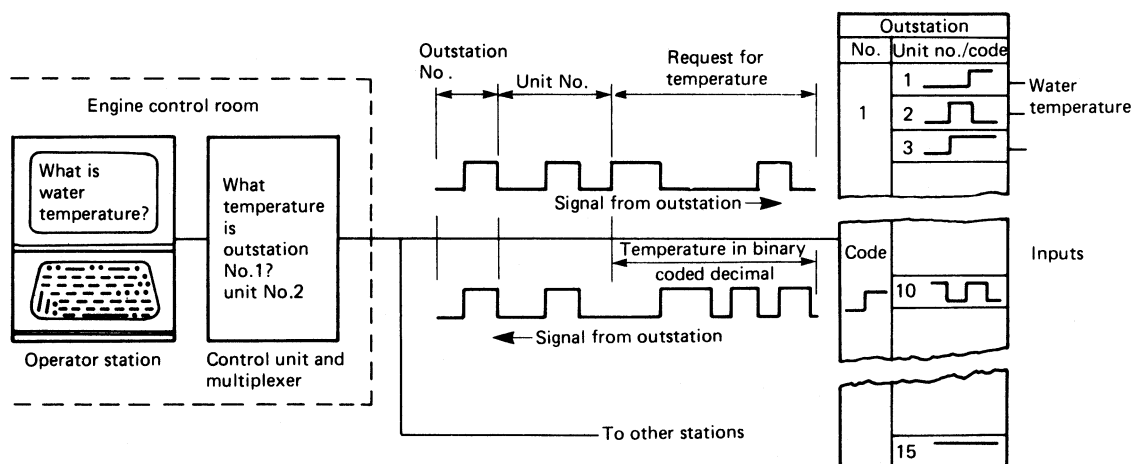

Figure 46.10 A totally distributed control system—form of signal on the data link

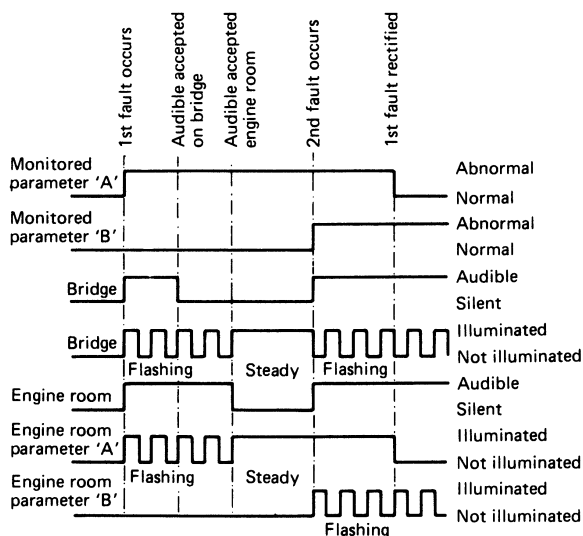

Figure 46.11 Functional diagram for an alarm system

### 46.19.3 Reliability

No matter how comprehensive the control and protection systems provided, they are of little value if the equipment used is not reliable. Experience has shown that many items of control equipment do not operate satisfactorily at sea. Control equipment, designed for use ashore, is all too often unsuitable or unreliable when used on board ship.

In order to improve reliability, the majority of classification societies have adopted and developed criteria to which equipment should be tested. This is known as 'type approval', a procedure whereby a prototype or a production unit is tested under conditions of environmental and mechanical stress that simulate severe shipboard operating conditions.

Basic minimum requirements specified by Lloyd's Register of Shipping include the following.

- (1) *Visual inspection*: to ensure that workmanship is good and materials used are adequate for the duty of the equipment.
- (2) *Performance tests*: to ensure that the manufacturer's specified limits of accuracy, repeatability, etc., are fulfilled.
- (3) *Fluctuations in power supply*: voltage variations, steady,  $\pm 10\%$  with simultaneous frequency variation of  $\pm 5\%$ . Transient,  $\pm 20\%$  voltage with  $\pm 10\%$  frequency. For hydraulic and pneumatic systems supply pressure variations of  $\pm 20\%$ .
- (4) *Vibration tests*: testing in frequency range 1–13.2 Hz at  $\pm 1.0$  mm displacement and 13.2–100 Hz at  $\pm 0.7$  g. Endurance tests carried out at each major resonant frequency for 2 h.
- (5) *Humidity*: 90–100% for 12 h at  $55 \pm 2^\circ\text{C}$ , then reduced to  $20 \pm 5^\circ\text{C}$  over a period of 1–3 h and remaining at the lower temperature for not less than 6 h. This test repeated over two full cycles.
- (6) *Dry heat*: at manufacturer's stated maximum operating temperature if greater than  $55^\circ\text{C}$  for 16 h.
- (7) *Inclination test*: at least  $22\frac{1}{2}^\circ$  each side of the vertical in one plane, repeated in a second plane at right angles to the first.
- (8) In addition, for electrical equipment, high-voltage and insulation resistance tests are required.
- (9) *General*: further requirements may include low-temperature and salt mist tests. As applicable, intrinsic safety certification may be called for.

### 46.20 Tankers

It is of vital importance to take account of bending stresses in the hull resulting from unequal buoyancy. These may arise from ballasting or from different grades of oil, or may occur during loading or discharging. A large number of valves control the filling and unloading of cargo tanks, and these must be operated in logical sequences. Trim and list must also be taken into account. There is obviously a fertile field for computer controlled centralised operation. Because of explosion risks, hydraulic power is favoured for valve operation. For instrumentation and control purposes,

pneumatic and intrinsically safe electronic circuits are suitable, subject to classification approval.

## 46.21 Steam plant

Correct relationship between fuel supply, feed-water supply, temperatures, forced draught, engine load and sea-water temperatures depends on a large number of interdependent controls. Optimum efficiency is rarely, if ever, achieved without some form of automatic control. The essential factors are: (a) maintenance of steam pressure under varying loads by fuel control; and (b) optimum control of combustion air flow and fuel/air ratio.

## 46.22 Generators

Two or more generators are always provided, but for economy it is undesirable to run more sets than necessary for the prevailing load. Preferential tripping of non-essential loads has already been dealt with. This is only a temporary expedient and, to prevent overloading, systems are available for automatic starting, stopping and synchronising of sets according to demand. In confined waters it is necessary for safety reasons to have a margin in reserve, and it is therefore usual practice to have two sets on the board. An overriding provision should be included in automatic schemes.

Advances in technology have led in recent years to the introduction of micro-based systems for efficient power management. Escalating fuel costs and the need for reliable unmanned operation have stimulated this development.

## 46.23 Diesel engines

When bridge control of main propulsion engines is installed, it is necessary to make provision for a repeat start if the first sequence is not completed. After a set number of false starts (usually three) an alarm operates. If acceleration to the firing speed is not reached in about 3 s, a further period of about 4 s is allowed and the complete cycle is then repeated.

For auxiliary generator plant, standby sets can be prewarmed by continuous circulation of hot water from the main engine cooling system. It is usual to bring in another set before full load is reached. However, a short time delay is advisable to prevent starting on a spurious load demand.

## 46.24 Electric propulsion

The popularity of propelling ships using electric motors has varied considerably over the past 80 years, but electrical propulsion has always offered several advantages over traditional mechanical systems. These include, installation flexibility, high torque across the whole speed range, low vibration and noise, smooth variation of speed and reduced fuel consumption and maintenance (not always so in d.c. systems). It should be noted, however, that both the initial cost and size of an electrical system are generally greater than those of mechanical systems.

### 46.24.1 Methods of propulsion

The mechanical power produced by the electric motor may be transmitted to propel a vessel in a number of different ways:

- (1) by direct coupling, or via a reduction gear box, to a conventional fixed pitch propeller (FPP) or to a controllable pitch propeller (CPP);
- (2) by hydrojet thrusters;
- (3) by an azimuthing or fixed ducted propeller assembly; or
- (4) by a cycloidal propeller system.

The electric motor may be the sole means of propulsion, or it may be used in conjunction with a mechanical drive, as in some types of naval vessel. In these types of ship electric motors are used at low speed, often when the vessel is required to minimise radiated noise for sonar activity, and at high speed gas turbines are used to provide the boost power as required.

Steering of a vessel may also be achieved by the propulsion unit, as in the case of the azimuthing propeller assembly, but such systems must conform to specifications as laid down by Lloyds Register of Shipping's Rules and Regulations for the Classification of Ships.

### 46.24.2 Traditional electrical systems

#### 46.24.2.1 D.c. generators, d.c. motors, fixed pitch propellers

In series-connected d.c. systems the generators and motors are all connected in series in one circuit. In the parallel-connected system all generators and motors are arranged in parallel. In both cases the speed and direction of rotation of the motors is changed by varying the generator and motor excitations, as shown in *Figure 46.12*.

Both parallel and series-type systems have been used widely in the past, particularly in ice breakers, but the build up of carbon dust from the commutator brush gear has always been a problem with d.c. systems. As the size of vessels has progressively increased, the popularity of this method of propulsion has declined, and there are only a few vessels still in service employing full d.c. propulsion systems.

#### 46.24.2.2 A.c. generators, a.c. motors, variable-frequency supply

An a.c. generator, often driven by a steam turbine, supplies a synchronous motor. Speed control of the motor is achieved by varying the speed of the prime mover and hence the generator and motor frequency, as shown in *Figure 46.13*. Below 25% of normal speed, i.e. when manoeuvring is being carried out, it is usual to operate the propulsion motor as an induction machine, i.e. with the motor field removed. Precautions need to be taken during this manoeuvring period because high slip-ring voltages can be induced.

During the past two decades there has been a steady decline in the number of turbo-electric systems in operation, mainly because prime-mover limitations make it difficult to achieve high torques at low propeller speeds. The most notable ship still employing such a main propulsion system is the passenger ship *Canberra*, but low-power turbo-electric systems have seen some resurgence for bow thruster applications.

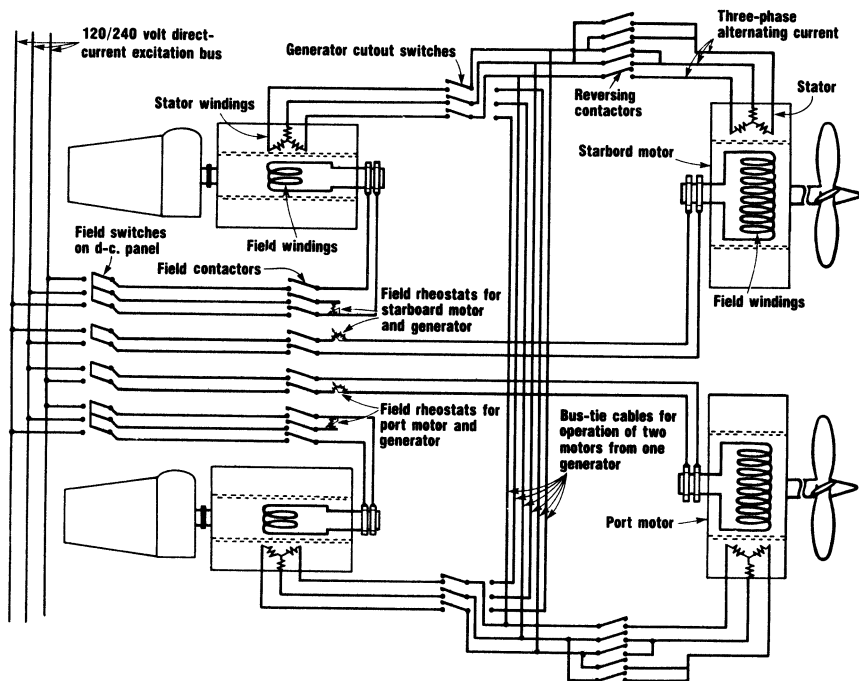

### 46.24.3 Modern electrical systems

The d.c. propulsion motor is normally supplied by a fully controlled bridge rectifier fed from the a.c. generator supply system, as shown in *Figure 46.14*. The speed of the motor is controlled by changing the firing angle of the silicon controlled rectifiers (thyristors), which in turn change the voltage supplied to the armature of the d.c. motor. Motor reversal is easily achieved by reversing the polarity of the field of the motor.

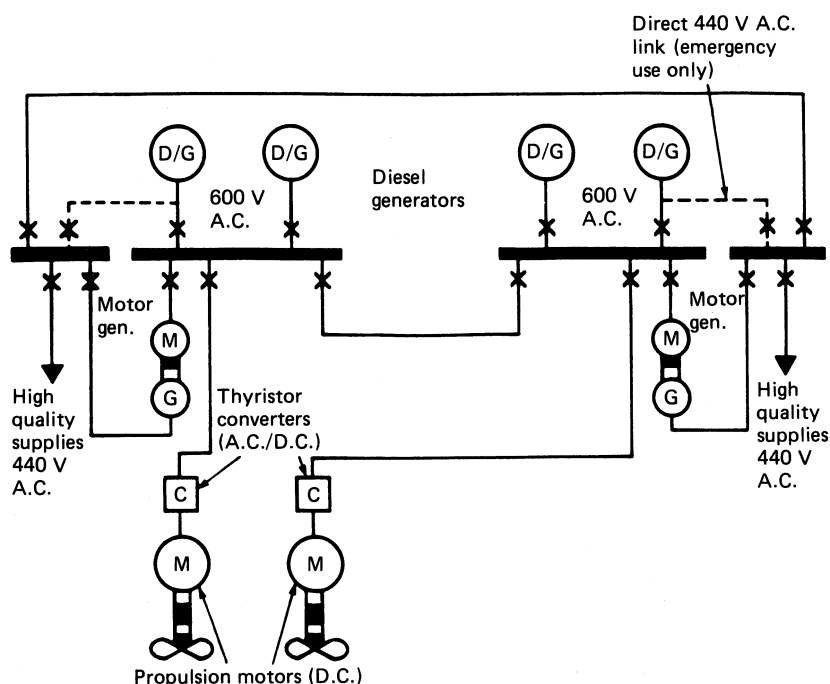

$$1.5 \times 10^6 = \text{Power (kW)} \times \text{Speed (rev/min)} \Leftarrow$$

#### 46.24.3.2 *A.c. generators, fixed-speed a.c. motors, fixed-frequency generation*

In fixed-speed systems a constant-speed a.c. motor is used in conjunction with a controllable pitch propeller, as shown in *Figure 46.15* for a North Sea support vessel. The motor may drive the propeller directly, such as in the system employed in the New Zealand ferry *Arahura*, or via a gearbox, an example of this being the *BP Iolair*. Both synchronous and induction motors are used in these types

**Figure 46.13** Electrical propulsion system with variable frequency generation

**Figure 46.14** A.c. generators/d.c. motor configuration employing motor generator sets to ensure that harmonics generated by the fully controlled converter are not transmitted on to the 440 V a.c. bus-bars

of electric propulsion system, the motors being fed directly from the 50 or 60 Hz generator system or via transformers. Speed control of these vessels is achieved solely by the use of the controllable pitch propeller (CPP), so this type of system is employed in vessels that are operated extensively at high speed or in vessels that require dynamic positioning.

#### 46.24.3.3 A.c. generators, variable-speed motors, fixed-frequency generation

In this type of system the speed of the a.c. motor is controlled by a frequency converter, and is generally used in conjunction with a fixed-pitch propeller, as shown for an ice-breaker in *Figure 46.16*. Shaft-speed variation is achieved by varying the supply frequency to the propulsion motor, since the motor speed is proportional to frequency/number of poles:

$$\text{Rev/min} = \frac{120 \times \text{Frequency (Hz)}}{\text{No. of poles}}$$

A synchronous motor is normally used in preference to an induction motor in many applications. This is because synchronous motors can be manufactured with larger air gaps to withstand arduous mechanical conditions. They can also be operated at unity power factor across the whole speed range, and generally have higher overall efficiencies. In addition, the synchronous motor has the highest power/weight ratio of any electrical machine. Induction motors, because of their reduced construction costs, tend to be used in low-power propulsion systems only.

There are two main types of static converter used to feed the synchronous machines with the variable frequencies they require, the cycloconverter and the autosynchronous

inverter. Both are reversible and, if necessary, both systems can be designed to provide motor braking provided dynamic resistors are included.

Induction motors are generally fed using autocommutated or forced-commutated inverters, although cycloconverters have recently found favour in systems requiring power above 8 MW.

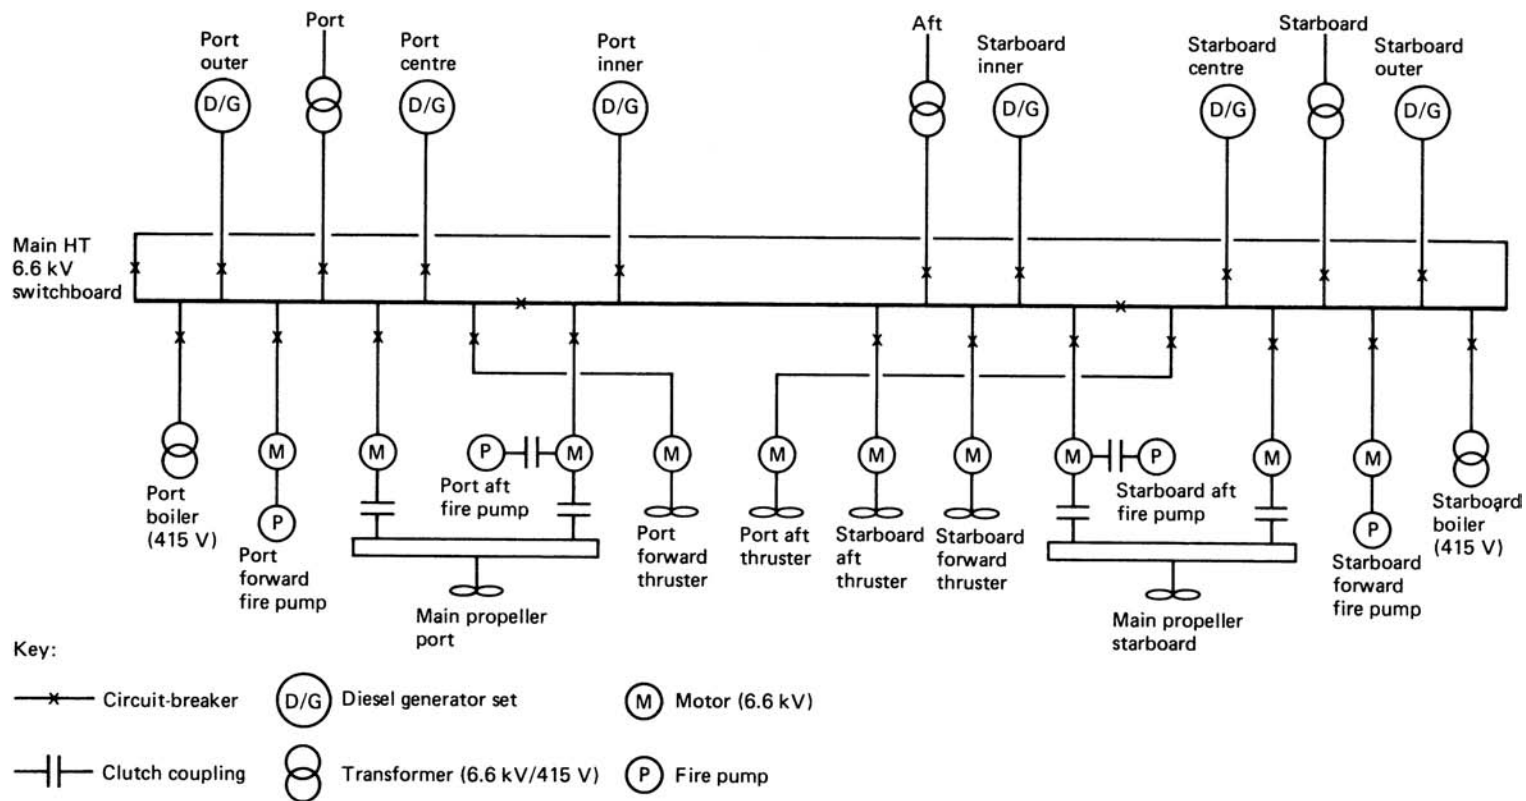

This type of electric drive has become the accepted system in many different types of vessel, including cruise liners and ice-breakers. The *Queen Elizabeth 2* employs a modified version of this system, and includes CPPs for manoeuvring at lower speeds, and an autosynchronous drive that is used for speed adjustment at higher speeds.

#### 46.24.4 Voltage levels and harmonics

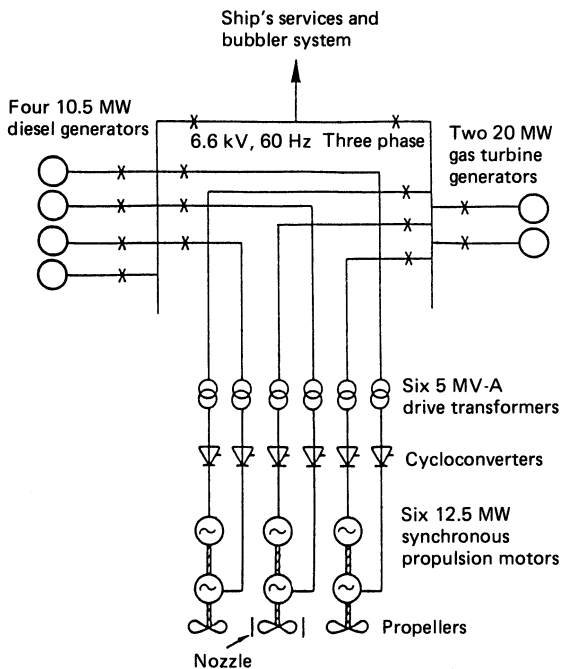

The choice of system voltage for an electric propulsion system is determined predominantly by the size of the propulsion plant and the short-circuit fault currents. Where the capacity of individual generating sets exceeds 2.5 MW, or the fault level under normal operation exceeds 50 MV-A, a high-voltage system is usually selected as specified in Part 6, Chapter 2.1 of the Rules and Regulations of the Classification of Ships. Standard marine high voltages now in use are:

50 Hz	60 Hz
3300 V	4160 V
6600 V	6000 V
	10 000 V

IEC 92:Part 304 also applies to the installation and performance of static converters using semiconductor

**Figure 46.15** A.c. generators/a.c. motor configuration employed on a typical North Sea oil-field support vessel. Speed variation is achieved solely by the use of controllable-pitch propellers

**Figure 46.16** A.c. generators/a.c. motors employing cycloconverter variable-speed drives commonly found on ice-breakers

devices. In ships using converters, harmonic problems, such as electrical resonance, may occur in the electrical system. In some instances the problems can be quite severe, and the high power levels of the converters usually makes in-line filtering impractical. The recommendations for eliminating harmonic problems using motor generator sets, or low-power filters local to the equipment to be protected, is governed by the IEE Regulations for the Electrical and Electronic Equipment of Ships with Recommended Practice for their Implementation 1990.

#### 46.24.5 Electric propulsion employing superconductivity

The development of niobium–titanium d.c. homopolar motors in the UK and USA during the 1960s demonstrated that high shaft torques could be produced with almost no motor power loss if the motor could be cooled using liquid helium. An electromagnetic thruster system has been developed in Japan. In this system superconducting coils are used in a linear motor configuration. An electric current is passed through sea-water and a propulsion thrust is generated without the use of rotating propellers. The disadvantage of superconducting systems is that large cooling plants are required to maintain the motors at the very low temperatures needed ( $-268.6^{\circ}\text{C}$ ). Recent research has been directed towards obtaining super-conductivity at ambient temperatures using ceramics rather than alloys but, although significant advances have been made, it is unlikely that super-conductivity will become a viable commercial option in the near future.

#### 46.24.6 Electromagnetic slip couplings

In diesel-engined ships in which the propeller is driven through mechanical reduction gear, up to four engines per shaft can be coupled to the gear through slip couplings. It is necessary to protect the gears from torsional vibration transmitted by the engines, and the slip coupling serves both this purpose and that of a disconnecting clutch, enabling the numbers of engines in service to be altered without stopping the engines already operating. A typical four-engine arrangement is shown in *Figure 46.17*.

Manoeuvring can be carried out by having some engines running ahead and the others astern and selecting the direction required by switching.

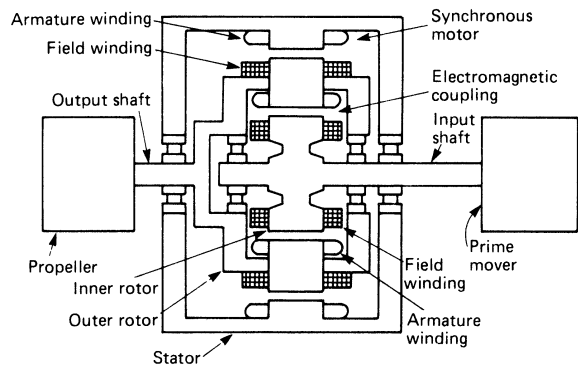

A coupling can exert a starting torque from rest, with the engine at full speed, equal to full-load torque. The efficiency is high, the only losses being windage, excitation and the  $I^2R$  loss due to slip. Slip varies with speed and rating and is generally 1–2%.

#### 46.24.7 Electromagnetic gearing

Elements of a speed reduction and reverse gear which can also act as an auxiliary a.c. generator, clutch and flexible coupling are shown in *Figure 46.18*. An inner rotor carries the input shaft, field windings and slip-rings. The outer rotor carries the electromagnetic coupling armature winding on the inner side which is connected, through a switching device, to the synchronous motor field windings on the outside, and two sets of slip-rings.

## 47.1 Introduction

Modern aircraft have come a long way since the Wright brothers built their first aircraft in their bicycle shop in Dayton, Ohio, and made the first powered flight of an airplane in 1903, at Kitty Hawk, North Carolina. This first crude biplane, however, embodied the two basic elements of all modern airplanes; namely a propulsion system and lifting devices (wings). Since that time, the technologies of propulsion and wings have made significant strides in the science of aviation.

Progress in technology, as in medicine, is stimulated significantly during wartime and World Wars I and II played a major role in advancing the basic design concepts of the modern (military and civil) airplane, as well as bringing about major improvements in the power plants. Prior to World War II, aircraft were powered initially by internal combustion engines in the 1600–2800 hp range, but during that war the first jet-powered aircraft emerged.

## 47.2 Engine technology

From the simple rudimentary two-stroke gasoline piston engines developing a mere 60 hp, engines moved from the small 150 hp piston engines that powered the World War I biplanes (such as the Bristol Bulldog, Sopwith Pup, Avro 504, the French SPAD and the German Fokker aircraft) to the 1600 hp/1800 hp 'radial' and 'in line' piston engines that were used in the four-engined bombers in World War II. The radial engines were designed for propeller/ram-air cooling: the air stream from the former being used to provide blast-air cooling of the 'finned' piston housings (during static conditions on the ground) and ram-air cooling, during taxi and flight conditions. The 'in-line' engines, in contrast, were liquid cooled, as exemplified by the Rolls-Royce Merlin engine that powered the early Spitfire at some 340 mile/h in its record-breaking test run at a Schneider Cup Race in 1927. The advantages of the 'in-line' engine in this case were its low frontal area, which permitted power-plant streamlining and, therefore, reduced power-plant drag.

From these early World War II engines, the designers explored other piston-engine technology such as Bristol's 'sleeve-valve' engine, named the Centaurus, that had a take-off power rating of approximately 2800 hp. This engine was unique in that it eliminated the complex 'poppet-valves', with their push rods, cams, etc. In the Centaurus engine, the equivalent of the conventional inlet/exhaust valves was provided by an inner 'sleeve' cylinder, within the piston housing, that had machined ports (openings) that successively exposed the inlet and exhaust manifolds to the combustion chambers; as the sleeve moved up and down with an oscillatory motion. Napier also developed a double '12-pot' engine arranged with the rear 12-pot engine 'staggered' (for cooling purposes) behind the first: this 24-cylinder engine was rated at 2850 hp. Another novel engine development by Napier was the Nomad engine which uniquely combined a turbine engine with a diesel engine, to yield attractive fuel and weight savings. The following is Napier's weight estimate of typical four-engined aircraft, carrying the same payload over a range of 2860 miles.

4 × turbojets (10 000 lbf each) 153 000 lb total  
 4 × turboprops (3780 shp each) 140 000 lb total  
 4 × compounds (3780 shp each) 123 500 lb total

(where lbf is pounds-force and shp is shaft horsepower).

Higher horsepower engines were developed in the 1940s and were used during World War II. The most notable US fighter at that time was the Curtiss I-40 Warhawk which used an Allison 12-cylinder liquid-cooled in-line engine that developed 1200 hp. This period was also of note in that engine (propulsor) technology moved on from the internal-combustion-engine design to the turbojet and turboprop designs. Frank Whittle's gas turbine engine, built and tested in 1930, was the precursor of these jet engines which were to set the trend for these advanced propulsors in the military and commercial aircraft. The first early military aircraft application of the jet engine in World War II was in Germany's Messerschmitt Me262A which had a maximum speed of 540 mile/h. This jet-engine-powered aircraft was followed by the UK's Gloster-Meteor aeroplane with two Rolls-Royce Derwent engines, developing 2000 lbf each: these two engines provided the Meteor with a top speed of 520 mile/h.

Early turbine engines were rated in the 2000–5000 lbf range, but this was soon to increase to 10 000 and 20 000 lbf. The Pratt & Whitney PW7000 is an example of a modern 20 000 lbf engine.

During the 1950s, engine thrusts increased to 48 000 lbf as in the case of the Rolls-Royce RB.211, the GE-CF6 and United Technologies P&W JT-9D engines. These engines powered the Lockheed L-1011, Douglas DC-10, Boeing B-747 and many other aircraft. These engines foreshadowed the emergence of even larger engines, in the 80 000–100 000 lbf range, which will power the Boeing B-777X and other new aircraft.

During these years, the engines were defined as 'low-pass' and 'high-pass' engines. In the latter type an increasing amount of the ram-air was bypassed around the 'engine core' and then mixed with the core-flow air in the 'nozzle': such engines are known as 'turbofans'. To pump the bypass air, a large 'fan' was mounted in the front of the engine and this was powered by the engine's low-pressure turbine, which furnished the necessary shaft power for the fan.

The thrust power developed by these engines was derived by accelerating the air-mass flow through the engine to effect a significant change in air energy momentum ( $\text{lbf} \equiv \text{MN}$ ). Fuel economy being a quintessential objective of all modern aeroplanes, engine technology was directed toward increasing engine compressor ratios, decreasing tolerances and improving the science of high-temperature metallurgy. These high-temperature materials were developed primarily for the hot turbine sections of the engine to permit higher turbine inlet temperatures. These advanced metallurgical developments led to the use of high temperature aluminium alloys, titanium alloys and Inconel. Ceramic-coated turbine blades were also used in the first and second turbine stages to permit turbine inlet temperatures in excess of 2500 °F. The following is the power relationship of typical gas turbine engines.

$$\text{HP}_t = \Delta^\circ F \times \text{pps} / 2.95 \quad (47.1) \Leftarrow$$

where

$$\Delta^\circ F = T^\circ R \times \left[ 1 - \frac{1}{(\text{PR})^k} \right] \eta_t$$

$\eta_t$  is the turbine efficiency,  $k$  is the ratio of specific heats,  $\text{HP}_t$  is the turbine horse power, pps is the engine core flow in pounds per second, PR is the (turbine) pressure ratio,  $T$  is the temperature,  $R$  is the gas constant,  $\Delta^\circ F$  is the temperature drop across turbine, and  $T^\circ R$  is the temperature in degrees Rankine ( $T^\circ F + 460$ ).

As a concomitant technology objective, turboshaft engines were developed in which nearly all the core energy of the engine was converted to shaft power, rather than thrust power. From the earlier 1600–2800 shp ratings of

World War II, large turboshaft/turboprop engines were designed, worldwide, in ratings up to 5500 ehp (equivalent horsepower) and higher. In these engines, the residual thrust power in the engine nozzle was added to the shaft power to provide a total 'equivalent' horsepower. These turboshaft engines found wide application in aircraft, marine and utility installations. The turboshaft engines were particularly suitable in aircraft where fuel economy was a key consideration. Typical of these aircraft were the antisubmarine warfare (a.s.w.) and the aircraft early warning (a.e.w.) aircraft, which were required to remain 'on station' for anywhere from 10 to 20 h. Another example of a 'widely used' turboshaft-powered aeroplane is the Lockheed C-130 (Hercules) which has a take-off gross weight of approximately 155 000 lb and is powered by four Avco/Lycoming T-56 engines rated at approximately 4500 eshp each: this aircraft has a payload capacity of approximately 44 000 lb.

Marked improvements in fuel efficiency (low specific fuel consumption) are obtained with turboprop engines compared to turbojet aircraft. In fact the engines are 'propfans' which use large highly curved, highly twisted blades that deliver superior performance, *vis à vis* the conventional turboprops.

Helicopters are also prime users of turboshaft engines as in the case of short take-off and landing (s.t.o.l.) and vertical take-off and landing (v.t.o.l.) aircraft. The US V-22 Osprey is an entirely novel application of a turboshaft v.t.o.l. airplane in which the turboprops are rotated vertically for take-off and translated back to the horizontal position during flight. The significant design advantage of this is that where the speed of a conventional helicopter is limited to a percentage of the propeller-tip speed to some 140–180 mile/h, the V-22 can operate as a conventional turboprop aeroplane, in straight and level flight, and achieve speeds of 300 mile/h and above.

Turboprop engines are exemplified by their fuel efficiency and by their fast response to changes in power settings, which derives from the fact that the propellers typically operate at constant speed and the thrust power is changed simply by a change of the propeller pitch. The manoeuvrability and the ability of turboprop aircraft to execute a short take-off run and a rapid pull-up (after take-off) are, therefore, the main attributes of these aircraft. These turboprop aircraft are also very fuel efficient and this commends them to a.s.w. and a.e.w. roles.

In addition to the unique applications of the turboshaft/turboprop engines, a.s.w. aircraft such as the Lockheed S-3 (GE-TF-34 tf), Lockheed P-3 (4 × Lycoming T-56 tp) and a.e.w. aircraft such as the Grumman E-2C (2 × Lycoming T-56 tp), Boeing E-3A (4 × P&W TF33 tf) used turboprops and turbofans. These a.s.w./a.e.w. aircraft are the backbone and workhorse of the US patrol and surveillance activities.

For reconnaissance activities, the US used the McDonnell-Douglas RF-4C (2 × GE-79 tj), Northrup's RF-5E (2 × GE-85 tj), but the most notable reconnaissance aircraft were the Lockheed SR-71 (2 × P&W J-58 tj) and the Lockheed U-2 aircraft (1 × P&W-75 tj).

To improve the fuel-efficiency of the turbojet engine, NASA sponsored and funded the development of the energy-efficient engine (e.e.e.). This engine is identified by a very high bypass ratio and a very small core section. For these fuel-efficient engines, the number of compressor stages was increased and the compressor ratio changed from the typical value of 16:1/20:1 and later 60:1. A caveat, implicit in the e.e.e., is that its low amount of core-flow air makes it very sensitive to compressor bleed-air extraction. As a result, its prospective use for powering passenger services such as the environmental control system (e.c.s.) and engine/wing de-icing is highly penalising to the engine's aerothermodynamic efficiency.

## 47.3 Wing technology

In the preceding section an overview was given of the significant progress in aircraft propulsion technology, as derived from the design and development of the internal combustion engine, the turbojet, turbofan, turboprop and the energy efficient engines. It is axiomatic, however, that unless the engine technologies were matched by comparable air frame/wing technologies, they would abrogate and offset the benefits of the new engines.

The two key elements highlighted for aircraft efficiency are the 'engine' and 'wing' technologies. Fortunately, these technologies have seen major advances in the last 30 or more years, resulting in outstanding military aircraft such as the World War II Spitfire, the Lockheed F-104G, the Lockheed P-38, the Messerschmitt Me262A, the USSR MIG-24, the French Mirage and many other high performance military aircraft built in the USA, Europe and other countries worldwide. Similar aerodynamic improvements were implemented in commercial aircraft such as the Boeing B-757/B-767, B-727, the Lockheed L-1011, Douglas DC-10, the BAC A-320/330, as well as many European and Russian/Chinese commercial aircraft.

In the following discussion, wing technology is reviewed from the standpoint of the different wing plan forms and their respective advantages *vis à vis* high lift/drag efficiency, etc. Simply, an aeroplane's operating efficiency  $\eta_{sc}$  can be defined as

$$\eta_{sc} = \frac{M}{L} \times \frac{L}{D} \quad (47.2) \Leftarrow$$

where  $M$  is the mach number,  $L$  is the lift and  $D$  is the drag.

Figure 47.1 shows a number of 'optional' wing plan forms, which the aircraft designer evaluates from the standpoint of which parameter best fits his particular airplane. Where 'fuel efficiency', for example, is key (because it impacts on the direct operating costs), a wing with a high aspect ratio is desirable. (Note: the aspect ratio may be defined approximately as the relationship of the wing span to the average wing mean chord.)

When fuel efficiency is the important design option, an aspect ratio of 10:1 to 15:1 would be efficacious, recognising that these are heavier wings. However, if 'acquisition costs' are important, then (at the other end of the scale) an aspect ratio of 7.5 would be appropriate. Clearly, there is no single 'optimum' aspect ratio that meets all criteria, so the designer must make an acceptable compromise. Aircraft weight and wing weight are important to the overall performance of an aeroplane so the designer's objective is to achieve a maximum  $L/D$  ratio for a minimum wing weight. An integral part of this design activity centres on an evaluation of wing materials that yield the maximum strength-to-weight ratios. Other than this, composites (non-metallic materials) such as Kevlar (aramid and graphite), light-weight materials, such as new aluminium alloys, titanium, lithium alloys, etc., are candidates. Most composites have the advantage that double curvatures and unique aerofoil configurations can be fabricated, which are difficult to achieve with metallic structures.

The wing 'aerofoil' cross-section is another key aspect of wing performance and the wing camber must be such as to optimise the lift and suction forces across the wing. The important objective is to obtain a laminar airflow over as much of the wing as possible and to delay the break-up of airflow, which results in turbulence and drag. Addressing such wing designs, aerodynamicists have developed customised aerofoil sections (such as used in 'supercritical' wings), whose distinctive aerofoil section keeps the airflow laminar, over much of the wing's forward cross-section. Complementary to this, the designers have evaluated and

Figure 47.1 Design aspects of wing aspect ratio transport

developed 'natural' and 'forced' techniques of laminar flow control. In the former case, natural laminar flow is accomplished by an efficient wing-camber design, such as the 'supercritical wing'. With forced laminar flow control, a complex wing manufacturing design is involved in which slots or small openings are fabricated in the wings to permit the wing's boundary air to be sucked close to the wings, by means of 'suction air' derived from engine compressor bleed air.

Wing design is a key to fuel efficiency. Figure 47.2 shows a comparison of an early wing design and an 'advanced' wing design; the latter is derived from computer modelling, wind-tunnel testing, etc. The curves show that the advanced wing design yields a 11–12% improvement in fuel consumption (at the 25% and 40% positions of the wing's mean aerodynamic chord (m.a.c.)). Furthermore, as the

centre of gravity (c.g.) moves aft of these neutral points, another 1.5–3.0% improvement can be achieved. However, when the c.g. travels to 35% m.a.c., it reaches a point of relaxed static stability (r.s.s.) and, further back, to a point of 'negative' static stability, where the aircraft becomes longitudinally unstable. In this condition, the pilot cannot fly the aeroplane manually and must rely on a sophisticated (and highly reliable) stability augmentation system (s.a.s.). This type of system dictates the adoption of an electronic flight control system, known as a *digital flight control system* (d.f.c.s.). Apart from providing stable flight management (of a basically unstable aircraft), the primary function of the d.f.c.s. is to reduce the trim drag on the tail of the aeroplane. This trim drag is due to a down force on the tail, when the c.g. of the aeroplane is forward of the wing's m.a.c. and it results in a fuel penalty.

Figure 47.2 Lift/drag versus centre of gravity (c.g.) position. m.a.c., Mean aerodynamic chord

## 47.4 Integrated active controls

A fall-out 'benefit' from the adoption of a sophisticated d.f.c.s., is a reduction in wing weight which can be achieved by the use of integrated active controls (i.a.c.s). Active control technology (a.c.t.) involves a duplicative use of the ailerons, such that the ailerons can be operated symmetrically in addition to their normal (differential) mode of operation. The purpose of a.c.t. is to modify the spanwise wing-lift distribution from the wing root out to the wing tip. Normally, the spanwise wing-lift distribution is elliptical as shown in *Figure 47.3*, but when a.c.t. is used the wing-lift distribution is reshaped as indicated. This results in a reduction in the wing-root bending moment, to permit either a lower weight wing design or a wing design with a higher aspect ratio. Lockheed opted for the latter in the L-1011 aeroplane and added a 3.2 ft extension on each wing to achieve a higher aspect ratio wing and a more fuel-efficient aeroplane.

In summary, it is clear that aircraft designers have kept up with engine designers and have taken advantage of minimum-weight materials (and composites) to achieve efficient aerofoil designs. These physical changes, when combined with the use of a.c.t., have enabled the aeroplanes to operate in regions of r.s.s. and so achieve improved fuel efficiency (see *Figure 47.2*). When a.c.t. is applied to the three axes of the aeroplane it affords fuel-saving benefits. The Boeing B-757/769, Douglas MD-11 and the Airbus Industrie A-310/A-330 series (and other aircraft) exemplify the application of sophisticated flight-control systems.

Figure 47.3 Spanwise wing-lift distribution

## 47.5 Flight-control systems

Historically, the flight-control surfaces in early aircraft were operated directly by mechanical control cables (or torque tubes) running between the control stick and the surfaces. Such mechanical controls were in fact still used on modern aircraft such as the Lockheed L-1011. These systems though reliable are mechanically complex, as they involve many bell cranks, walking beams and differential levers, etc. The complexity of the design, the close manufacturing tolerances and the necessary adjustments (to minimise backlash problems, etc.) characterise this as a high maintenance support flight-control system. Given the prospective obsolescence of such mechanical systems, the aerospace industry moved to the adoption of electric/electronic flight-control systems based on the use of fly-by-wire (f.b.w.) and power-by-wire (p.b.w.) systems.

In a f.b.w. system, triple or quadruple redundant computers transmit a serial digital bit stream to the power electronics of the remote f.c.s. actuators, which operate the control surfaces. A block diagram of a typical f.b.w./p.b.w. system is shown in *Figure 47.4*: the actuators can be duplex hydraulic jacks, electric or electrohydraulic. A view of a typical rotary electric actuator shown in *Figure 47.5* is used for spoilers.

Early f.b.w. systems used analogue data transmission and they go back to the early applications in the Mercury Space Vehicle (1960) and the XV-4B experimental aeroplane (in the mid-1960s): the US Air Force F-8 (1974) was the first aeroplane to adopt a *digital* flight control system (d.f.c.s.) (see *Figure 47.6*).

As discussed in Section 47.3, modern d.f.c.s. brought to commercial and military aeroplanes benefits that were not possible with mechanical control systems. In addition to the ability to fly unstable aircraft, i.a.c.s. provided better 'ride quality', eliminated (or damped) incipient wing-flutter conditions and allowed the aeroplane to fly through strong gust conditions without structural damage (*Figure 47.7*). Computerised flight control (with different flight options) also became possible and autoland systems were implemented that could meet the FAA's (Federal Aviation Association) category IIIb/IIIc class conditions for landings in low-visibility conditions.

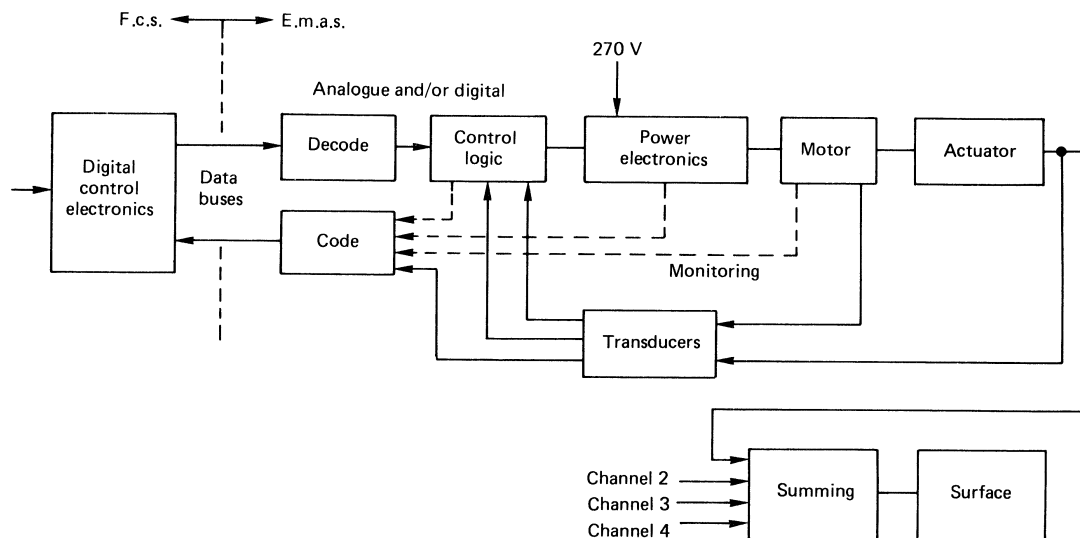

Figure 47.4 Digital fly-by-wire/power-by-wire system

**Figure 47.5** Typical rotary electromechanical actuator. (Courtesy of Sundstrand Aviation)

In the military aeroplane, manoeuvre load control (m.l.c.) is a feature that can be added to the d.f.c.s. and this enables the pilot to pull high g forces, during tight combat manoeuvres, without exceeding the vehicle's structural load limits. The d.f.c.s. also provides superior flight-management features in high-performance aircraft, which use interactive engine/f.c.s. controls. In these aircraft, the engine's two-dimensional thrust-vectoring system complements the flight-surface controls. The engine's sophisticated management system is typically effected via a computerised full authority digital electronic control system. These technologies are key to the complex control and flight management of aircraft such as the Harrier, AV-8A and other sophisticated aircraft.

## 47.6 Systems technology

Whilst an aeroplane's performance and operation are strongly tied to the engine, wing and f.c.s. technologies, the

aeroplane is also strongly dependent on systems technology. As an aeroplane's 'propulsor system' is its 'primary' power source, the systems are defined as the *secondary power system* and they consist primarily of:

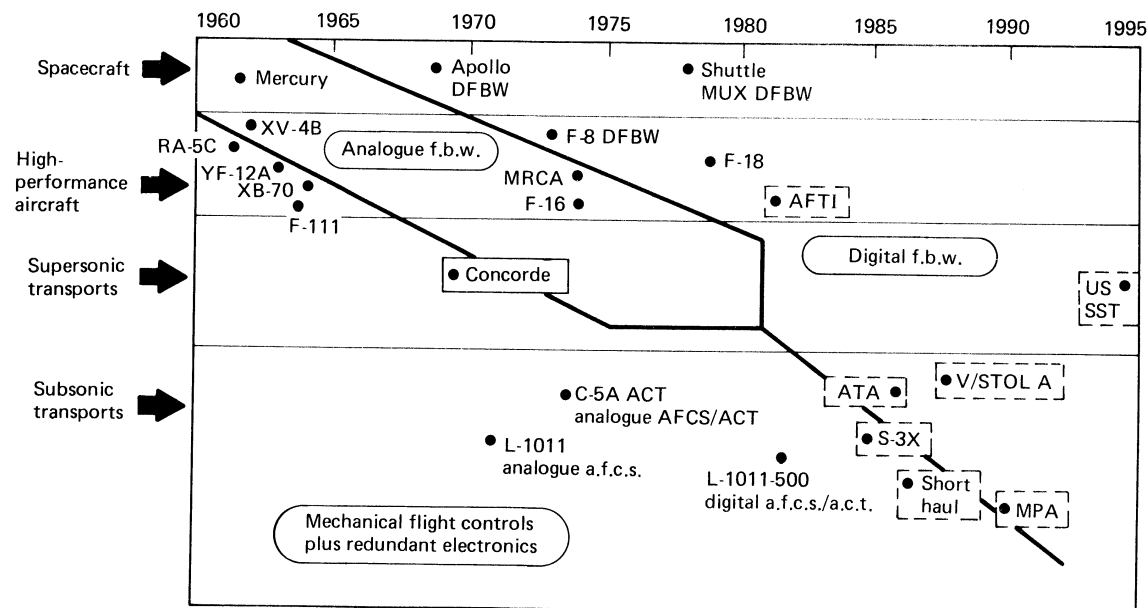

- (1) engine bleed air,
- (2) pneumatic,
- (3) hydraulic, and
- (4) electric.

As associative (dependent) parts of these 'power-source' systems, there are 'utility' or 'subsystems' such as the environmental control system, landing gear system, nose gear steering system, thrust reversing/wheel braking system, hydraulic, pneumatic and electric systems. These subsystems all extract power from the propulsor system (in pneumatic, hydraulic or electric form).

In a turbojet aeroplane, pneumatic power is extracted from the engine's compressor via annular 'taps' at the mid and last stages of the compressor. This high-pressure high-temperature air is then used typically for 'hot-wing' deicing, where hot pressurised air is injected into a double-wall leading edge via 'piccolo' tubes and manifolds with 'stub outs'. Engine deicing and engine starting are also normally powered by engine bleed air.

Pressurisation and cooling of the cabin/cockpit air-conditioning system are normally accomplished with bleed air by ducting the air from the power plants up to the flight station, where 'air-cycle packs' are located. Each of these packs comprises a bleed-air-powered turbine which drives the compressor (mounted on the same shaft) and at the same time provides expansion cooling as the air passes through the turbine. The air-cycle pack is lightweight and compact, because the turbo machinery runs on air-foil bearings at speeds of 80 000 to 100 000 rev/min.

In addition to providing bleed-air power, the engine normally has a 'waist-section' gearbox (located at the 60/C position) which provides multiple output (flange) pads to drive fuel/lube pumps, hydraulic pumps and electric generators. The engine gearbox also typically carries a pneumatic

**Figure 47.6** Genealogy of fly-by-wire systems

Figure 47.7 Benefits of integrated active controls

starter. Figure 47.8 shows a typical transition from a conventional accessory gearbox to an all-electric configuration using an integrated engine generator/starter.

A typical accessory gearbox configuration is that mounted on the Rolls-Royce RB.211 engine. This is of a novel modular design, being driven by a power shaft from the high-pressure spool. The accessory gearbox and its accessories are typically cooled by engine-driven oil-lube pumps. The Rolls-Royce RB.211 is classified as a 'high bypass' turbofan engine which is able to furnish low and high pressure bleed-air; however, at high altitudes (35 000 to 42 000 ft) the engine core flow is much decreased, compared to low-altitude core flows. In a large commercial aeroplane carrying 300–400 passengers, there is a large e.c.s. bleed-air demand that, unfortunately, remains constant up to the high altitude and, thereby, creates an unfavourable fuel penalty. In contradistinction to this, if the e.c.s. were powered electrically the fuel penalty would only be some 25% of the bleed-air penalty. The difference between the thrust loss as applicable to the RB.211 in a commercial transport aircraft such as a Lockheed L-1011 or a McDonnell-Douglas DC-10 is shown graphically in Figure 47.9.

## 47.7 Hydraulic systems

Almost without exception, hydraulic systems (in past and current aircraft) used direct or indirect, engine-driven pumps that were typically of the constant-pressure/variable-displacement type. These pumps operated with delivery pressures of 3000, 5000 or 8000 lb/in<sup>2</sup> and at typical flow rates of 5–65 gallons per minute (gpm). The pumps normally have good efficiency (80–85%) at high flow rates, but at low flow rates, the efficiency falls off sharply. Therefore, under conditions when the flaps, spoilers, slats and landing gear have all operated (and the aircraft is in cruise flight) the fluid demand is very low, but the pumps still deliver some 92% of the take-off flow rate; consequently, there is a major mismatch between supply and demand! Another problem with conventional hydraulic systems is that the pumps exhibit constant heat dissipation, regardless of the flow rates (Figure 47.10). As a result, a comprehensive oil-to-fuel thermal management system is required.

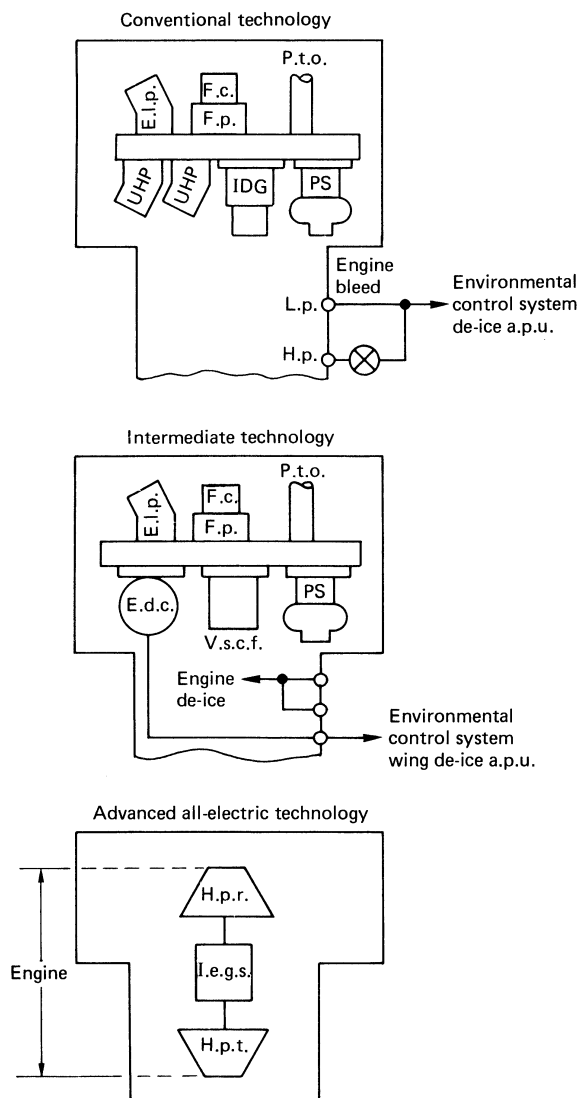

Figure 47.8 Secondary power system transition. E.l.p. engine lube pump; f.c., fuel control; f.p., fuel pump; u.h.p., utility hydrogen pump; i.d.g., integrated drive generator; p.s., pneumatic str.; e.d.c., engine driven component; h.p.r., hydraulic-pump rotor; h.p.t., hydraulic-pump turbine; i.e.g./s., integrated engine generator/str.; p.t.o., power take-off; v.s.c.f., variable speed constant frequency; a.p.u., auxiliary power unit

Hydraulic systems are, in the main, complex labour-intensive systems that comprise accumulators, reservoirs, pressure regulators, filters, noise attenuators and other fittings; but it is the 'distributed' hydraulic system that introduces the main problems of hydraulic systems because of leakage and contamination problems associated with the use of long fluidic lines.

In the majority of aircraft, the sources of hydraulic fluid power are typically pumps driven off the engine's accessory gearbox or off air-frame mounted accessory drives (see below). The latter are normally associated with high performance, small aircraft and their characteristics are discussed later in this text. In a centralised hydraulic system, one or

Figure 47.9 Thrust loss/bleed air versus shaft power extraction

Figure 47.10 Typical performance curve for a hydraulic pump

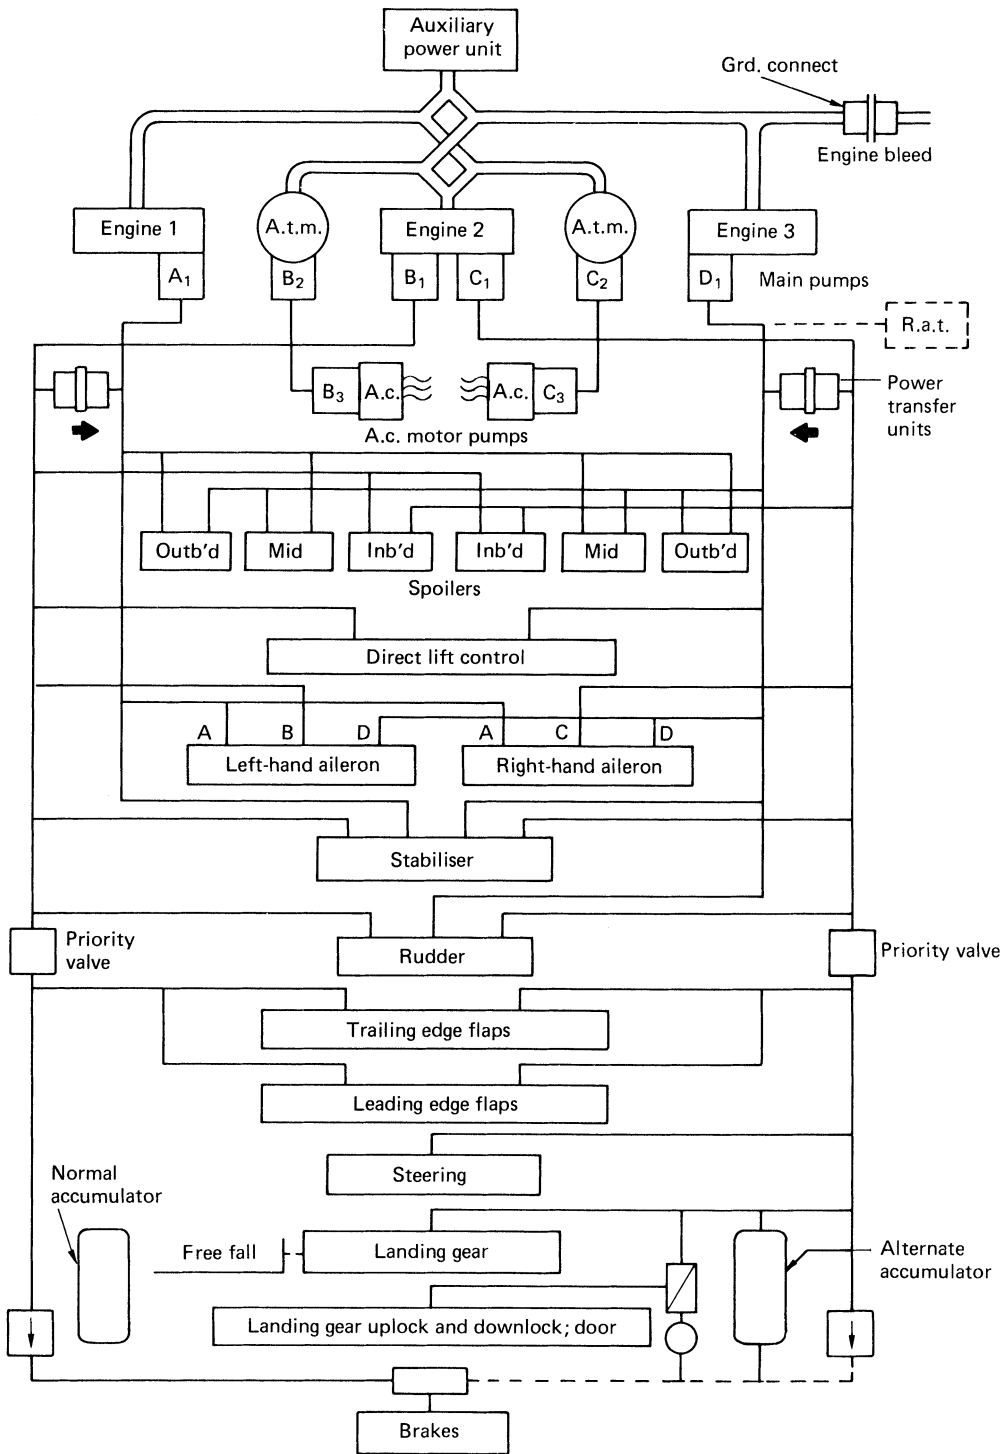

Figure 47.11 Diagram to show the location of the hydraulic bays in the Lockheed P-7A ASW

more 'hydraulic load centres' are set up in the aircraft and the engine pumps feed into these load centres from which the hydraulic power is then distributed to the hydraulic loads (flaps, slats, landing gears, etc.). A multiple load-centre configuration, as used in the Lockheed P-7A ASW aeroplane, is shown in Figure 47.11.

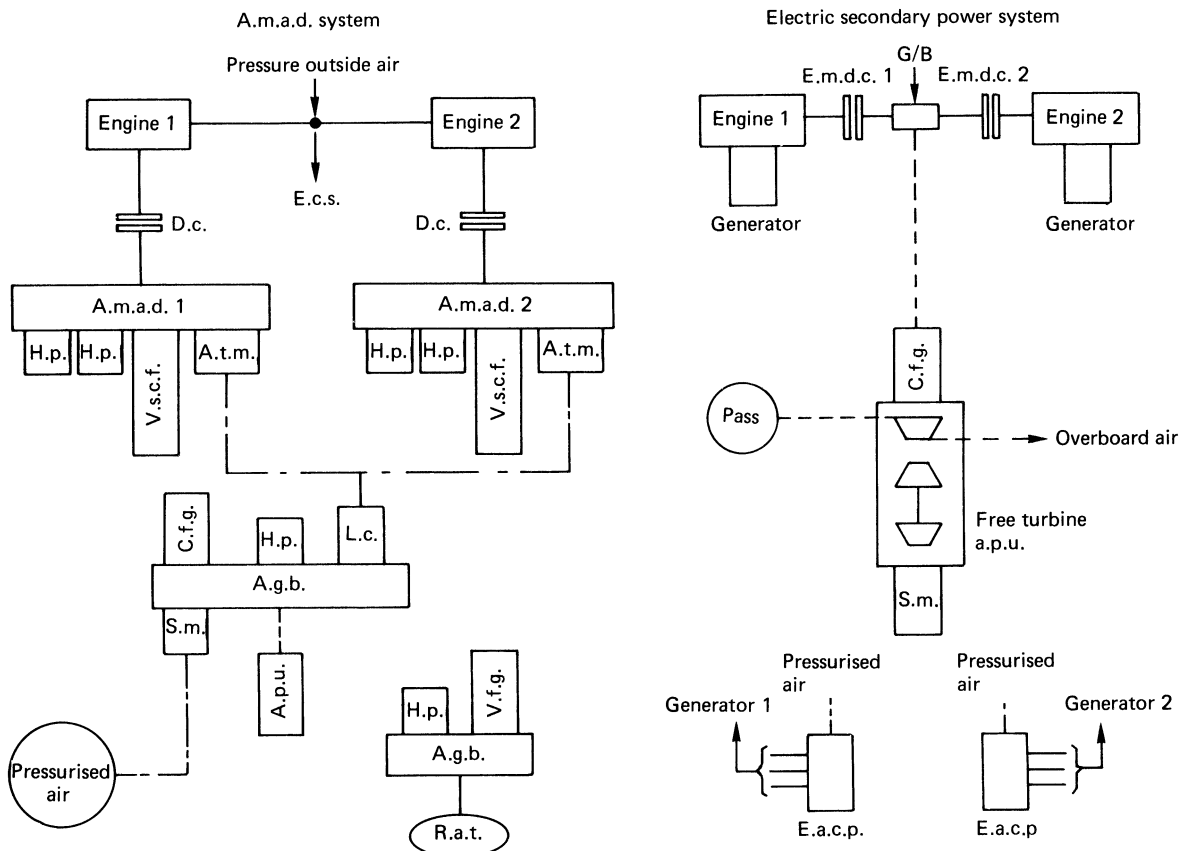

In both these systems, many, many high-pressure (3000, 5000 or 8000 lb/in<sup>2</sup>) lines thread their way through the aircraft creating a difficult physical installation. Also, because of vibration, the line joints are exposed to incipient leakage problems and, in military aircraft, to prospective fire hazards when missiles penetrate the aeroplane. The facts, nonetheless, are that hydraulic systems have a significant historical record of reliability over 40 years, and it is difficult to compete with the simplicity of a duplex (double piston) hydraulic jack. Furthermore, it is only recently that electrics could be used to take over the hydraulic functions such as landing gears, and the more sophisticated loads associated with the aircraft's primary/secondary flight-control surfaces. A new trend, however, has now been established under the umbrella of the US Airforce/WRDC MEL programme, which could lead to the use of electrohydraulic and electric actuators (see later sections). A typical two-channel hydraulic configuration is shown schematically in Figure 47.12.

## 47.8 Air-frame mounted accessory drives

The secondary power system normally comprises direct engine-driven electric generators (or integrated drive generators (i.d.g.s)) and hydraulic pumps. These accessories are typically mounted on a 'waist-section' accessory gearbox (a.g.b.) normally located at the 6 O/C position on the engine. On the Lockheed L-1011 aeroplane all the accessories such as the engine lube/fuel pumps, tachogenerators, generators and hydraulic pumps are driven by this gearbox. However, in advanced performance aircraft, such as the US Air Force YF-22 and YF-23 aeroplanes, two air-frame mounted accessory drives (a.m.a.d.s) are remotely driven (via disconnectable drive shafts) and the secondary power system components are mounted on these gearboxes.

**Figure 47.12** Dual hydraulic system. a.t.m., Air turbine motor; r.a.t., ram air turbine. (Courtesy of Lockheed Aeronautical Systems Co.)

**Figure 47.13** Comparison of a.m.a.d. and electric secondary power systems. a.m.a.d., Air-frame mounted accessory drive; d.c., disconnect coupling (engine); e.c.s., environmental control system; h.p., hydraulic pump; v.s.c.f., variable speed constant frequency; a.t.m., air turbine motor; a.g.b., accessory gearbox; e.a.c.p., electric air cycle pack; a.p.u., auxiliary power unit; c.f.g., constant frequency generator; r.a.t., ram air turbine; e.m., electric motor; l.c., load compressor; s.m., ...; v.f.g., ... Engines are turbojet/turboshaft engines

The reason for the a.m.a.d. configuration in the advanced technology fighters (a.t.f.s) is that these aircraft are committed to high sortie rates (and short turn-round times) and these objectives cannot be met with hydraulic pumps mounted directly on the engines. A.m.a.d.s were therefore the practical alternative, since they could be mechanically isolated when the engines were dropped from the aeroplane. This also avoided the prospective leakage and contamination problem that occurs when hydraulic lines are opened up. The a.m.a.d.s tend to be a legacy of the flight controls and, as shown in Figure 47.13, they are a complex, heavy, costly addition to the aeroplane. In addition, a.m.a.d.s decrease mission reliability and abrogate the possibility of achieving low maintenance-support objectives. Another problem with a large-capacity system using say four 156 fhp pumps is the *constant* heat dissipation which requires a dedicated oil-to-fuel heat exchanger to absorb the approximate 5800 British thermal units (Btu)/min heat losses: this is equivalent to about six 5 ton air conditioners!

In addition to the hydraulic pumps (and a variable speed, constant frequency (v.s.c.f.) generator), each a.m.a.d. carries an air turbine motor, which is used for ground and emergency flight operation. As shown, the aircraft's auxiliary power unit (a.p.u.) is interfaced with the a.m.a.d.s via pneumatic ducts. The a.p.u. also has an electric starter and a gearbox, on which are mounted a hydraulic pump, electric

generator and a compressor. The compressor provides hot pressurised air (at approximately 52 lb/in<sup>2</sup>) that can be selectively routed to either a.m.a.d. to permit running and checking of the a.m.a.d.s. The a.p.u. can also be operated in flight in the event of a single or dual engine 'flame-out'. In the YF-22/YF-23, there is almost critical dependence on an in-flight operation of the a.p.u., since the a.t.f.s are able to operate in regimes of aerodynamic instability. The a.p.u. also has an important ground-operation role, providing the a.t.f.s with power autonomy when they are dispersed at remote bare sites around an airfield.

In summary, a.m.a.d.s are a result of the selection of hydraulic flight controls; but with the trend to 'more electric' (m.e.l.) aircraft and the use of electric flight controls, electric (starter) generators could be the only components mounted on the engines. These generators however, could power electro-hydraulic and other advanced flight-control actuators in addition to the aircraft electrical and electronic systems.

## 47.9 Electrohydraulic flight controls

Electrohydraulic flight control units were used in the Vickers VC-10 (commercial transport) in the 1960s and each consisted of a compact integration of a motor pump,

Figure 47.14 Electrohydrostatic actuator

a servo-control, a self-contained fluid, etc. A total of 11 units were used in that aeroplane; four *aileron* units, four *elevator* units, and three *rudder* units. Two units in each group incorporated an integral autostabiliser/autopilot control consisting of an electrical torque motor, operating on electric signalling. These primary flight controls were operated successfully and they complemented the three spoilers in each wing, which provided air-brakes, direct lift control and back up for the ailerons.

Recognising the major technology improvements that have taken place since the 1960s, e.h.a.s are now a low-risk technology. Also, many international companies produce a variety of electrohydraulic actuators. Some employ a constant speed/variable displacement/bidirectional pump or a constant-speed pump operating with a servo-valve control. More recently, however, an 'electrohydrostatic' actuator was developed which operates uniquely as a 'pressure-on-demand' actuator with low heat losses (Figure 47.14). A US company, H. R. Textron, California, also offers a novel actuator design which uses dual hydraulic jacks to impart a rotary via a high-lead-angle ball screw jack.

## 47.10 Electromechanical flight controls

Electromechanical actuators (e.m.a.s), like e.h.a.s, are attractive candidates for the new flight-control systems since they offer the same operational flexibility and advantages as e.h.a.s. In addition, losses in the motors and electronics decrease at light loads and e.m.a.s only dissipate high heat during the brief periods of high hinge moments. In an e.m.a. the motor current is proportional to torque:

$$T = K \times I_A \phi \cos \theta \quad (47.3) \Leftarrow$$

where  $T$  is the motor torque,  $\phi$  is the stator flux,  $I_A$  is the rotor current, and  $\cos \theta$  is the motor power factor.

Typically, the preferred implementation of an e.m.a. is a motor-driven 'power hinge' using a relatively high speed motor driving a 'power hinge' (attached to the control surface) via a planetary reduction gear train. However, linear e.m.a.s using high-efficiency ball screw jacks have also been used and, where high mechanical loads were present, the French-designed 'transrol' actuator offered advantages. In the field of novel actuators technology a US designed 'eccentuator' is of note. This utilises a 'bent shaft' which is rotated while its drive end (located in a 'carrier') is rotated in the opposite direction, so as to yield a planar output (Figure 47.15).

Figure 47.15 An eccentuator. The eccentuator motion compensates for the lateral displacement while doubling the output power. T.e., trailing edge  $\theta$ , Beam bend angle; c.w., clockwise; c.c.w. counter clockwise.

With digital flight-control systems (f.c.s.) tri- or quadredundant computers transmit a digital bit-stream which contains rate, surface-displacement and directional information to the power electronics modules, that control electric actuators. Passive stabilisation networks, loop closure signals, etc., provide the necessary stability and performance characteristics of the actuators. The e.m.a.s provide high static/dynamic stiffness and bandwidth response, comparable with the best hydraulic actuators.

As an example of e.m.a. status, a 'motor controller' design by General Electric for a 12 hp actuator has dimensions of approximately  $1 \text{ in} \times 3 \frac{1}{2} \text{ in} \times 6 \frac{1}{2} \text{ in}$ . These modules actually integrate low and high voltage chips on the same substrate and they interface directly with a 1553B type digital data bus.

With the adoption of electric flight controls and other electric technologies, there ensues a major simplification of the aeroplane, due to the elimination of the labour-intensive (distributed) hydraulic systems and the elimination of the untenable practice of bleeding the engine compressors for high-pressure high-temperature pneumatic power.

## 47.11 Aircraft electric power

In World War II, the electric demands of the large four-engine bombers were met by four 28 V d.c. 6 kW generators which supplied the power demands of some highly electrified aircraft using electric turrets, electric de-icing, and nominally

large electric/avionic systems. In the immediate post-World War II phase (1946 onwards), the aerospace industry realised that these low-voltage d.c. systems could no longer meet the projected future demands for electric power, so Advisory Boards were set up (in the USA and the UK) to evaluate higher voltage, higher power electric systems. These systems were premised on the use of higher d.c. voltages of 112, 240 and 340 V and higher a.c. voltages of 120 to 400 V; based on frequencies of 250, 400, 800 Hz and above.

However, the trend was towards a.c. power systems because of their ability to transform voltages, the ease of power switching a.c. currents, and the availability of highly reliable, rugged squirrel-cage induction motors. The three-phase, 200 V, 400 Hz system therefore became the popular choice and was selected by the author for the Bristol Brabazon I, Mark I aeroplane; a very large commercial aeroplane, designed for cross-Atlantic operation. The Mark I aeroplane was powered by eight Centaurus 2800 bhp (internal combustion) sleeve-valve engines buried in the wings. The later Mark II aeroplane was slated to use eight 3500 shp Proteus turboprop engines, but the Brabazon Mark II was not brought into prototype flying status. Both the Mark I and Mark II aircraft were configured with four pairs of engines, each pair driving two Rotol contra-rotating propellers, driven from a propeller reduction gearbox.

The electric system in the Brabazon I, Mark I, was probably the first major a.c. power system in the world and it consisted of six 40 kV-A Rotax a.c. generators and two Rotol 40 kV-A auxiliary power units (a.p.u.s).<sup>1</sup> A companion *large*-aircraft programme was the Saunders-Roe Princess Flying Boat which was to be powered by 10 Proteus engines. Uniquely, the electric system was designed around a 250 Hz system, *using a.p.u.s rather than engine-driven generators*. A variety of electric power systems were therefore evaluated in those early post-World War II years, but the trend was strongly established for three-phase 400 Hz a.c. power in the military and commercial aircraft. Constant speed hydromechanical drives and the later integrated drive generators (by Sundstrand) dominated the electric systems in these post-World War II aircraft and these transmissions furnished constant-frequency power over the variable-speed range of the engines. Other constant-speed drives were developed by General Electric and Lycoming. General Electric's drive was based on a 'ball pump' configuration, while the Lycoming drive was designed around a roller/toroidal (mechanical) transmission. These drives, unfortunately, encountered some pervasive development problems and there was only limited production. The problems (characteristic to mechanical and hydromechanical drives), are the high Hertzian stresses, incident upon the use of back-to-back hydraulic motor pump units and the mechanical complexity.

In an attempt to offset the perceived problems of mechanical/hydromechanical drives, the aerospace electrical companies developed electronic approaches to generating constant-frequency power. These were known as variable speed constant frequency (v.s.c.f.) power systems and they were based on 'cycloconverter' and 'd.c. link' conversion techniques. These systems held the prospective advantages of higher efficiency and higher reliability; also they were able to take advantage of the burgeoning technology in power electronics and very large scale integrated (v.l.s.i.) chip technology.

Nonetheless, constant-speed hydromechanical drives and integrated drive generators remained the power systems of choice in modern aircraft, except for the new trend towards 270 V d.c. However, when large-capacity systems (300–500 kV-A) become necessary, a *direct-driven generator, operating with a constant volt/cycle characteristic, could become an efficient and practical alternative*. This would enable the generator

to operate over a 2:1 speed ratio, without compromising its weight and size *vis à vis* an optimally sized constant-speed machine. In addition, since it would be desirable to use such a large generator to start the engines, the synchronous generator could be operated as a synchronous motor, deriving its power from a *converter producing programmed voltage-to-frequency (V/F) power*. Furthermore, once installed, the inverter/converter can be used for other purposes in the aeroplane. For example, a motor-driven e.c.s. pack could be driven at speeds of 80 000 to 100 000 rev/min, permitting the use of 'air-foil' bearings, as used with bleed-air turbine/compressor units. For these speeds, a two-pole (low slip) induction motor would require a frequency of 1600 Hz for a speed of 94 000 rev/min, approximately.

Implicit in the adoption of a three-phase a.c. power system, operating with a constant volts per cycle voltage control, is the fact that the generator operates with a 'power proportional speed' characteristic. Thus, for the typical 2:1 speed range of the turbojet engine, the generator output would be reduced to 50% on the ground. There is, however, synergy in this because, in the real world, the generator would never be required to provide full power during ground operation since loads such as windshield heating, galley, wing/engine de-icing, the utility electric loads, and the avionic loads would never all be switched on at one time. Similarly, electrohydraulic pumps, landing gears, etc., would not be operating.

In contrast to the above, *aircraft power generators in almost all aircraft today are effectively 2:1 oversized*. For example, in the case of a generator designed to provide 270 V d.c. at 50% per unit (p.u.) speed, it 'wants' to produce 540 V at 1.0 p.u. speed, but it is harnessed by the voltage regulator to 270 V. Also, when the 270 V d.c. is developed by rectifying the a.c. generator output by a three-phase full-wave silicon controlled rectifier (s.c.r.) bridge rectifier, only a small part of each (rectified) sine wave is used to produce the 270 V d.c.; as shown in the lower half of Figure 47.16. There is the irony also that the bridge-rectifier/filtration components are only efficient on the ground, at 0.5 p.u. engine speed!

In the case of a hydromechanical transmission, the 'speed penalty' shows up as a 'power mismatch'. As shown in Figure 47.17, the integrated drive generator can produce full power (at half speed), *but the ground-power demand is very low*. It is also of note that the parabolic (power) curves tend to be asymptotic at the 0.5 and 1.0 p.u. speeds, so the electrical, fluidic and mechanical losses tend to remain high at these point extremes.

## 47.12 Summary of power systems

Clearly, there is no panacea for the problems typical of the 2:1 speed range of turbojet engines, and this is somewhat unique to the aircraft power systems. In utility electric systems, steam turbines drive generators at constant speed, so they intrinsically produce constant voltage/constant frequency power. In contrast, the aerospace electrical engineer must resort to innovative approaches to meet the speed-range problem. Basically, the choices are:

- (1) constant-speed drives,
- (2) v.s.c.f. cycloconversion,
- (3) v.s.c.f. d.c. link conversion,
- (4) 20 kHz resonant power conversion,
- (5) constant volt/cycle, or
- (6) 270 V d.c.

None of the above is without some disadvantages with regard to costs, reliability, weight, efficiency, maintenance

**Figure 47.16** Aircraft power generation system: 270 V d.c. power system

**Figure 47.17** Aircraft power generation system: constant-speed drive system

support, life-cycle costs, etc., but it is possible to draw on the expertise, resident in the above power generation systems to develop a simple 'universal' type power system that could furnish multiple, 'dedicated' power supplies for the different loads. One such system, shown in *Figure 47.18* utilizes a single high speed (direct driven) 500 kV-A generator, which can operate at a speed of 24 000, 36 000, or 48 000 rev/min. The figure shows a simplified scheme of a generator supplying three, or more, power supplies, such as:

- (1) three-phase 200 V, 400 Hz (or three-phase 400 V, 800 Hz),
- (2) 270 V d.c.,
- (3) 28 V d.c., or
- (4) other

Examples of such systems include the following.

- (1) A Westinghouse 500 kV-A unit furnishing multiple and different characteristic outputs—120 kV-A of three-phase, 200 V, 400 Hz power; 270 kW, 13.2 kV d.c., 17 kW (pulsed load), 28 V d.c.
- (2) An Allied Signal 500 kV-A generator with a weight of only 136 lb, when driven at a speed of 48 000 rev/min. This speed is somewhat high for a direct engine-driven generator, but it is suitable for a turbine drive.

The advantages offered by this hybrid system are that very high-capacity low-weight generators can directly power large loads such as landing gears, swing-wings, tilt-tails, de-icing systems, space-heating, lighting, utility loads, and (in commercial aircraft) galley loads. The dedicated loads such as 270 V d.c. and 28 V d.c. (and special high frequency power supplies) can be derived on an 'as-required' basis. However, with advanced power generation systems, in the 150–500 kV-A per channel capacity, 3% or less conversion may be more than adequate for each of the dedicated power supplies. This, therefore, significantly reduces the required sizes of the power diodes/filters, etc., compared to the sizes required in a direct engine-driven 270 V d.c. generator. Difficulties in rupturing the prospectively high short-circuit currents and the heat dissipation of solid state power controllers would be a concern in such high voltage d.c. systems.

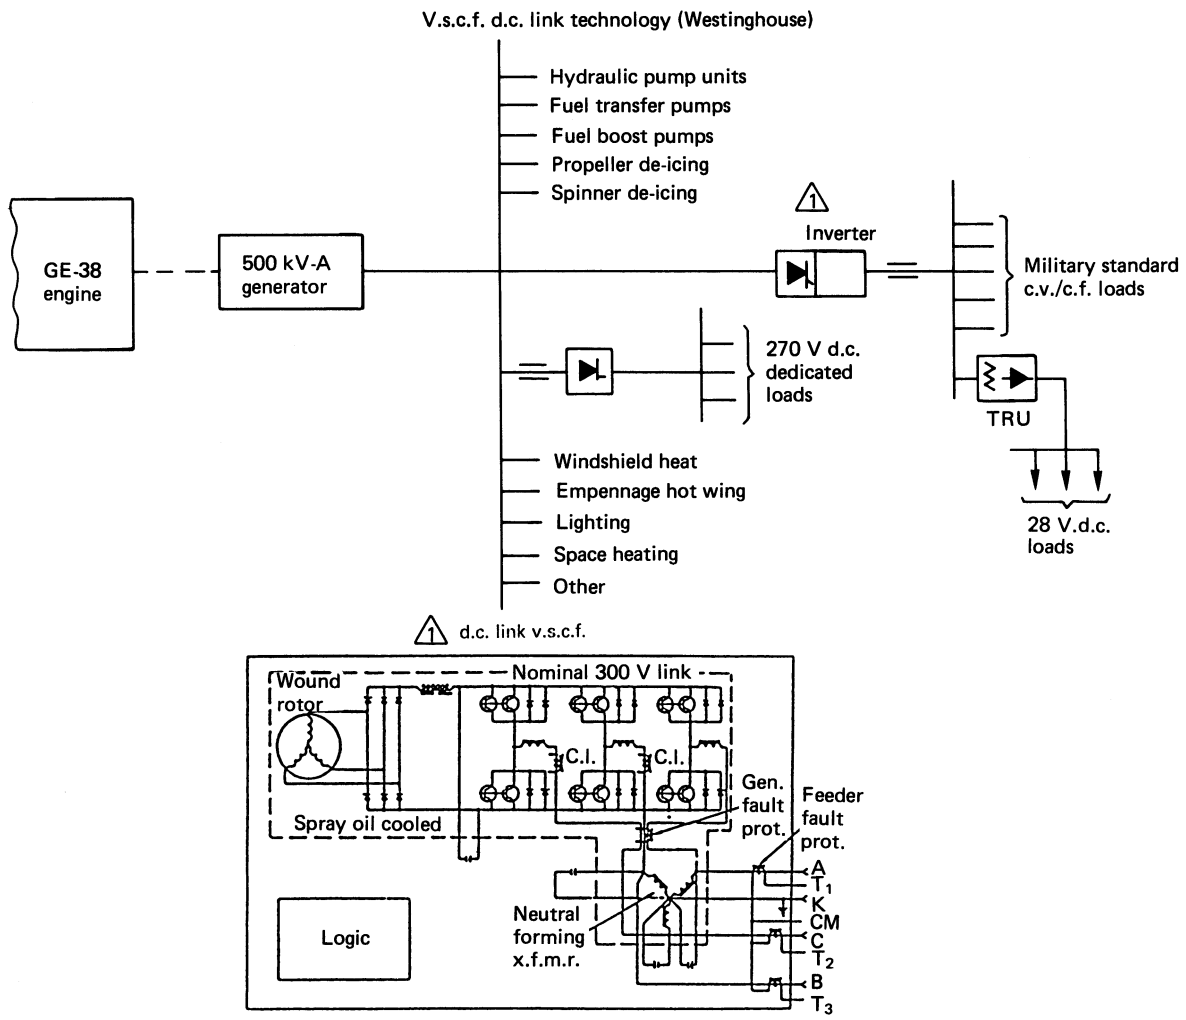

In contrast, the selection of an a.c. power system simplifies the switchgear problems and permits the use of transformers to provide multiple different voltages for windshields, props/spinners, etc. Also, three-phase a.c. power permits the use of highly reliable, lightweight squirrel-cage induction motors for many loads such as electromechanical actuators, fuel/oil motor-pump units, passenger/cargo/weapon doors, hermetically sealed Freon compressors, motor-driven, bootstrap/air-cycle machines, etc.

Loads such as constant-pressure electrohydraulic pumps may be operated over a 2:1 (or more) speed range and still provide constant torque (*Figure 47.19(a)*), as demanded by 3000 or 5000 psi pumps. The efficiency–torque characteristics (*Figure 47.19(b)*) also show that the efficiencies remain high for the four V/F curves shown.

One of the problems with 270 V d.c. systems is that the 270 V d.c. motors cannot operate directly on 270 V d.c., so the d.c. voltage must be 'inverted' to power the three-phase a.c. stators of the many drive motors; ironically, these inverters would actually furnish constant V/F power!

### 47.13 Environmental control system

The environmental control system (e.c.s.), unlike many other services, represents an almost constant-horsepower

**Figure 47.18** Advanced electric power system (with d.c. link v.s.c.f. power)

demand over the complete flight envelope, regardless of engine power settings and engine speeds. This, in the past, has been a significant problem for the bleed-air system and it impacts on any mechanical power system, including an electrically powered e.c.s.

For a 500 passenger advanced transport aircraft (a.t.a.), the increased fuselage length, the larger number of windows, and the higher thermal transconductance all result in a significant increase in the capacity of the e.c.s. Without taking advantage of air recirculation (50% or more), the horsepower demand could be excessive. Therefore, it is axiomatic that a.t.a.s utilise a degree of air recirculation: the usual problems of doing this will be ameliorated by the prospectively lower level of vitiated air which can be expected, in the future, when there will be less nicotine contamination of the air. Also, improved filtration methods are now available.

Basically, the e.c.s. performs the following functions:

- (1) cabin pressurisation,
- (2) cabin cooling,

- (3) cabin heating, and
- (4) cabin humidity.

Typically, cabin altitude is maintained at 6000 ft, which is equivalent to about 11.8 lb/in<sup>2</sup>a. At normal cruise altitudes, an intermediate tap on the engine compressor supplies the pressurisation needs, but at idle descent letdown it is necessary to change over to a last-stage bleed. Duct pressures and temperatures near the bleed ports are typically 100–300 lb/in<sup>2</sup>a and 200–700 °F. These higher pressures and temperatures are necessary, in conventional aircraft, where the hot pressurised air is used for wing anti-icing and for air-turbine motor drives. However, these temperatures and pressures are actually too high for the cabin e.c.s. requirements, so intercoolers and air cycle machinery are necessary to condition the air before it is introduced into the cabin. Outflow valves modulate to maintain the cabin pressure at the approximately 6000 ft altitude.

For all-electric e.c.s. (a.e.e.c.s.) pressurised air is derived from motor-driven compressors. For a typical 500 passenger a.t.a., the induction motor-driven compressors are

Figure 47.19 Performance of electrohydraulic pumps on constant V/F power: (a) speed-torque curves; (b) efficiency-torque curves

designed to furnish approximately 1.2 ppm per passenger, made up of 300 ppm of fresh air and 300 ppm of recirculated air. The pressure ratio of each compressor is approximately 3.4:1, so the heat of compression can be used to supply the heat requirement during winter operation. The temperature rise across such compressors is defined as:

$$\Delta F = \frac{T_a + 460}{\eta_c} [\text{PR}^{\frac{K-1}{K}} - 4] \quad (47.4)$$

where  $T_a$  is the ambient temperature (in degrees Fahrenheit), PR is the pressure ratio,  $K$  is the ratio of the specific heats, and  $\eta_c$  is the compressor efficiency.  $\Delta^\circ\text{F}$  is temperature rise in degrees Fahrenheit.

The power to drive each compressor is given by

$$\text{HP} = \frac{\dot{\omega} \Delta T}{2.95} \quad (47.5)$$

where  $\dot{\omega}$  is in pounds per second and  $\Delta T$  is  $\Delta F$  in equation (47.4).

Equations (47.4) and (47.5) show that the  $\Delta T$  value for air across the compressors is approximately  $225^\circ\text{F}$  and the compressor power is approximately 120 hp. To avoid overloading the motor compressors during low-altitude, high engine speed conditions, the compressors incorporate an inlet-guide-vane control and a pole-changing motor, which changes speed from 48 000 to 24 000 rev/min nominal.

The cooling requirements can be furnished by three vapour-cycle cooling units, which employ a reverse-Rankine cycle with a R-114 refrigerant: the moisture content, which affects the capacity of the cooling system, was taken as 130 gr/lb. Condenser cooling is effected by fan-induced

air flow on the ground, and ram air in-flight. Inlet-guide-vane control is used to modulate the Freon flow and cooling capacity during light-load conditions.

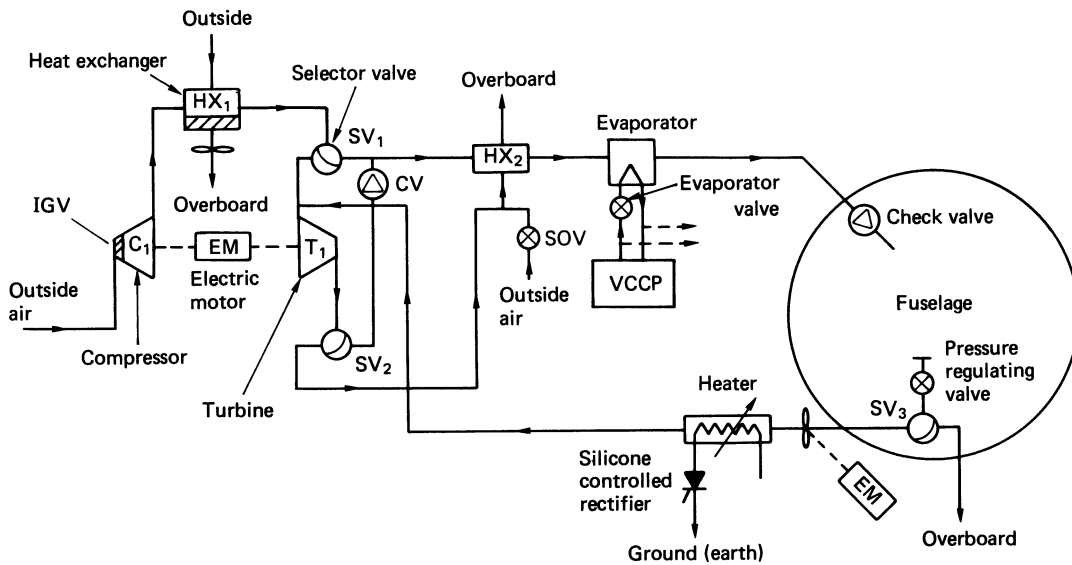

Cabin cooling is a major load on the ground, with a fully loaded aircraft and outside air temperatures at  $\geq 100^\circ\text{F}$ . The metabolic load of 476 passengers and 24 crew members, the solar input, and other internal heat dissipation factors add up to a total cooling load in excess of 375 000 Btu/h for the large a.t.a. In a conventional aeroplane such as the L-1011, cooling is derived from three air-cycle units, which are an integral part of three e.c.s. packs. To furnish this power on the ground, an a.p.u. driven compressor is used.

Cabin heating tends to be a less significant requirement than cooling in that there is still a demand for cooling, during high-altitude cruise when there is a maximum passenger complement. The heating demand therefore applies mainly to cold-day conditions with low passenger densities, i.e. low internal losses. Evidently, with bleed air, there is an adequate supply of hot air.

As is typical with industrial or commercial vapour-cycle cooling systems, the liquid R-114 is flashed to a cold two-phase low-pressure liquid gas system, as it flows through the expansion valve; this liquid gas is supplied to the evaporators (for cooling the motors driving the compressors).

While a minimum weight was not emphasised in this e.c.s. design, a 1500 lb weight saving was achieved by using an all-electric e.c.s. instead of a conventional bleed-air powered e.c.s.

Figure 47.20 shows an a.e.e.c.s. that is a power regenerative system which utilises 'air cycle' and 'vapour cycle' cooling. The former consists of an air-cycle pack in which a compressor and a turbine are driven at high speeds (75 000–90 000 rev/min) by a low-slip, squirrel-cage induction motor supplied with high frequency. This whole

**Figure 47.20** Electric e.c.s. with air cycle and vapour cooling. EM, electric motor; IGV, inlet guide vanes; C, compressor; T, turbine; SV, selector valve; VCCP, (electric) vapour cycle cooling pack; HX, heat exchanger; PRV, pressure regulating valve; CV, check valve; SCR, silicon controlled rectifier; EV, expansion valve

assembly runs on air-foil bearings to provide long life and reliability. The compressor employs an inlet guide vane to improve efficiency and to modulate the air mass flow through the single-stage centrifugal compressor. The turbine itself furnishes two functions: it offsets the amount of power supplied to the compressor by the electric motor and provides cold air to the cabin. As mentioned above, the purpose of the e.c.s. is to provide conditioned air to the cabin and passengers.

The simplified scheme given in *Figure 47.20* shows the e.c.s. operating in a typical flight condition (at 35000 ft) where power 'regeneration' is effective. For example, at 35000 ft, the atmospheric pressure is  $3.5 \text{ lb/in}^2$  and the cabin pressure (for 6000 ft equivalent altitude) is approximately  $11.6 \text{ lb/in}^2$ : this is equivalent to a pressure ratio of 3.3:1. This pressure ratio is then effective across the turbine, as the cabin outflow air is dumped overboard (to modulate the  $11.6 \text{ lb/in}^2$  pressure). As the outflow air discharges through the turbine, it develops shaft power to offload the motor-compressor drive. (Note: this a.e.c.s. is shown operating as a 100% 'fresh-air' system, but it can utilise a 50% 'recirculation' system; if this were adopted, however, the power regeneration would be reduced by 50%.)

During hot-day ground operating conditions, the total cabin-heat load is very high, so in this mode the compressor and turbine are connected in series by changing the position of the selector valves. With the selector valves in this position some of the heat of compression is removed by the heat exchanger (HX<sub>1</sub>) and further heat is removed by the turbine: The actual drop in temperature across the turbine is determined using Equation (47.4). From the turbine, the air passes through a second air-to-air heat exchanger (HX<sub>2</sub>) and then through the Freon evaporator; the flow of Freon through the evaporator may be modulated in accord with the desired evaporator exit temperature (typically  $40^\circ\text{F}$ ). In this ground operation mode, the pressure rise across the compressor is reduced in the same ratio as the pressure drop across the turbine. The air entering the cabin is, therefore, at the same pressure as the outside ( $14.7 \text{ lb/in}^2$ ) and is

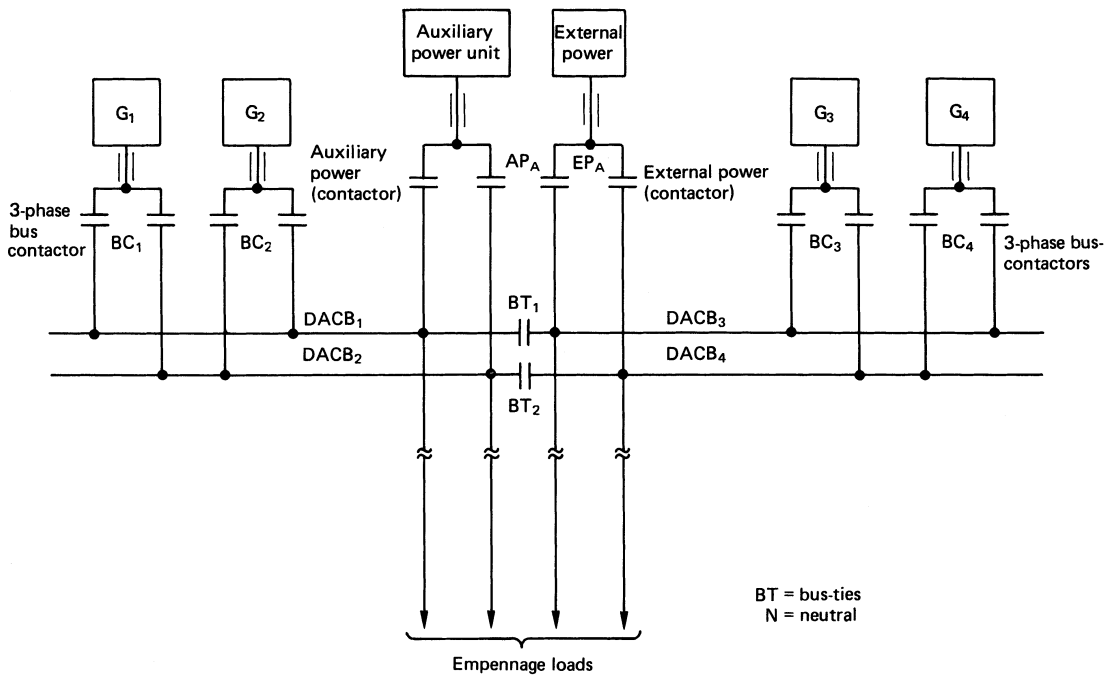

discharged overboard with minor pressure loss. On cold winter days, electric heat may supplement the metabolic heat load of the passengers by passing fan-recirculated air over an electric heater, whose power-dissipation is varied by a silicon controlled rectifier.

#### 47.14 Digital power/digital load management

Presently used aircraft are still flying with 1960–1975 electrical technology and very little design activity has taken place to bring electric systems into line with the digital avionic and engine management systems. The NASA and the US Air Force/Navy laboratories have long promoted advanced digital power systems that would interface with solid state power controllers (s.s.p.c.s), controlled and monitored by a 'data handling system'. The US Navy Air Development Center (NADC) has also installed two A-7 mock-ups in their laboratories at Warminster and have successfully demonstrated the advantages of modern power management over conventional power management.

Another key objective of the NASA and US military services is to adopt a 'distributed power bus' system, which would simplify power distribution to the loads and constrain the *power wires to the areas in which the loads are located*. This technology also inhibits the 'bus-proliferation' problem, which is a legacy of the conventional radial power systems now used in aircraft. For example, power feeders typically route from the engine-located generators to a remote (forward fuselage) main electric load centre. Radial power feeders then feed back to remote areas where the power feeders originated!

In the advanced power distribution system, insulated power feeders traverse the wings and the fuselage. The concept is that in a four-engine four-generator configuration *there are only four distributed buses*. The feeders are also redundant, i.e. insulated/isolated quadri-redundant feeders route in the fuselage and two sets of feeders in each wing are

**Figure 47.21** Advanced power generation system with distributed buses. APU, auxiliary power unit; G, generator; DACB, distributed a.c. bus; BC, bus contactor; EP, external power contactor; AP, APU power contactor; BT, bus-tie/buss

interconnected by bus ties. The distribution system may be operated as a 'closing-ring' system in which, in an extended-emergency condition, any one generator can feed all bus sections (Figure 47.21).

In the implementation of such a distributed bus system, subfeeder taps are made into the buses (as they traverse past key load areas) and they are protected *at the tap points*: this is essential *in order not to compromise the primary feeders*. The key and enabling technology in this advanced power system is a digital power/digital-load management system (d.p./d.l.m.s.).

To preserve the philosophy of isolated quadri-redundant power supplies, *the generator channels are not paralleled*. In addition, the health and status of each generator is monitored by a microprocessor-based generator control unit (Figure 47.22) that communicates with the flight station computer display unit over a 1553B, or other dedicated digital data bus (Figure 47.23). In addition to the management of the individual power channels, the d.p./d.l.m.s. controls the bus ties and the interfaces with the external/a.p.u. power systems.

Figure 47.24 shows a simplified scheme of the d.p./d.l.m.s. management system designed by the Leach Corporation. The electric load management centre (e.l.m.c.) interfaces with the 1553B bus and a MIL-STD-1750 processor (with a 128k word memory) manages the complete electric system via a dedicated load management distribution bus. This bus interconnects the 'remote power modules' (similar to the one identified in the e.l.m.c.) to control the ON/OFF

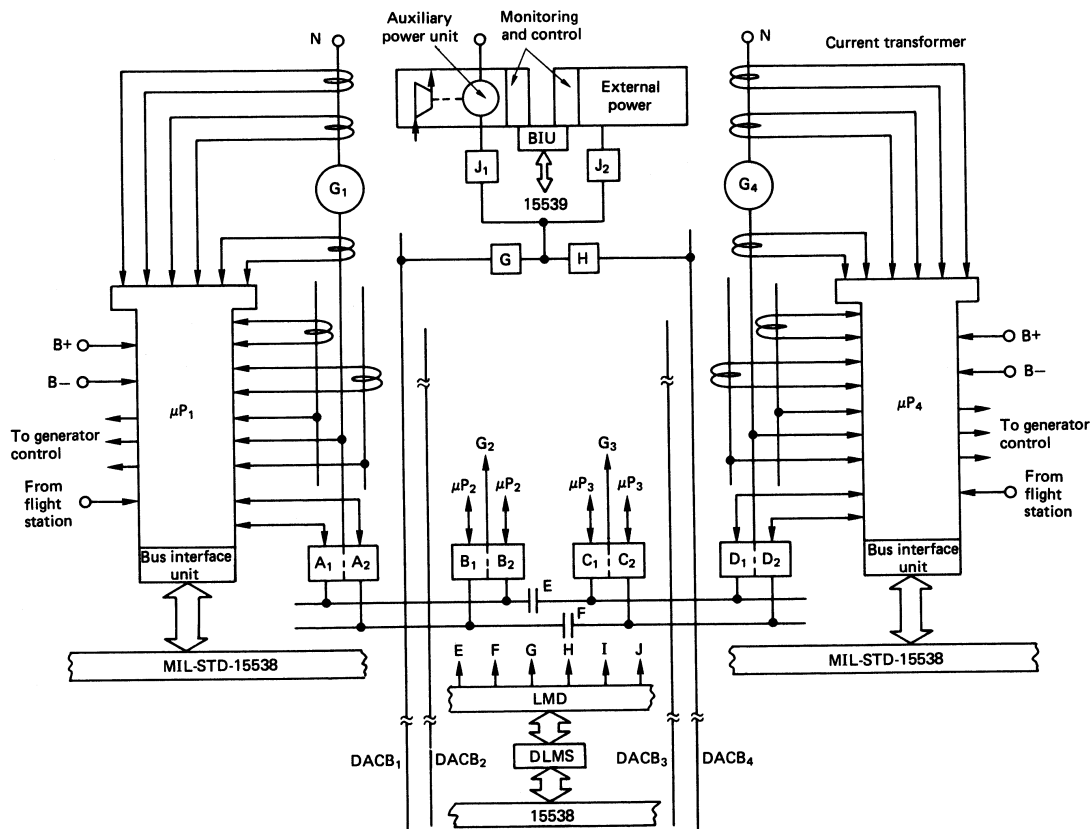

status of the s.s.p.c.s and the smart remote power contactors (s.r.p.c.s).

The digital load management system makes possible the control of all loads via the distributed bus system and discrete (multi-bit) address code and a logic code. This code also ensures that the s.s.p.c. closes only when all the circuit parameters are correct. In addition, the individual loads are given a 'priority tag' which establishes their level of importance in the overall hierarchical structure of the loads in the aeroplane. Loads may therefore be in, say, four levels; in which loads in group 1 would be first isolated, followed by those in groups 2, 3 and 4, as the level of emergency increases. For example, if smoke occurs in the vehicle, all four groups would be disconnected, leaving only the flight-essential loads connected. From this, it is clear that power reduction is effected *not by dropping dedicated buses, but by a software-controlled dumping of individual loads*.

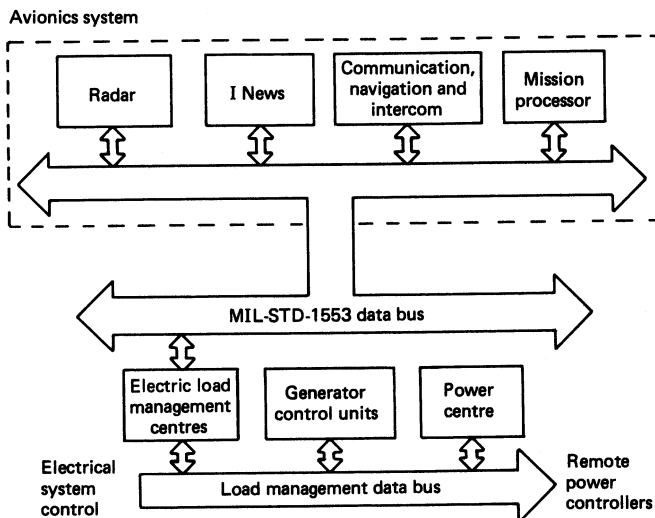

The s.s.p.c./s.r.p.c. combines the features of a relay and a circuit-breaker but, unlike circuit-breakers, they can detect open-circuit and open-phase faults. By the use of the d.p./d.l.m.s., multiple circuit-breaker panels are eliminated and there is a significant reduction in the amount of load wiring.

## 48.1 General

In order to deep-mine coal, the sinking of two vertical shafts or inclined roadways must be established to access the coal seams. Underground roadways are then established to the winning area of the coal-face. There are usually two roadways to establish a ventilation system. One shaft and roadway is used to transport the coal, the other usually to transport men and materials to the coal-face. One shaft and roadway is referred to as the *intake* and the other as the *return* airway, signifying the direction of the ventilating air flow with all precautions taken to separate the air flows to maintain adequate ventilation.

Whenever coal is mined, methane gas is liberated, and the electricity regulations require that the electrical power must be removed from that part of the mine if the methane gas content exceeds 1.25% by volume. The regulations allow an exception to this rule to permit communications and certain safety monitoring equipment to be maintained even in the heavy concentrations of methane; in this case the equipment must be intrinsically safe—that is, the equipment must be tested and it must be certified that, in the event of open sparking in either normal or faulty condition, insufficient energy would be released to ignite the most easily ignitable methane concentration.

The regulations place on the manager the responsibility to state where gas may be present in areas of the mine in sufficient quantity to be a potential hazard. In these nominated areas approved equipment is certified Flameproof (FLP) or Intrinsically Safe (IS) for Group 1 (methane) gases.

It will be appreciated that the ventilation for the dilution of liberated methane is the first safety measure in the use of electricity in mining, with the added precaution of approved apparatus should concentrations of methane occur.

Ventilation of the mine is normally achieved by reducing the pressure at the surface end of the return shaft (upcast) by means of an axial- or radial-flow fan, one fan working and one fan on stand-by. A typical installation would operate at 10–15 in water gauge (2.5 kPa) and 125–250 m<sup>3</sup>/s air flow. Since the fan is running continuously, efficiency is of prime importance; consequently, detailed attention is paid to this factor. The prime mover used is a cage or slip-ring induction motor, or a synchronous machine with speed change effected by gear or V-belt drive. More recently, variable-speed machines have been used such as a.c. commutator motor, Kramer, cascade arrangements and the pole-amplitude modulated (PAM) motor.

Where underground workings are extensive it may be necessary to provide booster fans in the underground system, usually powered by cage motors up to 400 kW.

In order to ventilate single headways, i.e. roadways being driven, auxiliary ventilation fans are used providing air at the end of the tunnel by ducting. These are smaller machines of 10–35 kW and, where they are exhausting, a situation could exist where gas flows over the fan blades; in this condition it is important to ensure that sparking cannot occur at that point. For this purpose vibration monitoring is extensively used. Two frequency ranges are monitored (500 Hz and 5000 Hz) to detect bearing failure and mechanical imbalance. The equipment will first give a warning and later 'trip the power' if the force on the bearing or imbalance exceeds the preset value.

For some years the analogue computer has been used for ventilation calculations for a mine, but is now being superseded by digital computer techniques.

### 48.1.1 Load growth

All activities at the mine make extensive use of electricity. Steam winders are being eliminated and compressed air as a power medium is almost non-existent. Coal is now almost exclusively won by electrically powered machines, and roadways are driven by large roadheading or tunnelling machines with extensive use of electronics to provide protection, control and monitoring. The trend in electricity consumption over the recent past is shown in Figure 48.1.

### 48.1.2 Regulations

Rules were introduced for electricity in mines in 1905. These became statutory when they were replaced by Part 3 of the General Regulations dated 10 July 1913 (SR&O 1913 No. 748) made under the 1911 Coal Mines Act and relating to Electricity in Mines. In 1954 the duties of mine electrical staff were set out in the Coal Mines (Mechanics and Electricians) General Regulations 1954.

With the advent of the 1954 Mine and Quarries Act, the above were revoked, replaced and their scope increased during the years 1956 to 1965 by new legislation as follows:

The Coal and Other Mines (Electricity) Regulations 1956  
The Miscellaneous Mines (Electricity) Regulations 1956  
The Coal and Other Mines (Safety Lamps and Lighting) Regulations 1956  
The Coal and Other Mines (Mechanics & Electricians) Regulations 1956

Other regulations, although not dealing directly with electricity, had some effect on its use. For example, Regulations relating to Qualifications (MQB Rules), Shot firing, Ventilation, Locomotives, General Duties and Conduct. All of which are printed in *The Law Relating to Safety and Health in Mines and Quarries, Parts 1 to 4*. (Note, the booklet relating to coal mines (Part 2) was reprinted in 1979 in three sections (A, B and C), but account must be taken of any amending legislation since that date, e.g. see below.)

With the arrival of the Health and Safety at Work, etc. (HSW), Act 1974 on 1 January 1975, a programme commenced to replace all existing law made under the M&Q Act 1954 by law made under the HSW Act 1974.

To date (1990), only two principal pieces of legislation have been introduced, i.e. the Mines (Safe Exit) Regulations 1988 and the Electricity at Work Regulations 1989. Both of these are accompanied by Codes of Practice approved under Section 16 of the HSW Act and having special legal status described in Section 17 of the HSW Act.

The latter legislation revoked and replaced the Coal and Other Mines (Electricity) Regulations 1956, the

Figure 48.1 Annual coal output and electrical energy consumption (UK)

Miscellaneous Mines (Electricity) Regulations 1956, and amended several sections of other Regulations to update them and eliminate the need for Special Regulations and Exemptions which have been issued over the years to take account of modern practices and techniques.

Work is at present taking place on:

- (1) A Mines Administration Package which will revoke and replace the Mechanics and Electricians Regulations and others relating to mine management; and
- (2) A Haulage and Transport Package and a Shafts and Winding Package which will revoke and replace the Shafts, Outlets and Roads Regulations.

*Note* While the nationalised coal industry has changed its name from the National Coal Board to British Coal Corporation, the industry standards continue to be printed as NCB Specifications. The author has therefore used BCC and NCB where appropriate.

## 48.2 Power supplies

The supply of electricity to collieries is given priority by the Electricity Boards because of the high degree of risk to human life which could arise owing to failure of supply. Winding engines, ventilating fans and pumps are the items of prime importance if men are trapped underground, and the restoration of supply to these items, in particular, must be achieved as quickly as possible.

Before 1939 it was common for collieries to generate their own electricity supply but, with the advent of mechanisation of underground operation, there was a dramatic increase in demand. It was at this period that mine generation was eliminated and supplies taken from the Electricity Boards. Small generators are, however, being introduced, powered by gas engines or turbines burning methane gas extracted from the mine.

The supply usually takes the form of an Electricity Board primary substation located adjacent to the colliery premises into which a duplicate supply is taken at 33, 66 or 132 kV. Alternatively, the colliery may be fed with at least duplicate supplies from the Electricity Board's 11 kV network.

To comply with the requirements of *NCB Mining Department Instruction PI/1957/31*, Electricity Boards are required to provide a minimum of two supplies to a colliery, each supply being taken from a separate point in the Electricity Board's network and routed so as to prevent a complete failure due to a common hazard. Each supply must be capable of handling the full output of the colliery (in the case of a large modern mine, 15–20 MV-A), the system being capable of handling the fluctuating load of electric winders, etc., which could be 3–4 MW.

### 48.2.1 Distribution

#### 48.2.1.1 Surface

The supply to the colliery substation from the Electricity Board's primary substation (which is usually adjacent to the colliery) is in most cases 11 kV and consists of a minimum of two feeders. Larger collieries may have three or four feeders; a typical distribution layout for a large colliery would be as shown in *Figure 48.2*.

All incoming cables, circuit-breakers, bus-section switches and metering equipment located within the colliery substation remain the property of the Electricity Board,

whereas all outgoing circuit-breakers would be the property of the British Coal Corporation (BCC).

Large drives on the surface such as winding engines and ventilating fans are generally supplied direct from the 11 kV switchboard. To ensure continuity, such supplies are usually duplicated in the form of a ring main or duplicate feeders.

The coal preparation plant, the largest energy consumer at the surface of the mine (usually 1.5–2.0 MV-A), is also supplied direct from the 11 kV switchboard by duplicate feeders.

The greatest proportion of load at a colliery is from the induction motors (mainly cage), which leads in some cases to a low power factor on the supply. In the majority of cases this is corrected by manually switched static capacitors on the 11 kV switchboard.

It was the practice to use 3.3 kV as a standard distribution voltage for underground activities. With increase of electrical powered units in operation and increased rating of coalface machines, there may be several 500 kW units being switched direct-on-line at a distance of several miles from the pit bottom; a common distance would be 8 km. The 3.3 kV distribution voltage becomes inadequate and there has been a change to the extensive use of 6.6 kV. While 11 kV is not widely used, at present for underground distribution, flameproof 11 kV switchgear and transformers have been developed and several systems are in operation.

It is envisaged that 11 kV will become the standard underground distribution voltage for systems operating 10 km or more from the source of supply, as in undersea workings.

To provide a 6.6 kV supply for underground distribution, 11/6.6 kV surface installed transformers are used with ratings ranging from 6 to 8 MV-A. Further transformation is provided from the 6.6 kV switchboard to provide lower voltages for other surface auxiliaries such as workshops, stores, stockyards, lamp rooms, offices, pithead baths, lighting, etc.

#### 48.2.2.2 Underground

A minimum of two h.v. supplies are provided to underground workings to increase security, being installed in each of two shafts or drifts. The shaft cables are usually 185 mm<sup>2</sup> three-core polyvinyl chloride (PVC)-double wire armoured (DWA)-PVC and are secured to the shaft wall by large wooden cable cleats spaced at approximately 25 m intervals.

At the shaft bottom, a main h.v. substation is provided from which all supplies radiate to the various districts of the mine. The supply is taken to the coal-face, where it is transformed to the coalface utilisation voltage of 1.1 kV, three-phase 50 Hz. This voltage is proving inadequate for the latest larger coal-winning machines (500 kW), in these cases 3.3 kV is being utilised.

Substations are provided at various points along the cable route to provide a h.v. supply for the main coal conveyors/haulages, etc., or a medium voltage (m.v.) 1.1 kV supply for smaller drives such as secondary conveyors, haulages, pumps, auxiliary ventilation fans, etc. It was the practice to use the utilisation voltage of 550 V for underground activities, and this still remains in some parts of the mine; this, however, proved to be inadequate for the large modern machines, e.g. coal-winning machines (shearers), roadheading machines and armoured face conveyors.

The three-phase system at the mine is earthed to its own earth plates at the surface, and is normally maintained at 2 Ω. Earthing resistors are normally included. The practice was generally to limit the earth faults to the full-load

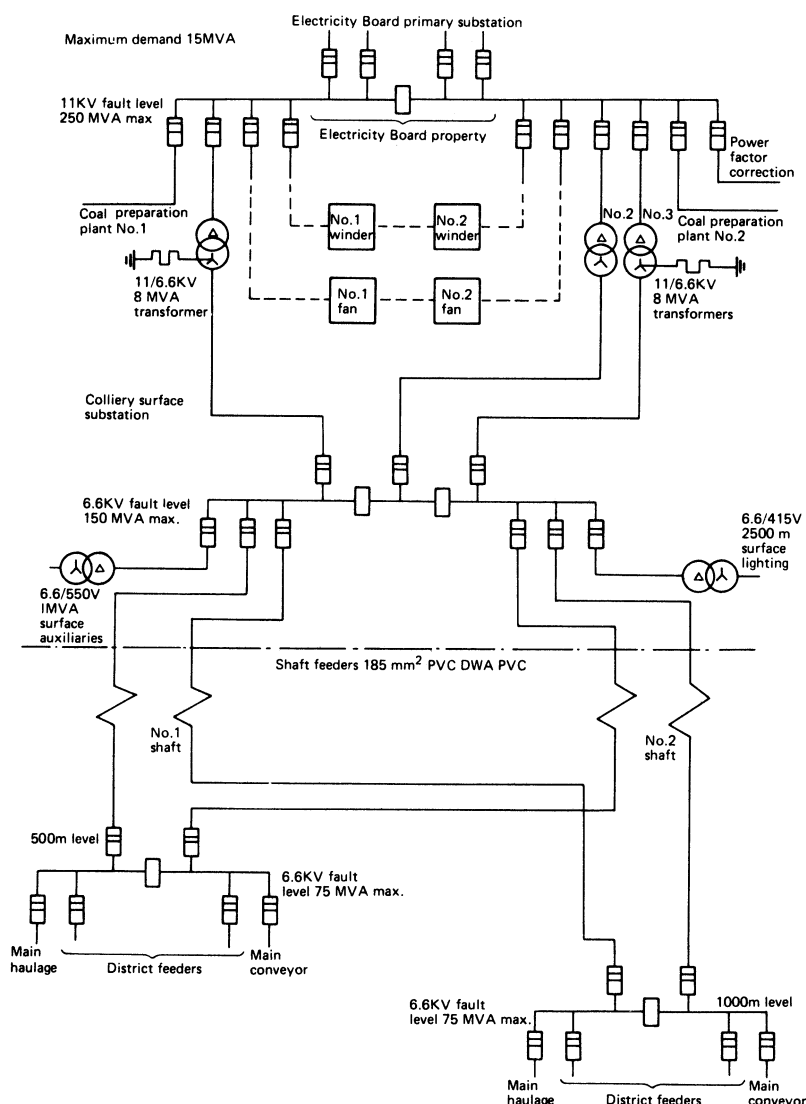

Figure 48.2 Typical colliery h.v. distribution

current of the transformer, but modern practice is to limit the 6.6 kV systems to 100 A and the older 3.3 kV systems to 150 A. Standard protection of overload, short-circuit and earth leakage is provided on the outgoing feeders.

Improved short-circuit protection is provided near the coalface, referred to as phase-sensitive short-circuit protection. This phase-sensitive protection was developed in order to permit the through current necessary to start the high-rated (500 kW) machines—which may be five or six times full-load current at a power factor of 0.2—and yet trip the supply on short-circuit of around twice full-load current which is mainly at a power factor of 0.8.

The earth-leakage protection near the face is restricted to a prospective earth fault current on the 1100 V and 550 V systems to 750 mA. Two forms are used, one a restricted core balance, the second being multiple earthing. Extensive use of electronics is made to provide the necessary detection.

## 48.3 Winders

Early colliery winding engines were powered by steam. Owing to the superior efficiency of electric motors and the greater ease in the provision of automatic control, nearly all winding engines in British mines are now driven by electric motors. These can vary from the very small a.c. winders in the range 100–200 kW, to the large d.c. thyristor automatically controlled winders of 4000 kW. Winding engines exist in several different forms (*Figure 48.3*), and, whereas the majority of the older designs were of the ground-mounted type (with unsightly headgear), new mines generally adopt the tower winder, with its cleaner lines.

*Figure 48.4* shows the comparative power-time diagrams for the four different types of winding engines with the same output, net load, depth and decking time (net load, 12 t; depth of shaft, 1000 m; output, 450 t/h). There is little

Figure 48.3 Types of winder

difference between the power requirements for a particular duty for ground and tower mounted Koepe winders, but it is obvious that a comparable Koepe winder does not need such a large motor and the energy consumption is less.

*Koepe-type winders* are specially suitable where extremely heavy loads are to be handled, owing to the fact that a multi-rope arrangement can be adopted instead of one large single rope. Two or four ropes are generally used, with special devices added to ensure that the ropes share the load equally. With Koepe winders the drive is transmitted from the winder motor by a 'friction' drive; the winding ropes may therefore have a tendency to 'creep' or 'slip'. A 'rope-creep compensating' device is provided, which automatically corrects this situation at the end of a winding cycle if it occurs, bringing the depth indicator and other safety devices into line.

Automatic winding techniques have been developed for modern winding engines, and many winders are arranged to wind coal in the automatic mode. Usually such winders

employ skips attached to the winding rope/ropes, instead of cages containing tubs or mine cars. Such skips may hold some 10/12 t and would be loaded automatically from a weigh pocket located at the side of the shaft in the shaft bottom, coal being transferred from the workings to the weigh pocket by conveyor or mine car.

As the skip arrives at the shaft bottom, it is first automatically sensed for being in the correct position and stationary. The weigh pocket door is then operated, and 10/12 t of coal is deposited in the skip in a few seconds. With the skip full and all loading/unloading doors closed, a signal is automatically given to the winding engine to start the wind. The winder is automatically started and accelerated at a predetermined rate to maximum speed. Deceleration commences at a set point in the wind, causing the winder to retard at a predetermined rate to standstill.

With the winder proved stationary and the skip in line, the surface skip door is opened, discharging the coal onto the run-of-mine conveyor at the same time as the shaft-bottom skip is being filled, the whole winding cycle being repeated automatically.

The run-of-mine conveyor transfers the newly won coal to the coal preparation plant, where it is washed, cleaned and loaded into wagons/lorries, etc., for transfer to the customer.

The most common electric winder in the UK mining industry is the a.c. winder employing the slip-ring induction motor with either liquid controller or contactor-operated metallic resistors, with a measure of speed and torque control to limit the acceleration or deceleration. Dynamic braking is used on all but the smallest winders; this is compensated to avoid saturation of the machine and ensure control. A typical layout is shown in *Figure 48.5*.

D.c. Ward-Leonard winders have been used since the turn of the century. The basic layout is shown in *Figure 48.6*. Closed-loop control was introduced to make the machine start from a signal and automatically come to rest at the surface, i.e. acceleration, deceleration, torque, current control, etc.

In the late 1950s, the mercury arc converter replaced the Ward-Leonard generator, but was replaced in the early 1970s by thyristor control. The modern machine is now fully automatic, all control and protection being solid state with thyristors in an antiparallel connection to give complete automatic winding.

Figure 48.4 Winder power-time diagrams: (a) parallel drum without balance rope; (b) parallel drum with balance rope; (c) bicylindroconical drum

## 48.4 Underground transport

Coal mining has two main transport problems. One is to convey the mineral from the coal-face to the pit bottom for winding to the surface. Conveyors are the main means for transporting the mineral. The second problem is the transport of men and materials to and from coal-face to pit bottom, this is in the main either by rope haulage or by locomotives.

### 48.4.1 Conveyors

To meet the higher levels of coal-face performance, recent advances in the technology of conventional belt conveyor design and belting have resulted in average conveyor capacities in excess of 2000 t/h. Current underground coal transport systems utilising high-capacity belt conveyor, multi-motor drives and booster drives, together with manless transfer points, remote conveyor control techniques and sufficient automatically controlled bunkering facilities, provide the most efficient system for the tonnage rates now being produced.

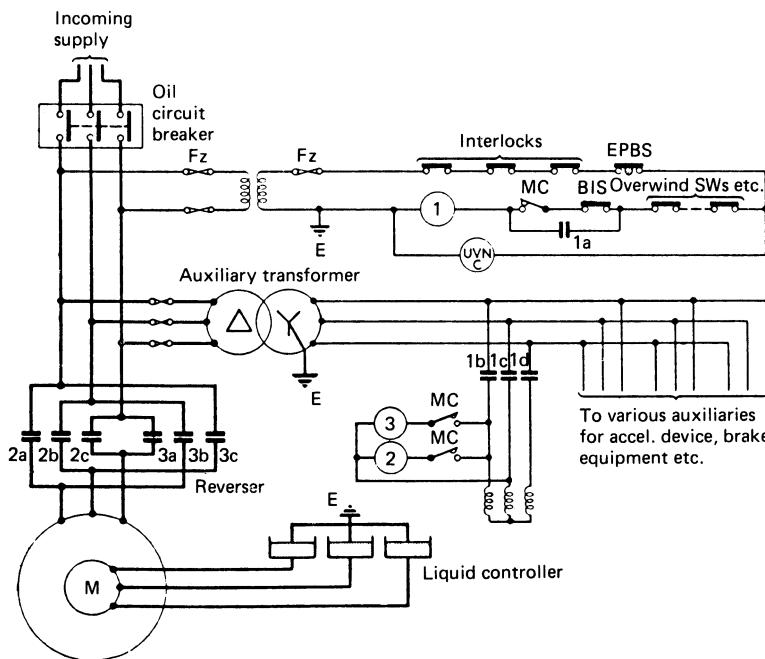

Figure 48.5 A.c. winder control

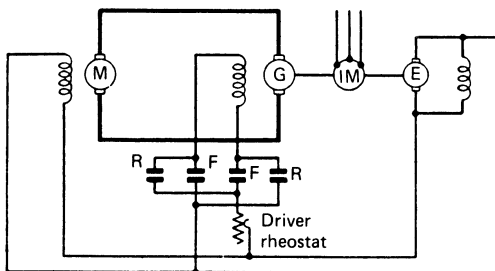

Figure 48.6 Ward-Leonard control

A Code of Practice (NCB Mining Department Instruction PI 1979/5) has been introduced, requiring full compliance to standardise on the protective devices for the safe operation of all underground roadway belt conveyor drive units. For the additional requirements appropriate to manless operation a memorandum of Guidance Minimum Requirements for Man-less Transfer Points on Conveyors was issued. The provisions of the codes are in amplification of the Health and Safety at Work, etc., Act 1974, the Mines and Quarries Act 1954, statutory regulations and mandatory BCC instructions.

The basic type of conveyor drive used underground is the solid mechanically coupled arrangement employing a single flameproof National Coal Board (NCB) specification 542 or 291 motor supplied at either 550 V or 1100 V from a standard flameproof gate-end box starter fitted with a vacuum contactor. The conveyors are started direct-on-line in sequence, and interlocked with the conveyor pre-start alarm system, signals and drive head protection sensors. Local control of starting may be used.

Main trunk roadway conveyors require higher belt speeds, coal-carrying capacities and power. To provide a soft and smooth acceleration to the belt, single- or multi-

motor drives with traction-type couplings are used. A limited acceleration period is provided by the fluid coupling. Specially designed fluid couplings with coolers are fitted to keep the starting torque under the fully loaded conveyor conditions to a low level. NCB Specification 625 flameproof motors up to 112 kW rating and flameproof gate-end box starters at 1100 V may be used to supply this type of drive, but a more common arrangement is either 3.3 kV or 6.6 kV flameproof direct-switching vacuum starters supplying higher rated flameproof motors.

The conveyors are started remotely via a telemetry data transmission link from the surface control room. The high-voltage flameproof starters can be fitted with additional auxiliary equipment to provide, for example:

- (1) manually controlled electrical loop-winch take-up facilities, used for the higher belt tensions and for accommodation of greater amounts of belt associated with longer conveyors;
- (2) integral contactors included in the control gear at 550 V for disc or drum brakes fully interlocked with main drive motors;
- (3) forward reverse contactors included in the control gear at 110 V or 550 V for electrically inserted scoop controlled fluid couplings, the arrangement allowing the main motors to be started first, and for separate insertion of scoops to provide drive to the belt; and
- (4) electrical controls for acceleration-torque-limit control (ATLC) fluid couplings, which incorporate a separate hydraulic power pack unit for insertion of scoops at a pre-set rate.

Steel-cord belting is used for some drift belt installations and where drive arrangements are similar to those described for main trunk roadway conveyors, utilising ATLC fluid couplings. Microprocessor techniques have been successfully used to control and limit the torque to 150% full-load torque during start-up and acceleration.

At the Prince of Wales colliery in North Yorkshire, the second longest cable belt conveyor in the UK is installed. Powered by a single 2240 kW drive unit, the 1706 m conveyor is the sole underground-to-surface conveyor at the mine. Coal is transported to the surface at a rate of 1000 t/h. The vertical lift is 334 m. The conveyor is designed to operate 24 h per day, with an annual operating time of 4500 h. It is capable of an annual tonnage of 2 million t and the system has the capacity to be extended to a 3000 m length.

The Selby Project (the development of an integrated mine with a capacity of 10 million t/year from five mines) utilises two drift conveyors each capable of dealing with the whole mine's output. The conveyor in the South Tunnel is 14 800 m in length with a total lift of 1000 m. The belting is steel-cord type SC7100, 1.3 m wide, with a rated breaking strength of 9054 kN (923 t). The conveyor drive is a single 2.67 m diameter drum powered by two direct-coupled thyristor controlled BCC type 'E' rationalised winder motors providing an available input to the belt of 10 MW. The speed will be variable up to a maximum of 8.4 m/s (1650 ft/min) and the conveyor is capable of delivering a maximum 3276 t/h at the surface. The conveyor in the North Tunnel is a cable belt conveyor and has duties similar to those of the South drift conveyor. The conveyor is 14 923 m long, with a maximum lift of 1000 m. The drive consists of twin 6.7 m diameter friction wheels driven by two thyristor controlled type 'D' rationalised winder motors via differential and single reduction gears. Available power input to the drive is 8.3 MW.

With the introduction of multiplex data transmission equipment and computer controlled coal clearance systems, a much wider range of FLP and IS sensors is now used to protect the conveyor. The range of sensors includes protection against belt slip, motor overheat, belt misalignment, bearing overheat, blocked chute, torn belt, brake overheat and limit switches for brake and scoop 'on' and 'off' proving.

#### 48.4.1.1 Bunkers

Underground horizontal storage bunkers of the moving-bed and moving-car type with variable speed outfeed metering conveyors are used extensively for capacities up to 500 t. The BCC bunker automation system is now fitted to bunkers of 100 t and over to provide local/remote bunker infeed/outfeed control, using a capacitance probe system, bunker contents and bunker position facilities.

Staple shaft bunkers mounted vertically in the seam incorporating variable speed thyristor controlled outfeed vibro-feeders are used for large coal storage facilities up to 1000 t.

### 48.4.2 Rope haulage

Underground steel wire rope haulage systems employ vehicles running on (conventional) two rails or, alternatively, on single or double captive rails and a limited use of overhead monorail, for the transport of men and/or materials, with operating speeds of 1.61–32 km/h.

The prime mover of the haulage engine is usually a cage or a slip-ring induction motor with a range of 7.5–375 kW at voltages of 550, 1100 and 3300 V three-phase 50 Hz. The electrical equipment would normally be certified flameproof to Group 1 requirements.

Motors up to around 75 kW are generally started direct-on-line with a 'soft start' feature provided by a fluid coupling of traction or scoop type, although some 10–50 kW designs use a manually operated friction clutch. Also used are electrical devices which control acceleration by automatically increasing frequency and voltage from zero.

The larger machines use slip-ring motors having FLP rotor resistors and drum-type controllers to provide a variable speed drive. Another speed control for motors of 120 kW and above is the cycloconverter, which uses a thyristor converter controlled by a signal to give a varying frequency/voltage output to supply a purpose-designed cage motor.

Generally haulage systems are operated manually from a position local to the haulage engine, with a guard travelling with the vehicle(s) (either riding or walking) to stop and start the system via hardwire transmitted signals presented in audible and visual form to the operator. For higher speed haulages (above 8 km/h) the BCC type 986 Radio System, which operates on the 'leaky feeder' principle for transmission, is used for signalling from the travelling guard to the haulage engine operator.

For small ratings only, transporting haulages are operated by a man walking with the vehicles, from frequently spaced key operated hardwired connected switches, controlling forward or reverse and brake operating contactors. Because of the unattended (i.e. remote operated) haulage, the system must comply with requirements additional to those of conventionally operated haulages to obtain exemption from mining legislation, which normally requires an operator to be in attendance at the haulage engine.

The BCC type 986 Radio Communication System has been extended to provide control, by a travelling guard, of the speed and direction of the vehicles, in conjunction with the cycloconverter drive. The control transmission uses a coded address binary-function digital signal to switch specific function relays of the haulage drive control system.

### 48.4.3 Locomotives

In most modern mines the coal is transported from the coal-face to the shaft bottom by belt conveyor. There are, however, some mines where the coal is conveyed from the coal-face to an inbye loading point, where it is loaded into 4–5 t mine cars.

From the inbye loading point a train of mine cars will be hauled to the shaft bottom by either diesel, battery or trolley locomotives. These are currently 75 kW diesel locomotives and battery locomotives ranging in size from 6 t, 22.5 kW up to 40 t, 70 kW.

The larger battery locomotives are powered by a 100-cell 550-A-h lead-acid battery with a nominal voltage of 200 V. The battery is contained in a large robust ventilated steel container located in the centre of the double-ended locomotive (Figure 48.7), the battery weight being about 4 t.

Figure 48.7 Battery locomotive

When a battery change is required, the locomotive enters the battery-charging station and positions itself between a pair of charging racks. The batteries are mechanically connected by the use of specially designed links and a racking device is set in motion. The discharged battery is racked onto the empty rack and the charged battery onto the locomotive, the whole process being completed in a few minutes.

Because the large lead-acid batteries on underground locomotives give off large quantities of hydrogen during the charging process, special requirements are laid down (Locomotive Regulations) governing the design of battery-charging stations. One of the principal requirements is that charging apparatus must be located on the intake side of the battery-charging racks and that ventilation air, having passed over the batteries, is directed into a return airway and does not subsequently ventilate a working face.

Storage battery locomotives for general use underground in coal mines are required by the terms of the Locomotive Regulations to be of a type 'approved by the Authority'. 'Health and Safety Executive—Testing Memorandum TM12' details the test and approval requirements. All electrical equipment used on storage battery locomotives, with the exception of the battery, is required to be certified flameproof.

Most locomotives have two driving motors, one on each of two sets of driving wheels. Series motors are employed with the armatures directly coupled to the driving wheels. Each motor is equipped with a bank of grid resistors controlled through a flameproof contactor and a speed controller. Each driver's cab is equipped with a speed controller, the two electrically interlocked to ensure that only one controller is in operation at any one time.

New locomotives incorporate thyristor chopper control, and methods are being devised to convert some of the existing locomotives to this form of control.

Most battery locomotives in mines are fitted with a battery leakage monitoring device, which consists of an electronic detection unit connected to the battery and an audiovisual alarm unit mounted in the driver's cab. The detector unit has a selector switch which allows the sensitivity at which the unit operates to be varied, a feature necessary to take account of the varying conditions under which the locomotives operate.

Four settings are available, giving battery leakage resistance values of 0.8, 1.3 and 2.6 k $\Omega$ . Operation of the alarm indicates that a fault has developed on one pole of the battery and that remedial action should be taken before a second fault develops on the other pole and sets up dangerous circulating currents.

Battery fires underground in coal mines are particularly dangerous and extremely difficult to extinguish once initiated.

Within the UK, trolley-wire locomotive installations have been tried in the past 30 years, but the system has not found universal acclaim, owing principally to the fact that the operating area of the locomotive is restricted to that covered by the trolley wire.

No statutory regulations exist covering the use of trolley locomotives underground in coal mines; consequently, when such installations are considered, special regulations are drawn up to suit each installation.

As coal-faces recede further from the shaft bottom and the need for increased efficiency demands quicker transport of men, materials and minerals to and from the coal-face, the advantages of trolley locomotives in certain circumstances have caused the BCC to look at further trolley installations. One such installation is currently operating on a single overhead 500 V d.c. conductor rail-return system, at a distance of 7 km from the shaft bottom, subsequently extending to 10 km.

Work is currently being undertaken on the design and development of a trolley/battery locomotive which will have complete shaft-bottom to coal-face capabilities, a distinct advantage over trolley systems. It is envisaged that the new trolley/battery locomotives will be rated at 20 t/120 kW, consisting of four 30 kW motors, and incorporating a 250 V, 500 A-h lead-acid battery capable of giving a 75 kW output over a 5-h period. The locomotives will operate on a twin 250 V overhead conductor system, and battery charging will take place while the locomotive is drawing power from the trolley wire. On reaching the end of the trolley wire the locomotive will change to battery power and will carry out excursions away from the trolley area.

The speed at which trolley locomotives operate is 15–20 km/h, compared with the 10–12 km/h of conventional diesel or battery locomotives. With improvements in roadway conditions and better standards of track, speeds of 30 km/h can be expected.

## 48.5 Coal-face layout

When a new coal-face is started, two roadways are driven from the main intake and return roadways, to form the intake (main gate) and return (return gate) roadways for the coal-face. In each roadway a 6.6 kV DWA PVC three-core aluminium 185 mm<sup>2</sup> roadway cable is installed. This supply is obtained from a local substation which, in turn, obtains its supply from the pit-bottom substation via the parallel district feeders. The main and return gate roadway cables are supported on special hangers attached to the roadway arches at approximately 2 m spacing. These are adequate to support the cable but, in the event of a roof fall, the additional weight causes the cable supports to give way and allows the cable to fall to the floor.

Each roadway cable terminates into a 6.6 kV flameproof 400 A, 150 MV-A circuit-breaker incorporating overcurrent, earth leakage and short-circuit protection. This breaker is a semi-permanent unit, being moved up periodically by the insertion of 100 m of roadway cable as the coal-face advances (Figure 48.8).

Advancement of the h.v. circuit-breaker and armoured roadway cable is always carried out with all power isolated, as opposed to all other equipment (flexible wire armoured cables, transformers, contactors, etc.), which is advanced automatically by hydraulic power as the coal-face advances.

From the h.v. circuit-breaker a 6.6 kV, 50 mm<sup>2</sup> flexible pliable wire armoured (PWA) cable takes the h.v. supply to a flameproof transformer. The PWA cable is supported in loops from a monorail attached to the crown of the roadway arches. Special cable supports with rollers permit automatic advancement.

Flameproof air-cooled transformers are used underground. Common ratings in use are 500, 750 and 1000 kV-A; they weigh about 5 t.

To permit automatic advancement, the transformer, hydrostatic power pack, flameproof contactors (gate-end boxes) and face signal/communication unit, along with spares container, oil drums, stretchers, first aid and fire fighting equipment, etc., are mounted on a robust rail-mounted pantechicon which straddles the main roadway conveyor. The pantechicon is securely attached to the stage loader conveyor, which, in turn, is attached to the coal-face armoured flexible conveyor (AFC).

As the coal is cut by the power loaders, the AFC is pushed forward by hydraulic rams attached to the hydraulic roof supports. This action causes the stage loader (AFC) to advance forward, which, in turn, automatically advances

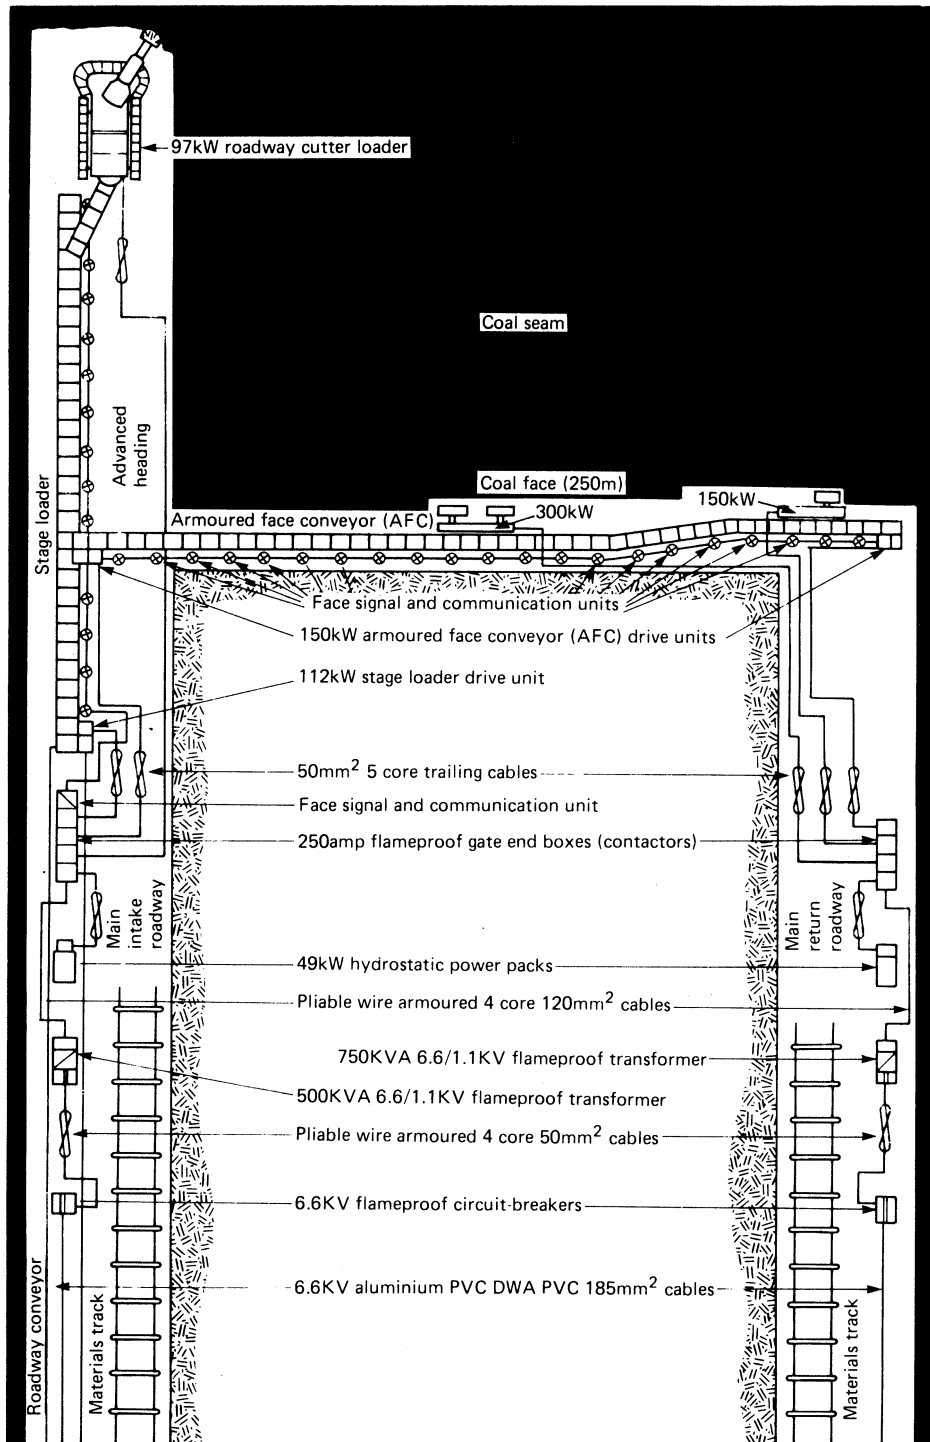

Figure 48.8 Layout of a typical 250 m coal-face

the pantechicon. When the h.v. PWA cable has been fully extended, power is isolated, allowing the h.v. circuit-breaker and PWA cable to be moved forward, and a new length of 185 mm<sup>2</sup> aluminium PVC-DWA-PVC roadway cable to be installed.

Armoured roadway cables are installed in 100 or 200 m lengths and are sent into the mine already fitted with 300 or 400 A flameproof cable couplers, which are normally connected on site with copper connecting pins, rubber gasket, bolts and nuts.

PWA 120 mm<sup>2</sup> four-core cable is used to take the m.v. 1100 V supply from the transformer to the bank of flameproof contactors (known in the industry as gate-end boxes). Each gate-end box (Section 48.9) is equipped with a 200 A flameproof restrained plug and socket which permits supply to the machine via a 50 mm<sup>2</sup> five-core trailing cable. These cables pass along the side of the stage loader to the machines on the coal-face. The static parts of power-loader trailing cables are located in specially designed cable troughs attached to the AFC, whereas the part of the trailing cable which flexes backwards and forwards as the power loader moves along the coal-face is contained within a robust flexible steel or plastic cable handler. Such handlers also contain a water hose which supplies the machine with water for dust suppression and motor cooling. A typical coal-face could be established as in *Figure 48.8*.

The right-hand single-ended ranging drum shearer (SERDS) cuts the right-hand end of the face to a distance of about 25–30 m, while the main machine, the double-ended ranging drum shearer (DERDS) cuts the rest of the face.

Attached to the bank of gate-end boxes in the main gate is a flameproof and intrinsically safe face signal and communication unit. Connected to this unit and spaced approximately every 7 m along the stage loader and coal-face conveyors are face signal and communication units. Each unit is equipped with a signal push-button and lock-out stop key, and every third or fourth unit incorporates a loudspeaker and microphone.

A control point attendant at the face signal and communication unit position controls the stage loader and face conveyor in response to signals transmitted by any of the signal pushbuttons. Upon operation of the start button for the stage loader (which, in turn, automatically starts the face conveyor) a seven-second pre-start warning two-tone 'bleep' is transmitted along the whole length of the stage loader and face conveyor, warning faceworkers that the conveyors are about to start.

Operation of a lock-out push-button causes the respective conveyor to stop. Should this conveyor be the stage loader,

the face conveyor will also stop, as they are connected in sequence.

Should the lock-out push-button be latched in the lock-out position, the conveyor cannot be started until that push-button has been reset. Each lock-out push-button has a specific number which is automatically displayed by a digital readout on the face signal and communication unit whenever a particular lock-out is operated. By the use of such communication facilities, the cause, necessary remedial action and subsequent duration of a stoppage in production can be quickly ascertained.

The face signal and communication unit is connected by cable to the main colliery control room on the surface, which permits instant and direct communication between the surface control room and any point along the working face, or vice versa.

Each power loader is controlled by an individual operator, sometimes by using radio control. Before the machine can be started, water must be turned on to the pre-start warning water jets positioned on either side of the cutting drum. This condition must persist for approximately 7 s before power can be switched on to the machine, thereby warning by wetting anyone inadvertently in a dangerous position that the machine is about to start.

## 48.6 Power loaders

The modern coal-getting machine is termed a 'power loader' because it not only cuts coal, but also loads it onto the armoured flexible conveyor (AFC), which is, in effect, a steel scraper conveyor running the full length of the working face. *Figure 48.9* illustrates a typical modern power loader which has a rotating cutting disc at each end of the machine, mounted on a ranging arm to cater for thicker seams of coal which could be 2–3 m or more. This type of machine is known as a double-ended ranging drum shearer (DERDS). Certain methods of mining call for the use of a machine with only one cutting disc. Such a machine, similar to that illustrated, is termed a single-ended ranging drum shearer (SERDS).

The majority of power loaders are driven by a single 150 kW motor, operating at 1100 V. Some larger machines, however, have been developed using a single 300 kW motor or a two 300 kW motor arrangement. The supply is obtained from a gate-end box in the roadway via a flexible trailing cable, which on the coal-face is enclosed in a robust flexible cable handling device for protection.

**Figure 48.9** Power loader

Each complete machine is built up of a number of sections, consisting basically of electric motor, haulage unit and gearhead.

Incorporated in the motor are a reversing isolator, control facilities and fault diagnostic equipment, which are connected to the flexible cable by a flameproof plug and socket. A drive shaft protrudes from each end of the motor to transmit power to the adjacent units.

The motor at one end is attached to the haulage unit, which provides the hydraulic power, to haul the machine along the coal-face via a driven pinion on the machine, and a static rack attached to the AFC. Speed control is automatic, following the limits determined by the operator who travels with the machine.

Attached to the opposite end of the motor (single-ended machine) is a gearbox, which drives the rotating coal cutting disc. In a double-ended machine a similar gearbox is attached to the haulage unit at the opposite end of the machine.

Radio control techniques have been developed for power loaders, which allow the operator to control the machine from a comparatively safe area, some 15–20 m from the machine.

## 48.7 Heading machines

One of the principal requirements of modern mining is the ability to drive roadways quickly and safely. This is achieved in the main by the use of heavy-duty roadway cutter loaders (*Figure 48.10*). These machines are equipped with one or two rotary cutting heads, which cut out the stone and shape the profile of the roadway to 4 m × 3–5 m.

Debris from the cutting heads falls onto a rotary scraper conveyor at the front of the machine, which transfers the cut material to a bridge conveyor at the rear of the machine, and then on to the roadway conveyors (*Figure 48.8*).

Roadway machines are fed by flexible trailing cables at 1100 V and typically have a 50 kW motor driving a hydraulic power pack and a 50 kW motor driving each cutting head. The machine traverses on hydraulically powered caterpillar tracks, the whole machine being controlled by an operator sitting in the middle of the machine.

## 48.8 Flameproof and intrinsically safe equipment

During the process of extracting coal from the seam, methane gas is given off. It combines with the normal mine air flow and is eventually disposed of at the surface of the mine through the mine ventilation system. By this means the methane content in the mine air is kept to low and safe proportions.

Owing to possible malfunctioning of ventilation apparatus, power supply failure or heavy emissions of methane, the methane/air ratio can increase. Between approximately 5 and 15% methane to air, the mixture becomes explosive, the most explosive mixture being 8.3% methane to air. Electrical equipment in which sparking during normal operating may occur is capable of igniting an explosive methane/air mixture and must, therefore, be given special consideration. For equipment operating at a low voltage and current levels, the circuits can be designed such that the energy released at the spark is insufficient to cause ignition. This can be achieved by the use of non-inductive resistors, non-linear resistors, capacitors, shunt diodes, Zener diodes, full-wave rectifiers, etc., to give 'intrinsically safe' (IS) apparatus.

Apparatus classed as 'intrinsically safe' includes telephones, signals, communications, testing instruments, methanometers, sensors and remote control and monitoring. Since any open sparking produced within such equipment is incapable of igniting an explosive methane/air mixture, no other form of protection is required other than to house the components in a robust enclosure.

In the UK, it has been the practice to design IS apparatus to conform to the requirements of BS 1259 (IS Electrical Apparatus and Circuits). Equipment now, however, is designed to the CENELEC Standard, now BS 5501: Part 7.

IS equipment must be certified by an approved certifying authority for use in mines and the IS certificate number along with other specified information must be clearly marked on each item.

One of the principal requirements of the intrinsically safe certificate is that the equipment must be supplied from an approved source of supply, which can be either a.c. or d.c. The current British Standard covering such supplies is BS

**Figure 48.10** Boom miner with bridge conveyor

6182 (Intrinsically Safe Power Supplies) and caters for a.c. and d.c. supplies and rechargeable battery units.

There are three categories of d.c. supplies, i.e. 7.5, 12 and 18 V, and two of a.c. supply, i.e. 12 and 15 V. Rechargeable batteries of 8 and 14 V are specified, each capable of being charged from the respective source of supply, i.e. the 8 V battery from the 12 V d.c. supply and the 14 V battery from the 18 V d.c. or 15 V a.c. supply.

Power equipment operating on higher current levels which produce sparks during normal operation, and which cannot be designed to be intrinsically safe, must be enclosed in a robust enclosure. If an explosive methane/air mixture exists in a mine roadway and enters the apparatus containing spark producing components, the flame resulting from the ignition will not be transmitted to the ambient atmosphere and so ignite the general body of the mine air. The enclosure in which spark producing components are housed is termed a 'flameproof enclosure'.

Equipment coming within this category covers such items as motors, contactors, switchgear, transformers, light fittings, plugs and sockets, cable couplers, etc., and requires to be certified flameproof by the approved certifying authority as safe for Group 1 gases (methane). In the past, the relevant British Standards were BS 229 and BS 4683. Equipment now, however, is designed to comply with the CENELEC Standard, now BS 5501: Part 5.

A 'Flameproof Certificate' is issued, the number of which must be permanently displayed on each item of equipment along with other relevant details required by the Standard, i.e. manufacturer's name, type reference, number of British Standard, etc.

The harmonisation of European Standards resulted in the issue in 1977 by CENELEC (European Committee for Electrotechnical Standardisation) of the EN 50 series of standard, i.e. EN 50-014 to EN 50-020 Electrical Apparatus for Potentially Explosive Atmospheres. Equipment designed and certified to this standard is accepted by the European Community without further testing, etc.

The European Standards of 1977 were issued as British Standards: a list is given in *Table 48.1*. Since then, these Standards have been periodically updated and two further Standards have been issued, i.e. CENELEC Standard EN 50028 Encapsulation type 'm', i.e. BS 5501: Part 8, and Cenelec Standard EN 50039 (IS) systems, i.e. BS 5501: Part 9.

Gaps associated with any removable covers, doors, motor shafts, etc., must conform to minimum dimensions laid down by the standard. 'Flameproof' apparatus must be designed, installed and maintained at all times within those limits. As a typical example of the tolerances permitted, gaps with a length of 12.5 mm must not exceed 0.4 mm and for 25 mm flanges the maximum is 0.5 mm. During

normal maintenance procedures in the mine these gaps are periodically checked by colliery craftsmen using feeler gauges.

#### 48.8.1 Flameproof transformers

Providing sufficient electrical energy at the modern coal-face with a demand of some 1–1.5 MV-A at a distance of 6–8 km from the shaft bottom and at a depth of 900–1000 m requires an efficient h.v. electrical distribution system.

From the voltage regulation point of view it is essential that the h.v. supply be taken up to the working face, therefore transformation facilities are needed to provide the coal-face utilisation voltage of 1100 V.

Before the advent of flameproof dry-type transformers, standard industrial oil-filled transformers were utilised, often with flameproof oil circuit-breakers attached to each end. Mining legislation at that time, however, decreed that such transformers could not be used nearer than 300 yards from the coal-face and in no circumstances could they be used in a return roadway. As coal-face loading increased in the 1950s and early 1960s as a result of the mechanisation of coal-getting, it became of paramount importance to move the transformer right up to the working face and strengthen the h.v. distribution system. This led to the development of the flameproof air-cooled transformer, which has a flameproof h.v. circuit-breaker on the h.v. side and a flameproof m.v. chamber mounted on the opposite end to house the overcurrent, sensitive earth leakage and short-circuit protection equipment, which on operation causes the h.v. circuit-breaker to trip. Typical transformer ratings would be 500, 750 and 1000 kV-A. Comparing these with the old oil-filled types (which were usually of the order of 250 kV-A) indicates the change which has taken place in the mining industry since nationalisation in 1947.

*Figure 48.11* shows a typical 750 kV-A flameproof transformer viewed from the h.v. end, the circuit-breaker being a 6.6 kV, 400 A, 150 MV-A sulphur hexafluoride (SF<sub>6</sub>) unit complete with incoming cable adapter suitable to accept the 6.6 kV, 300 A, six-bolt cable coupler attached to the end of the incoming 6.6 kV h.v. cable. The m.v. chamber at the opposite end is approximately three-quarters the size of the h.v. circuit-breaker and is similarly equipped with flameproof adapters to accommodate the outgoing 1100 V cables.

The transformer is equipped with lifting lugs for loading and unloading and adjustable wheels for transportation underground. The total weight would be of the order of 5–5½ t.

**Figure 48.11** Flameproof transformer

**Table 48.1** Standards for electrical apparatus for use in potentially explosive atmospheres

<i>CENELEC Standard, EN 50-</i>	<i>British Standard BS 5501</i>	<i>Subject</i>

015	Part 2	Oil immersion 'o'
016	Part 3	Pressurised apparatus 'p'
017	Part 4	Power filling 'q'
018	Part 5	Flameproof enclosure 'd'
019	Part 6	Increased safety 'e'
020	Part 7	Intrinsic safety 'i'

### 48.8.2 Flameproof switchgear

Prior to the mid-1960s, nearly all the h.v. and m.v. circuit-breakers used in mines were of the oil-break type, usually of the order of 150/200 A, 3.3 kV, 25 MV-A and, although certified flameproof, they constituted a hazard owing to the oil-fire risk. In addition, maintenance of the oil was a problem due to the oil transport and cleanliness, and the disposing of waste oil. With the introduction of no-oil switchgear, maintenance was reduced and the oil-fire risk eliminated.

Modern flameproof mining-type circuit-breakers operate on either the air-break, vacuum interrupter or sulphur hexafluoride gas principle and can be arranged such that they can be utilised as single free-standing units, on a complete switchboard, or mounted on the h.v. end of a flameproof oil transformer.

Owing to the increase in demand for electrical power underground and the uprating of underground distribution systems, switchgear ratings have also increased. A typical modern flameproof circuit-breaker as shown in *Figure 48.12* would be a 6.6 kV, 400 A, 150 MV-A unit. This circuit-breaker is of the vacuum interrupter type and the illustration shown is a classical example of the construction of flameproof switchgear. The flameproof enclosure is divided into separate flameproof compartments electrically linked by the use of flameproof bushed terminals. In the bottom compartment the circuit-breaker is housed on a withdrawable chassis complete with overcurrent, earth leakage and short-circuit protection.

Two separate compartments are provided in the centre of the circuit-breaker which accommodate the isolator(s) and incoming or outgoing cable terminations. Also incorporated in the section are the isolator and circuit-breaker operating handles, which are mechanically interlocked

to ensure that the isolator can be operated only with the circuit-breaker in the 'off' position. Mechanical interlock is also provided between the isolator and circuit-breaker handles and the front cover of the circuit-breaker compartment, to prevent access until the interior has been made dead.

With slight modification to the basic design, flameproof mining-type circuit-breakers can be used in either of four different modes, i.e. incoming unit, feeder unit, bus-section unit or transformer switch unit.

### 48.9 Gate-end boxes

The control of individual drives in a coal mine, such as conveyors, power loaders, pumps, haulages, etc., is achieved as in any other industry, i.e. by use of contactors.

For mining purposes contactors must be enclosed in a robust flameproof enclosure or box. In the early days of electricity in mines, such a box would be installed at the end of the roadway leading to the coal-face. To use mining parlance, a roadway is a 'gate'; therefore, the 'box' installed at the 'gate end' became known as the 'gate-end box'.

Figure 48.12 Flameproof circuit-breaker

**Figure 48.13** Gate-end box

The term is still used today to refer to a flameproof contactor unit.

Figure 48.13 illustrates a typical flameproof gate-end box suitable for use on an 1100 V, three-phase, 50 Hz system, and rated at 300 A. The box can be adapted for use as a single unit or assembled to form a 'bank of panels'. Figure 48.14 shows a typical bank of panels mounted on a pantech-nicon over a roadway conveyor adjacent to a coal-face.

A gate-end box consists of upper and lower chambers interconnected by flameproof bushed terminals. The upper compartment contains 400 A throughgoing bus-bars and a three-phase isolator. The ends of the bus-bar chamber are designed to accept flameproof bus-bar trunking units and links to enable individual panels to be built up into a bank or to accept a bus-bar blank at one end and an incoming

**Figure 48.14** Bank of gate-end boxes

cable adapter at the other to form a single unit. In the lower compartment is housed the contactor of rating 150, 250 or 300 A, and a control unit, all mounted on a removable chassis for ease of maintenance, repair or removal.

A mechanical interlock is provided between the isolator operating handle and the contactor compartment cover to ensure that access to the contactor compartment is prevented until the isolator has been placed in the 'off' position.

Power is transferred to the drive from the gate-end box via a flexible trailing cable which, owing to the hazardous environment of the coal-face, is always susceptible to damage. Facilities must therefore be provided to enable the trailing cable to be changed quickly. This facility is provided on the gate-end box and the motor in the form of a 200 A restrained flameproof plug and socket (Figure 48.15).

Taking into consideration the control facilities, sensitive earth leakage protection, static overcurrent protection equipment, etc., the modern gate-end box is a complex piece of electrical equipment which has to work with a high degree of reliability in an atmosphere that can be hot, cold, dry, wet and, on occasion, subject to considerable vibration. Some of the electrical/electronic components can therefore be subject to abnormal abuse while in service. It is for this reason that the evolution of the modern gate-end box has resulted in the majority of the small electrical/electronic components being contained in a 'control unit', which is a plug-in unit on the contactor chassis. This control unit can be quickly changed in the event of trouble, and transported to the surface workshop for overhaul and repair.

Control of the gate-end box can be effected locally or remotely, the selection being by way of a changeover switch on the control unit. In the majority of cases the remote control facility is adopted: it utilises a pilot control core in the five-core flexible trailing cable and a flameproof starting device at the motor end. In the past, the pilot circuit or the remote control IS circuit was designed to the NCB specification P130, based on the following principles:

- (1) the circuit is energised from an intrinsically safe constant voltage transformer within the gate-end box, designed to give a constant 12 or 7.5 V secondary output over a wide variation of primary input—one side of the 12 or 7.5 V winding is earthed;
- (2) a pilot relay is provided in the gate-end box which will operate on half-wave but not on full-wave a.c.; and
- (3) at the far end of the trailing cable a diode is provided along with a start switch across which is connected a 30  $\Omega$  resistor.

With the upgrading of the specification for intrinsically safe (IS) equipment it has become difficult to design this

**Figure 48.15** Flameproof plug and socket

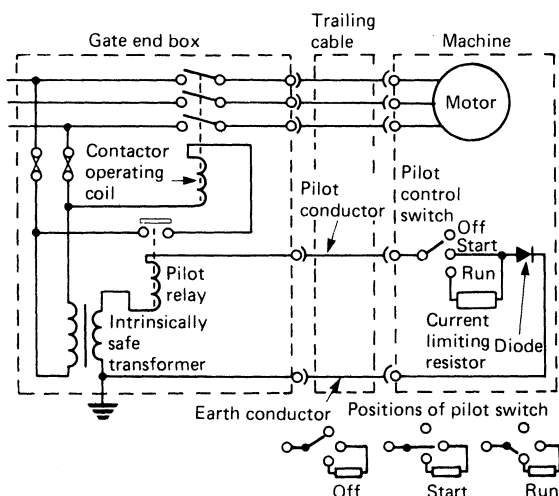

Figure 48.16 Contactor-coil/pilot circuit

pilot circuit to the latest IS requirements. A new British Standard (BS 7202: 1989 Non Incendive Low Voltage Control/Interlock and Low Voltage Earth Fault Monitoring Circuits for Use in Mines) has been issued to which the equipment is now being designed.

Figure 48.16 shows a basic arrangement of the contactor coil/pilot circuit within a gate-end box, the associated trailing cable and a face machine with in-built start switch. To start the machine, the switch is moved to the 'start' position. With only the diode in circuit the pilot relay (PR) energises and the machine starts. The start switch now reverts automatically to the 'run' position inserting the  $30\ \Omega$  resistor into circuit.

Should a power failure occur with the control switch in the 'run' position, following which the power is restored, the relay PR will not energise at a voltage below 120% of the declared voltage of the incoming supply. Operation of the start button causes PR to energise: it must do so down to 75% of the declared incoming voltage supply. Once energised and with the  $30\ \Omega$  resistor in circuit, PR must remain energised down to 60% of the declared voltage but under no circumstances continue to operate at 20% or below.

Should a damaged trailing cable result in a pilot core-to-earth fault, full-wave a.c. would be applied to PR which (on account of the increased impedance) would de-energise if in operation, or fail to energise upon operation of the start button. This condition, known as pilot core protection (PCP), would be indicated by a lamp at the front of the gate-end box.

Prior to 1959 most transformers used underground to supply coal-face equipment had the neutral point of the secondary windings solidly earthed, and earth leakage protection in gate-end boxes operated on the core-balance principle. Trailing cable damage on such systems resulted in very severe incendive arcing which, on the coal-face especially, was a very serious hazard. Following an explosion at Walton Colliery near Wakefield in 1959, H.M. Principal Inspector of Mines recommended that a further attempt should be made to devise an electrical protective system capable of eliminating, or at least substantially reducing, the dangers of incendive sparking resulting from damaged trailing cables. This led to the development of the sensitive earth leakage (SEL) circuit, which exists in two forms: single point and multi-point.

### 48.9.1 Single-point sensitive earth leakage

The basic principles of single-point earthing systems are similar to those of solidly earthed systems in that a core-balance transformer more sensitive than used on solidly earthed systems is employed. This system is sometimes referred to as sensitive core balance, and the main difference between the two systems is in the method of earthing the neutral point of the transformer secondary winding.

In the single-point system an impedance is inserted between the neutral point and earth of such value as to limit the earth fault current to a maximum of 750 mA (Figure 48.17). Although this is the maximum earth fault current permitted, individual earth fault trip circuits are set to trip at between 80 and 100 mA, giving a safety factor of approximately 7 to 1.

The core-balance transformer output under fault conditions is very small and an electronic amplifier is used to control the earth fault relay, which is energised under healthy conditions and de-energises on the occurrence of a fault. This arrangement results in a fail-safe system. The earth leakage relay contacts are inserted in the contactor coil circuit, which opens on the occurrence of a fault.

To ensure that a contactor cannot close onto a system on which an earth fault condition exists, an additional arrange-

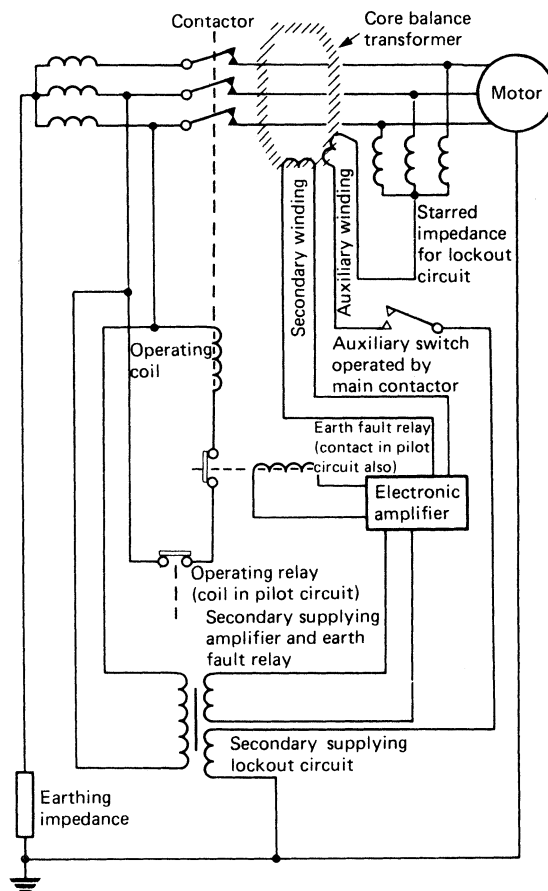

Figure 48.17 Protection unit for high-impedance single-point earthing

ment is provided which is termed the electric lockout circuit. It consists of three impedances, one end of which is connected to the three outgoing phases; the other ends are star-connected and, in turn, are connected to an auxiliary core-balance transformer winding, a pair of contactor auxiliary contacts (closed when the contactor is open) and an intrinsically safe source of supply which has one end of its winding earthed. Should an earth fault develop while the contactor is de-energised, the earth leakage lock-out circuit would operate to prevent the contactor coil energising, a condition that would persist as long as the earth fault was in existence.

#### 48.9.2 Multipoint sensitive earth leakage

In the multipoint system the transformer secondary is completely insulated from the earth, i.e. it is a free neutral (*Figure 48.18*). Each contactor is provided with a false neutral which, similar to the single-point system, consists of three impedances connected to the three outgoing phases. The star point is connected via a pair of contactor auxiliary change-over contacts to either the failsafe earth leakage detection circuit or the earth leakage lock-out circuit, depending on whether the contactor is energised or not.

The earth fault current on the multipoint system is limited to 40 mA on a 1100 V system. Since an earth fault on a system supplied from one transformer could cause all gate-end boxes on the system to trip, and in order to keep the maximum earth fault current to 750 mA, the number of gate-end boxes on a system must be limited to  $750/40 = 48$ .

When a contactor trips on earth leakage on either system, that contactor locks out and displays earth leakage trip conditions, which can only be re-set by an authorised craftsman with the appropriate specialised equipment.

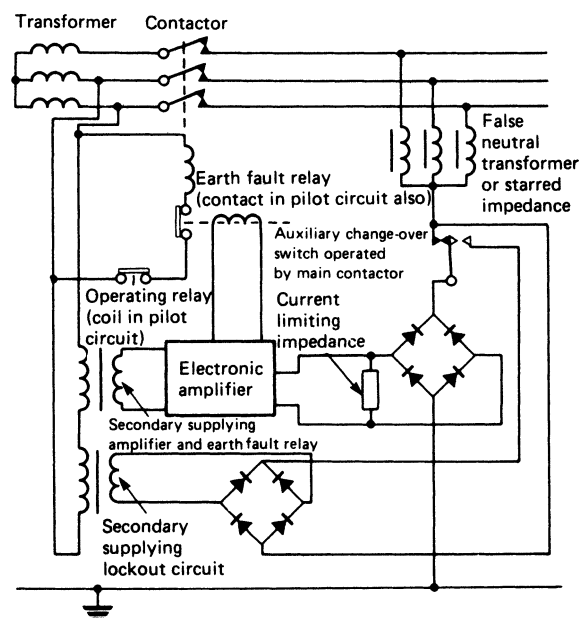

Figure 48.18 Protection unit for multipoint earthing

#### 48.10 Flameproof motors

Mechanisation of the coal-mining industry in the 1950s, followed by further mechanisation and automation in the 1960s and 1970s completely changed the face of the industry. Elimination of 'self-generation' at collieries and the introduction of duplicate and more substantial power supplies from the Electricity Boards plus the strengthening of colliery distribution systems made the direct-on-line starting of large cage-induction motors possible. BCC Specifications have been produced covering the majority of FLP motors used in British mines (see *Table 48.2*).

Motors associated with coal-face equipment need changing more often than those operating in roadways and engine houses, owing to the hazardous conditions in which the equipment has to operate on the coal-face, physical damage and ingress of water moisture being the prime causes of failure. To facilitate speed and accuracy in changing and lining up, such motors are designed for flange mounting. *Figure 48.19* shows a typical flange-mounted motor complete with flameproof terminal box and flameproof 200 A plug and socket.

Figure 48.19 Flange-mounted flameproof motor

**Table 48.3** National Coal Board (NCB) Specifications for cables

NCB Specification No.	Subject
P115	Short-firing cables (other than in shafts)
P188	Flexible trailing cables (for coal cutters and similar use)
P295	PVC-insulated wire armoured and sheathed cables
P492	PVC-insulated wire armoured telephone cables
P493	PVC-insulated wire armoured signalling cables
P504	Flexible trailing cables with galvanised steel pliable armouring
P505	Flexible trailing cables (for drills)
P610	Flame-retardant properties of flexible trailing cables
P648	Multicore PVC-insulated wire armoured and PVC sheathed 0.6–1.0 kV cables (with special screening for mine winder safety and control circuits)
P653	Flexible multicore screened auxiliary cables with galvanised steel pliable armouring
P656	EPR-insulated wire armoured and PVC sheathed cables

EPR, ethylene propylene rubber; PVC, polyvinyl chloride.

### 48.11 Cables, couplers, plugs and sockets

All cables used in mines for any purpose must conform to the requirements of the relevant BCC Specifications, which are listed in *Table 48.3*. Colliery surface and underground h.v. and m.v. distribution systems utilise, in general, PVC insulated and sheathed mains cables. DWA cables have up to a few years ago been exclusively used for underground systems but recently single wire armoured (SWA) cables have received favourable consideration, owing to reduced cost and flexibility in handling. Such cables conform to NCB Specification 295 or 656.

Wire armoured roadway cables are usually received at the colliery on 100 m drums with 300 A flameproof couplers already fitted at each end. On completion of assembly the cable coupler is filled with either bituminous compound or a cold-pouring compound, consisting of a bituminous oil and a hardener. A typical 6.6 kV, 300 A flameproof cable coupler is shown in *Figure 48.20*, the halves being connected by the use of three connector pins, a rubber sealing gasket and six connecting bolts.

Mobile machines such as power loaders and roadheading machines, which require to move while energised, must be powered by the use of a flexible trailing cable to satisfy the requirements of NCB Specification 188. Several types are available, ranging in size from 16 to 95 mm<sup>2</sup>. *Figure 48.21* illustrates a typical trailing cable (type 7). It consists of three power cores, a pilot control core and an earth core. The earth core is uninsulated, and is located in the centre of the cable, with the three power cores and the pilot core equally spaced around it. All four cores are insulated with ethylene propylene rubber (EPR); the power cores have an additional copper/nylon screen over the insulation. Overall protection is provided by a tough heavy-duty polychloroprene (PCP) oversheath. A similar cable but of slightly different

**Figure 48.20** Flameproof cable coupler

**Figure 48.21** Trailing cable (type 7)

construction is the type 10 cable shown in *Figure 48.22*. The three power cores and pilot core are again EPR insulated, but each has a conductive rubber screen, and all four cores are laid up around a conductive rubber cradle separator. The overall protective sheath is PCP.

Figure 48.22 Trailing cable (type 10)

Since trailing cables associated with mobile machines are susceptible to damage, means must be provided to quickly connect or disconnect the cable from the motor/gate-end box. This facility is provided in the form of a 200 A, 1100 V flameproof restrained plug and socket, a typical example of which is shown in Figure 48.23. The socket is attached to the motor/contactor and the plug is attached to the cable. A scraper earth facility is provided on the socket which mates with the nose of the plug as it is inserted to maintain the necessary earth connection. Four pins are provided on the plug-and-socket assembly, three power cores and one pilot control core. The pilot pin is shorter than the power pins, so that on insertion it makes contact after, and on withdrawal it breaks before, the power pins, preventing their making or breaking on load.

Pliable wire armoured cables are used to power permanent and semi-permanent apparatus such as transformers and gate-end box assemblies which move up automatically as the coal-face advances. Such cables must conform to the NCB Specification 504, and range in size from 10 to 150 mm<sup>2</sup> at voltages of between 660 V and 6.6 kV. Figure 48.24 illustrates a typical 6.6 kV pliable wire armoured cable (type 631) which has four cores insulated with EPR. A copper/nylon screen is provided over the insulation on the power cores, and all four cores are laid up around a PCP centre, over which is provided a PCP sheath. Over the inner PCP sheath is a galvanised steel strand armouring and an overall sheath of PCP.

Two, three-, four- and five-core pliable wire armoured cables of similar construction but with much smaller conductor size, e.g. 4 mm<sup>2</sup>, are used for control circuits and coal-face lighting installation. Such cables are termed types 62, 64, 70 and 71, respectively.

Five-core 6 mm<sup>2</sup> flexible cables are used to power hand-held drilling machines which operate at 125 V, three-phase, 50 Hz. Type 43 has three power cores, one pilot core EPR insulated and one earth core conducting rubber covered laid around a conducting rubber cradle separator, screened with conducting rubber and a heavy-duty overall sheath of PCP. Type 44 has five EPR-insulated cores with the three power cores copper/nylon screened, laid up round a PCP centre with a heavy-duty PCP sheath overall.

Cables for telephone communication are designed to NCB Specification 492, and can be either PVC-SWA-PVC

Figure 48.23 Flameproof restrained plug and socket

Figure 48.24 Flexible wire armoured cables

or PVC-DWA-PVC. The cores are laid up in one to 91 pairs of  $1.5 \text{ mm}^2$  conductors and follow a set colour code.

Signal cables conform to NCB Specification 493, and can also be PVC-SWA-PVC or PVC-DWA-PVC. These cables have conductor sizes of  $1.5 \text{ mm}^2$ , ranging from 2 to 91 cores, and are laid up as single cores to a colour code.

## 48.12 Drilling machines

Mechanisation and automation have reduced the application of hand-held drilling machines. A typical machine is shown in *Figure 48.25*. Such machines are rated at 1.1 kW, 125 V, three-phase, 50 Hz, and operate from a purpose-designed flameproof drill panel. Drill panels are approximately the same size and shape as gate-end boxes and are designed so that they can be connected together mechanically. The drill panel contains its own step-down transformer to feed the drilling machine, contactors, protection, etc. The supply to the drill is taken from the drill panel via a 30 A flameproof plug and socket, and a five-core drill cable, consisting of three power cores, a pilot core and an earth core.

## 48.13 Underground lighting

Illumination underground is provided in accordance with the Coal Mines Safety and Health Regulations and to improve environmental conditions. The areas illuminated are pit bottoms, haulage stations, locomotive stations, main trunk conveyors, assembly areas and main roadways where men pass to and from their place of work.

Lighting underground is provided in four ways:

- (1) by a portable lamp carried by each person underground;
- (2) by permanent lighting installations supplied by a power transformer at 120 or 240 V, 50 Hz;
- (3) by mains lighting which forms part of a mobile machine; or
- (4) by portable compressed-air turbines.

The cap lamp (*Figure 48.26*) comprises a headpiece provided with a main 4 V, 0.9 or 1.0 A lamp and a 4 V, 0.46 A

**Figure 48.25** Hand-held drilling machine

**Figure 48.26** Cap lamp

pilot lamp. The headpiece, which can be carried or worn on a special helmet, is connected by flexible cable two-core  $1.0 \text{ mm}^2$  vulcanised-rubber-insulated PCP sheath. The battery consists of two lead-acid cells in a polycarbonate moulded case giving 4 V output. A fuse is provided in the battery top to afford protection. The capacity of the batteries is 13 or 16 A-h.

The assembly was covered by BS 4945, but this has been superseded by the European Norm CENELEC 50 033: 1986, i.e. BS 6881:1987.

To prevent interference underground, all lamps are locked and sealed before issue at the surface lamp room. *Figure 48.27* shows a typical lamp-room layout. The miner enters the lamp room and collects his own personal cap lamp before entering the mine. On his return he places his lamp on the charging rack in the lamp room, when recharging commences automatically. During the period between shifts, the lamps are examined, cleaned and topped up ready for the next period of duty.

Permanent lighting installations below ground are similar to those provided on the colliery surface, viz. filament, fluorescent, discharge, sodium, and mercury lamps, in substantial

**Figure 48.27** Layout of a lamp room

dust-proof fittings outside hazardous areas, and flameproof to group I (methane) in the hazardous areas. Special attention is paid to the design of electric circuits, proper loading, and fault protection, i.e. earth fault, overload and short circuit.

Illumination on mobile machines is provided by equipment designed and tested for the automotive industry but fitted into flameproof lights with protection to prevent damage. In mining development work where the heading is progressively moving, the provision of lighting on machines is advantageous.

Coal-face lighting has had a long history. Numerous approaches and types have been used but have failed for various reasons. The conditions imposed by the Coal Mines Act 1911 limited such installations to 'naked-light mines' only; it was not until 1934 that mains lighting on the face in safety lamp mines was permitted. In 1973 mains fed intrinsically safe lighting was developed using 12 in., 8 W fluorescent tubes on a high-frequency supply. This has resulted in a smaller, lighter, more easily maintained system.

## 48.14 Monitoring and control

Different types of monitoring and control systems are in use at collieries: either 'surface only' installations, designed as for other industries, or 'surface/underground' systems, which are specifically designed for use underground, requiring IS.

A typical system for use underground consists of a surface control or central station, a number of two-way transmission links (called 'rings') to convey data over distances up to 8 km, to and from numbers of underground FLP/IS out-stations to which are connected sensors for monitoring and control facilities. These systems may perform individual functions (e.g. coal clearance by remotely controlling conveyors, environmental monitoring, pumping, or fan monitoring), or may be multifunctional.

A surface control or central station would consist of a mini-/micro-computer, controlling a number of transmission rings. Transmission rings are usually from two- to six-wire time division multiplex data transmission systems, capable of approximately 500 bit/s, coupled to a maximum of 32 outstations. Some frequency-multiplex systems are used: in this case the signals are passed along armoured low-loss coaxial cable. Audio frequencies, modulated low radio frequencies or modulated v.h.f. frequencies are employed.

The out-stations, sited underground near to the plant concerned, are constructed part FLP to give a number of IS supplies from 110/240/550 V, and part non-FLP to house the printed circuits and terminations. The out-stations are required to collect information from various sensors and other circuits, pass this information to the transmission rings and receive from them surface information and commands. Action can then be taken by the out-station on these commands, or independently appropriate shutdown and alarm action can be taken through fault-tripping logic, according to the state of the protective sensors and other monitors associated with the plant.

Where possible, all circuits are designed for 'failure to safety'; therefore a.c. signals are preferred, with the final control operator being a relay, supplied through an isolating transformer or 'diode pump' circuit, fed through two high-voltage series capacitors, the relay being energised in the healthy state.

On/off sensor signals are obtained using a half-wave rectifier at the sensor end and an a.c. IS supply to provide open- and short-circuit cable protection.

The surface control (*Figure 48.28*) could be in an air-conditioned room and may house many separate control and monitoring systems, together with a data collection computer system, using larger disc storage. The electrical supply is taken from a source as near to the colliery feed as possible, through constant voltage transformers (CVTs) to give as clean and permanent a supply as possible.

**Figure 48.28** A surface control room

### 48.14.1 Computer system

#### 48.14.1.1 Hardware

A list of the hardware used is given below.

- (1) Mini- and/or micro-computers;
- (2) floppy or hard disc loading and data storage;
- (3) all parity checks utilised; 'watchdog'-type timer system; system scan time with 1 s;
- (4) two-colour graphic visual display units (VDUs) displaying mimic representation of system (faults, alarms etc.) in different areas of the screen;
- (5) keyboard used to effect system changes and issue commands;
- (6) print—300 baud rate of print-out shift analysis of data, breakdown, etc.;
- (7) suitable intrinsically safe interface to the underground transmission system;
- (8) all changeable-type ROMs, marked to a standard by the suppliers; and
- (9) computer interconnections via 20 mA serial loops, terminals, VDUs, etc., connected via either 20 mA loop or VT24.

#### 48.14.1.2 Software

Software is normally written in assembler of Coral-66 languages. Most systems have executive type control software to give safer systems and provide rapid response to real-time requirements. Software is written to be as inherently safe as possible and is resident in the memory at all times. Some systems perform periodic check sums on ROM and RAM memory, as well as transmitted data. Entry to make system changes or give commands is restricted by level of password. Some diagnostic software is available to check much of the hardware, including on-line checks of transmission data. A software system is supplied to a colliery in package form, the package containing an operating system and a set of modules or application programs from which a particular system may be configured. Configuring, carried out in password, is on a questionnaire basis and allows the operator or engineer to: add or delete items of plant control facilities (sensor, etc.); change set points, levels and limits of analogue signals; set out-station types; build, using graphics, a representative mimic of the colliery system; select data to be periodically printed; etc.

### 48.14.2 Underground sensors

Listed below are some of the many different types of underground sensor, together with a few of the varied monitoring applications of each.

- (1) *Temperature*: bearings, brakes, and temperature rise.
- (2) *Pressure*: barometric, fluid, and differential (for flow).
- (3) *Flow*: liquids, ventilating air, and gas.
- (4) *Proximity*: position and movement (for velocity and acceleration).
- (5) *Weight, volume, force*: belt load, static weighers, chain force, torque, and tension.
- (6) *Vibration*: bearings.
- (7) *Gas and atmosphere analysis*: methane, oxygen, carbon monoxide, carbon dioxide, humidity, dust, and smoke.
- (8) *Electrical analysis*: power, voltage, and current.
- (9) *Level*: coal/stone bunkers, and fluid level (e.g. of lubricating oil).

Most sensors, including any electronic circuitry, are designed to be IS 'fail-safe'. With on/off switching, a.c. IS voltages are used, with a half-wave rectifier at the sensor. Analogue signals are 0.4–2.0 V, or 4–20 mA. Underground sensors must be manufactured from approved materials, such as brass, to eliminate incendive sparking risks.

*Analogue temperature* In these measurements, by virtue of the low energy capacity of the IS supply low impedance devices such as, for example, 100  $\Omega$  platinum resistors or thermistors are used in order to enable a number of points to be monitored.

Measuring electronics are designed to be 'fail-safe' throughout and provide a variable shutdown/warning level or in some cases (such as monitoring of compressors) fixed maximum shutdown levels, for example the maximum air temperature would be 160°C and maximum oil temperature 80°C.

*Pressure* Measurement ranges vary from 0–0.25 kPa to measure the differential pressures across mine stoppings to 1500 bar for hydraulic pressure.

In general the lower pressures are measured using a diaphragm-type transducer, higher pressures are usually monitored by strain-gauge bridges.

## 49.1 Introduction

Standards are vital components of UK marketing strategy. Ordering and procurement is increasingly done over the Internet and in order to ensure that the products are suitable for the purpose required, compliance with a nationally and internationally approved standard is of increasing importance to customers. Reflecting the growth of electronic communication, standards authorities such as the British Standards Institution have been making considerable investment in Information Technology in order to exploit the rapid communication possibilities of IT in providing industry with the standards it needs. From the year 2000 this will become the major means of communication in the standards field. Details of information sources are given in subsequent parts of this chapter.

A standard is defined as a technical specification or other document available to the public, drawn up with the co-operation and consensus or general approval of all interests affected by it, based on the consolidated results of science, technology and experience, aimed at the promotion of optimum community benefits and approved by a body recognised on the national, regional, or international level.

The National Standards Body recognised in the United Kingdom is the British Standards Institution (BSI) whose principal function is the preparation and/or publication of national standards and/or the approval of standards produced by other bodies. BSI serves as the national member of the corresponding international and regional standards organisations. The international standards organisation principally concerned with electrical standards is the international Electrotechnical Commission (IEC) and the corresponding regional standards organisation for Europe is the European Committee for Electrotechnical Standardisation (CENELEC). CENELEC is very important to UK manufacturers, because it has the power to issue *Directives* which are binding on all EEC member states and effectively outlaw any product which does not fully comply with the standard requirements contained in that directive. More detail of these and other standardising bodies is given in Section 49.2.

Standards are revised, when necessary, by the issue of amendments, or, in the event of the need for major alterations or additions, by the issue of new and revised editions. Users of standards must ensure that they use the latest amendments or editions. Standardising bodies supply regular information on all such changes (in the United Kingdom, this information is summarised annually by BSI who also issue their catalogue in electronic form. The information is up-dated monthly in *Update-Standards* and general information about standards is published bi-monthly in *Business Standards*. Both publications are available from BSI.)

More immediate access is provided over the Internet on the BSI Website : [www.bsi-global.com](http://www.bsi-global.com)

### 49.1.1 The need for standards and the aims of standardisation

The primary need for standardisation is to provide a set of criteria by which a product can be judged to be suitable for the purpose for which it is intended in comparison with like products from a variety of sources. This is of value to both manufacturer and user (see Section 49.1.1.1). Achievement of all the targets of performance set in the standard by samples taken from production at regular intervals is also a measure of the sustained quality of manufacture, the standard again providing the yardstick by which consistency of manufacture can be assessed (see Section 49.1.1.5).

Those preparing standards have common agreed aims (see Section 49.1.1.2) designed to make the standard of optimum applicability and usefulness to meet the needs of the application.

Standardisation is needed also to avoid the pitfalls of proliferation of sizes and performance specifications which in the absence of standardisation would make difficult the replacement of a damaged component by one of different manufacture or even from the same manufacturer if modifications have been subsequently made to the design (see Section 49.1.1.3).

Last but by no means least, safety requirements can be carefully thought through by a standardising committee which has representation of health and safety bodies, to ensure that there are clauses in the standard which spell out clearly the necessary requirements and design criteria which the product must meet in order to ensure that it is safe in normal use (see Section 49.1.1.4).

#### 49.1.1.1 The value of standardisation

Users are increasingly aware of the value of purchasing a product certified to national and international standards. They can rely on its performance to a known set of criteria, and if its quality of manufacture is regularly assessed, they know that the standard of performance is maintained and that the product does not have design faults which are likely to make it fail prematurely in normal service. This can ensure a financial saving not only of the cost of early replacement but also of the cost of the 'down-time'. Furthermore, with the more strict personal liability for health and safety at work applying today, the user is even keener to ensure to the best of his ability that the product he is using is not unsafe in use. If he buys a product which has not been tested to the appropriate safety requirements of the standard the chance of an accident is much higher. He also may consequently be legally liable, whereas if the product had been certified to the appropriate standards and correctly installed and applied, he would have done all that he could do to avoid an accident.

New regulations introduced in 1966 (detailed in 'RIDDOR 95' published by the HSE) put extra responsibilities on employers when accidents occur in the workplace, and legislation is becoming increasingly intolerant of those employers who neglect to provide adequate protection. Compliance with all safety aspects of standards is therefore paramount in producing a satisfactory risk assessment.

The commercial advantage to the manufacturer in having a range of products fully certified to the appropriate standards is therefore very apparent. His customers need to buy his products of demonstrated performance and safety, rather than making false economies by purchasing cheap untested competitive products which are likely to fail or malfunction in service, possibly dangerously. The certification to safety standards gives also a degree of protection against legal action in the event of accident involving the product.

The value to the general public at large of standardisation is the improved reliability of the equipment around them, giving longer uninterrupted service and greater personal safety.

Under the Directives of the EEC, larger users will be compelled to change their installations, replacing components not conforming with harmonised European standards. This is considered further in Section 49.2.3.

Standards are also needed to simplify contractual agreements, because the supplier can ensure that his products comply with all the relevant clauses of the appropriate

standard and such compliance can be written into the contract for any of his customers. Otherwise it would be necessary to prepare a detailed technical performance specification for each product for each customer. Having stated the appropriate standard it remains only to add any special requirements, delivery dates, price agreement etc. and both sides are presented with an unambiguous contract. Savings on stock levels are also facilitated, because it is generally only necessary to stock standardised items for which there is more general demand.

#### 49.1.1.2 *Specific aims of standardisation*

From considerations of the need for standards similar to those summarised above, five aims of standardisation have been identified in BS 0:1991:

- (1) provision of means of communication amongst all interested parties;
- (2) promotion of economy in human effort, materials and energy in the production and exchange of goods;
- (3) protection of consumer interests through adequate and consistent quality of goods and services;
- (4) promotion of the quality of life: safety, health and the protection of the environment; and
- (5) promotion of trade by removal of barriers caused by differences in national practices.

In the following sections we can see how well these aims have been achieved by national, regional, and international standardisation. BS 0 has only recently been completely revised, but with the advance of the electronic age it will doubtless soon require further revision.

#### 49.1.1.3 *Reduction of proliferation*

The issue of a standard promotes the reduction in proliferation of product sizes which do not fit in standard equipment, product ratings which are too restrictive for general application and products which are non-compatible with all the systems of which they are intended to be a component.

Standardisation therefore represents a major economy in the stocks of spares which have to be kept to replace spent or worn-out components, and considerably eases the task of designers of equipment incorporating a range of products, with standard ratings based where possible on the R10 series. This harmonisation means that the standard product can be specified, knowing that it will fit and will have the required technical performance with the specified level of safety.

This principle is increasingly being extended internationally through the work of the IEC (see Section 49.2.2) and in Europe by CENELEC (see Section 49.2.3). After 1992 many CENELEC harmonised documents will have the force of law, and the corresponding products will only be saleable in the UK and Europe if they comply in all respects.

#### 49.1.1.4 *Safety*

Standards also cover aspects of safety. In this respect they seek to define the acceptably reasonable level of risks of personal harm in the foreseeable use or misuse of a product, process or service.

An example of a standard specifically classifying different levels of acceptable risk is BS 60529 (identical with IEC 60529) 'Classification of Degrees of Protection Provided by Enclosures'. This standard specifies tests for a series of levels of protection and defines an IP (International Protection) code which identifies the degree of protection

against direct contact, against ingress of solid objects and/or water, etc. For example an enclosure classified as IP2X has been tested to ensure that an average finger cannot be poked into the enclosure in such a way that it can come into contact with live parts or dangerous moving parts. However, wires can be poked in. If protection is provided against touching by ingress of wires down to 1 mm. diameter, the category is IP4X. Space does not permit further detail here, and readers are referred to the standard, which is applicable to enclosures containing any electrical equipment, providing its rated voltage does not exceed 72.5 kV.

Standardising bodies also publish documents summarising up-to-date knowledge on safety related matters. An example of this is IEC 61479-1 'Effects of Current passing through the Human Body', which provides basic guidance on the effects of shock currents on the human body. This provides a most useful source of reference when establishing electrical safety requirements for products, or when devising regulations for electrical safety with respect to avoidance of death or injury from electric shock. Hazards due to overheating of electrical equipment can lead to oxidation of contact surfaces, deterioration of insulation, burns to personnel, or in an extreme case to ignition and fire. Consideration of these matters becomes complicated when a number of heat producing units are contained in a single enclosure because the temperature rises permitted in switch-gear standards result from conventional situations which may differ appreciably from the situation within an enclosure and connected to other heat producing equipment. In this case, guidance can be obtained from IEC 60943 'Guide for the specification of permissible temperature rise for parts of electrical equipment, in particular for terminals'. IEC also publishes a bound volume containing the text of all its electrical safety standards up to the time of publication. This is a very useful compendium, sold at a price significantly less than the total cost of the standards bought separately, and provides a most handy source of reference although it is necessary to check that a particular standard has not been up-dated since the date of publication.

Safety aspects contained within product specifications establish matters such as marking of the product to inform the user of the product ratings and limitations, and where necessary to warn of dangers of misapplication etc.

Safety tests are also included in standards, e.g. by limiting the emission of arc products, restricting temperature rise to prevent injury, decomposition and degradation of insulation or other properties of materials, or ignition leading to fire hazard, etc. Sometimes the level of safety is indicated in the title of the standard e.g. if it states that it is intended for use by authorised persons, which implies that there can be an additional level of hazard in untrained hands.

It is impossible to make any product completely safe. One cannot do without water, but one can drown in it. Safety regulations reduce the risk. In the same way the standard will generally set a defined level of acceptable risk, at a point where most hazards are eliminated as far as is possible without extravagant expenditure on remote chances of danger through misuse. A warning will normally be found in the standard where there could be any hazard that may arise in the use or foreseeable misuse of the products covered by the standard.

#### 49.1.1.5 *Quality assurance*

The quality of goods and services are provided for in standards by defining features and characteristics which establish their ability to satisfy the stated needs. A quality assurance procedure provides a standard framework for

regular checking to ensure maintenance of quality in production, and continued adherence of the product to the standard to which it is claimed to conform. It would be inappropriate to go into any great detail here, but the reader is referred to the following British Standards: BS 4891 contains a guide to quality assurance, terminology is in BS 4778, and specification of quality systems can be found in BS 5750.

Although not an electrical standard, firms of quality often also seek approval to ISO 9000 to demonstrate quality of management. Year 2000 revisions to the ISO 9000 series of quality management standards are expected to bring a great many new business benefits to companies making the transition to the new standard (details available from BSI head office).

## 49.2 Organisations preparing electrical standards

One of the problems facing a manufacturer developing a product for export is that the product is required to conform with the appropriate standard which applies to the particular country to which he is exporting. He may already have test certificates to certify complete compliance with the British Standard, as is necessary for sales within the UK, but the other country may have national standards which differ in significant details from the British Standard and local regulations and trade practices which enforce an expensive series of re-testing to slightly different prescriptions in a test station in the other country. This is particularly troublesome in the USA where manufacturers of tried and tested products find that they must spend considerable sums of money and time having their products tested once again at the Underwriters Laboratories (UL) or some similar test company before they are able to market that product in the USA. Now that Canada has joined with USA in a common market activity, it is likely that the same will apply to Canada in future. The organisation of standards in the USA is somewhat chaotic, compared with other developed industrialised countries. There are approximately 35 different bodies producing electrotechnical standards for the USA. These are loosely coordinated by the national body, The American National Standards Institution (ANSI) which does not develop standards, but may approve standards produced by the other bodies as American National Standards. Apart from UL standards and similar product standards, there are two basic standards generally recognised in the USA:

- (1) The National Electrical Code, produced by the National Fire Protection Association (NFPA); and
- (2) The National Electrical Safety Code, produced under the auspices of the Institute of Electrical and Electronic Engineers (IEEE).

The National Electrical Manufacturers' Association (NEMA), the US equivalent of BEAMA is also active in producing standards. The system is illustrated below for the case of the Underwriters' Laboratories Inc.

A parallel situation existed for many years in Europe, where approvals were needed in each country, especially for electrical equipment sold to the general public, and equipment sold in several countries would be studied with approvals marks for KEMA, VDE, SEMKO, NEMKO or DEMKO, etc. as proof to the purchaser that the local approvals authority had passed it. The European Committee for Electrotechnical Standardisation (CENELEC) since its

formation in 1972 has reduced much of the unnecessary duplication of testing activity and has introduced a new approvals mark which should eventually replace all the existing marks within the CENELEC regional group of countries. However, to ensure that all electrical equipment in the EEC is up to a uniform standard of quality and safety, it has become mandatory for all electrical goods to carry the 'CE' mark.

As detailed below, CENELEC is far advanced in actively converting all National Standards within the EEC into European Standards and in the process eliminating national differences in preparation for the removal of trade barriers in 1992. Although this gives many technical and commercial problems, it will undoubtedly simplify European trade when the process has worked through the system. Canada and the USA are going through a similar transition, having formed a similar regional group.

Other international and regional standardising bodies exist as detailed below, but most of the electrotechnical groups tend to follow the standards produced by the International Electrotechnical Commission (IEC).

The IEC was formed in 1906 to harmonise all electrotechnical standards world-wide and to rationalise the test and certification requirements in such a way that all nations can work to one set of electrotechnical standards. Considerable progress has been made this century in that direction, and it is only to be hoped that the strengthening of the regional groups will not delay the progress to World harmonisation by leading to the erection of more formidable regional barriers to trade.

### 49.2.1 British Standards Institution (BSI)

In the UK, the British Standards Institution is the recognised body for the preparation and promulgation of national standards in all fields. In 1901, it was set up by the professional engineering associations with the title 'Engineering Standards Committee' changed at the end of World War I to the 'British Engineering Standards Association'. A Royal Charter was granted in 1929 supplemented in 1931 when the body was retitled the 'British Standards Institution', an independent body whose Royal Charter was consolidated in 1981 as an independent body with the following objectives:

- (a) to co-ordinate the efforts of producers and users for the improvement, standardisation and simplification of engineering and industrial materials so as to simplify production and distribution, and to eliminate the national waste of time and material involved in the production of an unnecessary variety of patterns and sizes of articles for one and the same purpose;
- (b) to set up standards of quality and dimensions, and to prepare and promote the general adoption of British Standard Specifications and schedules in connection therewith, and from time to time to revise, alter and amend such specifications and schedules as experience and circumstances may require;
- (c) to register, in the name of the Institution, marks of all descriptions, and to approve and affix or license the affixing of such marks or other proof, letter, name, description or device; and
- (d) to take such action as may appear desirable or necessary to protect the objects and interests of the Institution.

BSI acts as the national member of the corresponding international and regional standards organisations and as such is responsible for paying the subscriptions to these bodies (more than a million pounds!). As a completely independent body, BSI has to raise income to meet its

expenditure. A large proportion of its income is derived from quality assurance activities, sales of publications, testing and technical help. The remainder of its income was in the main divided between subscriptions from the tens of thousands of members and Government grant-in-aid. Electrotechnical Standardisation represents a significant fraction of BSI activity, due to the high technological level and national importance of the industry, and its rapid rate of advance into new and exciting fields of discovery and development, necessitating the preparation of standards for products which did not exist in any form in earlier generations.

Preparing standards for such innovative products necessitates the formation of new committees to add to the present total of over 3000 technical and subcommittees, each committee being provided with a secretary by the BSI, with over 25 000 committee members nominated by organisations representing the views of users, manufacturers, health and safety authorities, testing authorities etc. BSI maintains more than 10 000 current British Standards and a similar number of standards projects. Approximately one third of these are electrotechnical in nature.

Membership of BSI is divided into several categories, for example: individuals, professional firms and partnerships, industrial and commercial firms in both the private and public sectors, professional institutions, research associations and similar bodies, local authorities, and other organisations. Members pay subscriptions related to the size of the organisation.

Committee members are mainly nominees of the organisations which they represent and are responsible for standardisation project work, and obtaining the consensus of opinion of interested parties on any matter to be raised at committee meetings, reporting back to their organisations.

Each of the tens of thousands of committee members is therefore reporting back to a large number of other persons and organisations which indicates the vast amount of effort and time devoted to standardisation matters, and the importance attached to it by all concerned.

British Standards may be used to promote standardisation in any of the following stages:

- (1) terminology, symbols;
- (2) classification;
- (3) methods of measuring, testing, analysing, sampling, etc.;
- (4) methods of declaring, specifying, etc.;
- (5) specification of materials or products;
- (6) dimensions, performance, safety, etc.;
- (7) specifications for processes, practices, etc.;
- (8) recommendations on product or process applications; and
- (9) codes of practice.

The most familiar type of British Standard Specification is one that lays down a set of requirements to be satisfied by the material, product, or process standardised and which embraces, often by reference, relevant methods by which compliance may be determined.

More information on the different types of British Standard Specifications and other British Standard publications are given in Section 49.3.1.

British Standards were originally all publicly available documents voluntarily agreed. However, the publication by the BSI does not at present ensure their use. This position is progressively changing, notably where the standard is also a harmonised European standard where compliance becomes mandatory. Otherwise a British Standard only becomes binding if a claim of compliance is made, if it is invoked in a contract, or if it is called up in some other legislation. Regulations made under a number of British Acts of Parliament call up approximately 300 British Standards.

Support for the application of British Standards as agreements produced in the public interest is given by the Restrictive Trade Practices Act 1976. The care exercised in the production of British Standards is relied upon by users who themselves owe a similar duty to the public. The compliance with the requirements of a British Standard does not in itself necessarily imply that a product is safe and suitable for all possible applications. It remains the responsibility of users to ensure that a particular British Standard is appropriate to their needs. Within their scope, British Standards provide evidence of an agreed 'state of the art' and may be taken into account by the Courts in determining whether or not someone was negligent.

In July 1982, the Department of Trade on behalf of HM Government issued a document entitled 'Standards, Quality and International Competition' (Cond 8621) in which the BSI was recognised as the main producer of standards in the UK, and HM Government agreed to maintain the annual grant-in-aid based on the level of contributions from other subscribers and to support BSI's efforts to achieve international harmonisation of standards through ISO, IEC, CEN, CENELEC, etc. in the interests of UK industry and trade, and to encourage fuller participation of public purchasing authorities in the preparation of and compliance with British Standards in their purchasing decisions, quality assurance requirements, and in their operational procedures. The BSI undertook the huge task of reviewing, and where necessary revising existing British Standards to ensure that these, and any new British Standards, will be suitable for reference in Government Regulations as unambiguous statements of technical requirements. With the rapid movement to international harmonisation, in particular within the European Regional harmonisation within CENELEC, BSI is somewhat hindered in fully carrying out this task, since agreement must be obtained with all the international partners before any change whatever can be made in a harmonised standard. However, the Public Procurement Directive enforces mandatory compliance with the corresponding European standard, and thus some apparent ambiguities may be ineradicable.

However, both BSI and CENELEC are agreed that IEC standards are the most suitable for harmonisation, since they have been formulated with the benefit of world-wide expert opinion and agreed by a substantial majority vote of all interested nations. They thus offer the best chance of achieving a common set of standards world-wide. There are two major benefits:

- (1) a major international trade barrier is removed if the trading countries have common standards; and
- (2) users specifying a common standard are ensured that they have a common and valid base for examining and comparing competing products.

British Standards and new European standards for electrotechnical products etc. are therefore almost exclusively generated by the IEC. In order to have any influence on the content of future British Standards it is therefore vital to have adequate representation on IEC committees and even more important to maintain active participation in all the Working Groups of IEC, since it is in the Working Groups that basic standards are formulated and contentious points are resolved.

#### 49.2.2 International Electrotechnical Commission (IEC)

The International Electrotechnical Commission (IEC) was established in 1906, and now comprises the national

electrotechnical committees of over 50 countries in all continents throughout the world. During the twentieth century the IEC had produced over 3000 standards compiled by over 80 technical committees, and over 120 sub-committees that collectively represented over 80% of the world's population that produced and consumed 95% of the total electrical energy. National committees include representatives from manufacturers, users, testing authorities, trade associations, governments, and professionals and academics from research organisations and colleges.

IEC Standards are widely adopted as the basis of national electrotechnical standards so far as local customs and conditions permit. They are also quoted in manufacturers' specifications and by users when calling for tenders. This widespread adoption facilitates international trade in the electrical and electronic engineering sectors.

The International Conference on Large High-Voltage Electric Systems (CIGRE), meeting in Paris when necessary, has a number of working groups which produce papers discussed at the meetings and subsequently form the basis of work to produce standards within the IEC. The IEC works in close cooperation with the International Organisation for Standardisation (ISO) which is mainly concerned with standards in non-electrical fields. However there are overlapping areas, for example the ISO deals with automotive electrics (see Sections 49.2.5), and IEC is responsible for standards for steam and hydraulic turbines, which are almost exclusively employed for generation of electrical power.

In 1982, the IEC began its Quality Assessment System for Electronic Components (IECQ). This was initially introduced for quality assessment of mass-produced components, such as resistors and capacitors, but it has been much extended to embrace components made for special purposes. The major exporting countries of electronic components, more than 20 countries, are members of IECQ.

The British Standards Institute is the UK member body for the International Organisation for Standardisation (ISO) and the European Committee for Standardisation (CEN).

The Electrotechnical Council forms the British Electrotechnical Committee, the UK national committee of the parallel International Electrotechnical Organisation, the International Electrotechnical Commission (IEC) and the parallel regional electrotechnical organisation the European Committee for Electrotechnical Standardisation (CENELEC). BSI also participates as the UK member in producing European Standards (EURONORMS) for the European Coal and Steel Community (ECSC).

Towards the end of the twentieth century BSI was working on over 10 000 standards projects, the major proportion of which were involved in international standardisation. At the same time they held the UK Secretariats of about 200 technical- and sub-committees of international standardising bodies, of which 17% were within IEC and CENELEC, and many more secretariats of working groups. The major importance to the UK of its electrical industry would suggest that Britain should be deeper involved in this activity, but BSI is compelled to keep its activities within the provision of services within the UK, due to the constraints of its limited budget. The sale of standards was anticipated to be enhanced by the pace of international standardisation in which case it could have offered some growth of income for promoting such work. Even this source could be threatened if, for example, a decision were made to sell all European standards from Brussels or some other profit centre outside the UK. With the revolution in Information Technology it has become possible to deliver Standards over the Internet, and BSI has invested large sums in the provision of

advanced IT facilities to meet this challenge. Standards are available to subscribers on-line ([www.bsi-global.com](http://www.bsi-global.com)), and many standards are also available on CD ROM as well as the traditional hard-copy format all available from the BSI bookshop (open to all every weekday from 0900 to 1730). 'Print on demand' has been introduced from images stored on electronic files and enquiries can be transmitted to BSI by e-mail: [info@bsi.org.uk](mailto:info@bsi.org.uk)

Many new strategies are being developed to support the continuation of BSI's standardisation work, and a substantial range of new services is being made available to customers in addition to the loan facilities available at modest cost from BSI library.

BSI has also established many centres overseas, which are listed in Section 49.5.1.

Every international committee in which the UK participates has an equivalent committee, usually a BSI committee which appoints and briefs the UK delegation. Each delegation has a leader who is the principal UK spokesman at the international meeting, and a Rapporteur to assist the leader in technical interpretation of documents at the meeting and to keep a record of the proceedings from which he produces a brief report of the main decisions of the meeting for BSI. Members chosen as delegates in international standards work are chosen for their special knowledge and powers of advocacy, and they are responsible for presenting the viewpoint of the UK as agreed in the corresponding BSI committee. Five responsible and properly briefed delegates would normally be the maximum number on any committee, ideally comprising the leader, a manufacturer, a user, a testing specialist, and a technical expert with an academic or industrial research background (although the size and composition of the delegation will vary depending on the availability of funding for the attendees, and the nature and importance of the matters to be discussed). If regulatory matters are to be discussed, the delegation should also, if possible, include a representative of the appropriate Government department serving also on the corresponding BSI committee. As stated above, this representative should also actively participate in the work of the working group preparing the voting document if there are any special UK requirements which need to be included. Special European standards which need to be developed where there is no equivalent standard available or under consideration in the IEC.

The IEC is governed by IEC council and its committee of action. It operates also certain special committees referred to by the following acronyms:

---

ACET	Advisory Committee on Electronics and Telecommunications
ACOS	Advisory Committee on Safety
CISPR	International Special Committee on Radio Interference
ITCG	Information Technology Coordination Group

---

### 49.2.3 European Committee for Electrotechnical Standardisation (CENELEC)

In 1959 the standardisation institutions of Western Europe formed the European Committee for Standardisation (CEN) which co-ordinated the drafting of standards within the two regional trading groups: The European Economic Community (EEC) and the European Free Trade Area (EFTA). Electrotechnical standards were then made the responsibility of CENEL (the electrotechnical counterpart of CEN). The CEN certification body was referred to under the acronym CENCER.

However, as the EEC began to be enlarged in 1972, the European Committee for Electrotechnical Standardisation (CENELEC) was set up which creates harmonisation documents (HDs) and European standards (ENs). CENELEC members are the national electrotechnical committees of Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, Netherlands, Norway, Portugal, Spain, Sweden, Switzerland and the UK. Once an EN is approved, by the agreed voting procedure, it must be printed or endorsed as a national standard in all the countries within the EEC. Electrotechnical ENs and HDs are preferably derived from, or exact copies of, corresponding IEC standards. However, after 1992, when all trade barriers were removed in the EEC (under Article 100 of the treaty of Rome), it became apparent that there were many national variants in the standards of the various EEC countries which would need to be resolved before a truly free-trade situation could exist. The Vilamouira procedure was rather quickly introduced to provide for such national standards which might be converted into regional standards. In the UK this has given many problems of possibly losing standards that are urgently needed to be maintained and gaining others which are not wanted. This is liable to produce problems unlikely to be resolved until well into the 21st century.

With the advent of CENELEC there has been a considerable change in the method of drafting British Standards in order to avoid conflict with HDs. When CENELEC begins work on a given subject, a 'standstill' or '*status quo*' arrangement comes into effect. Changes to national standards relating to that subject cannot then be made until harmonisation has been agreed, or permission obtained from CENELEC. It is still possible to have a national standard for a particular type of equipment which is of no interest to any other member countries of CENELEC, provided that the type of equipment is not just a local variant of an HD or EN. At the time of writing, individual customers may still obtain equipment to their own specification, sometimes as a 'special' carrying perhaps a delivery and/or a price penalty. However, freedom to obtain such 'specials' has been restricted from 1992 within the EEC especially for companies like the electrical supply industry, which are subject to the Public Procurement Directive whether or not they are privatised.

As the CENELEC standards are based on IEC standards wherever possible, active participation in IEC committee meetings and working groups has become more important than work in the BSI or CENELEC committees alone. Once a European Standard or a Euronorm is called up in an EEC Directive it is binding on Governments of all Member States, and the terms of the Directive will determine its status.

#### 49.2.4 Underwriters Laboratories Inc. (UL)

The Underwriters Laboratories Inc. (UL) is an independent not-for-profit organisation in the USA which was originally set up by the insurance underwriters to carry out testing for public safety, but is now completely independent. It was originally founded in 1894 and is chartered as a not-for-profit organisation without capital stock, under the laws of the State of Delaware, to establish, maintain, and operate laboratories for the examination and testing of devices, systems, and materials. A complete description of the organisation, purposes, and methods of UL can be found in a pamphlet '*Testing for Public Safety*' obtainable from UL. The UL is given here as an example of a major test organisation in the USA, which is also very active in producing national standards in that country, in cooperation with US manufacturers of the products standardised.

UL will grant a 'listing' which 'observes' the requirements of the UL standard. In this respect, a product employing materials or having forms of construction differing from those detailed in the requirements of the standard may be examined according to 'the intent' of the requirements, and if found to be substantially equivalent, may be listed. Listings may be granted in certain circumstances, partly on tests at UL and tests carried out by the manufacturer. Under the UL arrangements a US manufacturer can obtain a listing and get a product on the market much more quickly than with the normal standardisation approval delay elsewhere. However, this is by no means a 'soft option' because UL usually requires 'follow-up' testing to be carried out at regular intervals, and any failure at that stage will result in withdrawal of listing, stopping production until the matter is put right. In this respect compliance with UL standards could be regarded as intermediate between 'type testing' (tested once only) and a service such as the BSI 'kite mark' scheme (of which there is more detail in Section 49.4).

#### 49.2.5 Other bodies (ISO other national and regional committees etc.)

The International Organisation for Standardisation (ISO) was founded in 1947 in the aftermath of World War II, and the national standards bodies of approximately 90 different countries now participate in its work. ISO produces standards which are published on approval by 75% of the member bodies. ISO is governed by the ISO Council, and within the organisation there are in excess of 2000 technical committees, sub committees, and working groups involved in the preparation of International Standards. ISO had published approximately 8000 standards in the 20th century. In principle, ISO does not produce electrical standards, this being the province of its electrical counterpart the IEC. However, in practice, where the electrical standard relates to a product assembled within a larger product, ISO will take over the task of preparing a standard. An example of this is in automotive electrics. Electrical components in a motor vehicle constitute a significant proportion of the product, but such electrical components are not standardised by IEC but by ISO. A specific example is the standardisation of the fuses which would normally be the province of IEC/TC32. However, these are covered by an ISO committee concerned with the vehicles, although IEC/SC32C (Miniature Fuses) is kept informed of their decisions through a liaison system. This is typical of the type of liaison which exists between different standardisation bodies world-wide. Further detail of the ISO/IEC Code of principles on 'reference to standards' can be found in the following: Annex B to BS 0: Part 1: 1991.

The ISO Council organise their activities through a number of committees referred to under the following acronyms:

---

CERTICO	Committee on certification
COPOLCO	Committee on consumer policy
DEVCO	Development Committee (aimed at the needs of developing countries)
EXCO	Executive Committee (which is also responsible for finance)
INFCO	Information Committee
PLACO	Planning Committee
REMCO	Reference Materials Committee
STACO	Standardisation Principles Committee

---

The International Commission for Conformity Certification of Electrical Equipment (CEE) was set up immediately after World War II to harmonise electrical equipment standards. It comprised the national electrotechnical committees of 23 European countries together with observers from Australia, Canada, Hong Kong, Iceland, India, Japan, South Africa and the USA. A Certification Body (CB) was set up which could validate certificates of testing valid in all European member countries for electrical equipment tested in two of them at recognised testing authorities. This was known as the 'CB Scheme'. CEE also established the 'E' mark for marking a product to signify approval. This should be superseded by the 'CE' mark which should become mandatory throughout the EEC. CEE became later IECEE when it was taken over by IEC in 1985.

Most of the testing to this system is therefore now incorporated in the *IEC System for Conformity Testing to Standards for Safety of Electrical Equipment* (IECEE). IECEE's objective is the reciprocal recognition of test results among all participating countries, and offers the only world-wide recognition scheme for the safety of electrical equipment tested against IEC Standards. About half of the member organisations of the IEC are also members of IECEE. Addresses of most of these can be found in Section 49.5.1. The scheme is intended for electrical equipment used in homes, offices, workshops and similar locations and covers safety-related standards for the following categories of equipment:

- (1) electronic entertainment equipment;
- (2) measuring instruments;
- (3) cables and cords;
- (4) lighting equipment;
- (5) household and similar electrical appliances;
- (6) portable power tools;
- (7) accessories, including certain components;
- (8) switches for appliances and automatic controls;
- (9) protective equipment for installation, including fuses and fuse-holders;
- (10) low-voltage switchgear and controlgear;
- (11) transformers;
- (12) office machines and IT equipment; and
- (13) electromedical equipment.

Under this scheme a manufacturer can contact the national certification body in his own country (BSI in the UK) and have his equipment tested in conformity to standards for safety at the designated testing laboratory. The equipment is then included in the '*List of CB Test Certificates*', where new certificates are published each year. Importers can procure conforming equipment by having it tested fully to the same scheme, but it only needs to be tested once to cover all countries for testing standards included in the scheme.

Importers can confirm which recently successfully type-tested equipment is and where, by consulting the regularly published *CB Bulletin* available from the IECEE Secretariat at the IEC Central Office.

There are many other international and regional groups concerned with aspects of electrical standardisation, but in the main they tend to apply IEC standards or North American variations. An international body is IFAN, the International Federation for the Application of Standards, which comprises the official standards-user bodies recognised by their national standards organisations. Regional bodies include ARSO, the African Region Organisation for Standardisation, which was founded in 1977 by the United Nations Economic Commission for Africa (ECA)

and comprises the national standards bodies of the African countries who are members of ECA and the Organisation of African Unity (OAU), ASMO, the Arab Organisation for Standardisation and Metrology which was set up for the League of Arab States in 1965 as a specialised technical body in the field of standardisation, metrology and quality control, the Council for Mutual Economic Assistance (CMEA) which since 1949 acted to harmonise the national standards of USSR and Eastern Europe, and also later Cuba, Mongolia, and Vietnam, the Pan American Standards Commission (COPANT) comprising the standards bodies of the United States of America and 11 Latin American countries who since 1961 have been working to co-ordinate their policy of implementing IEC standards and recommendations within the Pan American region, the Pacific Area Standards Congress (PASC) which was founded in 1973 to assist countries in the Pacific area in international standards activities and promote closer cooperation between its members (active members Australia, Canada, China, Hong Kong, Indonesia, Japan, Republic of Korea, Malaysia, New Zealand, Philippines, South Africa, Thailand and the USA), and the Nordic Electrotechnical Standards Cooperation Committee (NOREK) comprising Denmark, Finland, Norway and Sweden, which reviews the work of national organisations and formulates regional policy for presentation to IEC and CENELEC and ensures that standards prepared by IEC can be implemented in the Nordic countries with as few modifications or deviations as possible.

Although all major developed countries and regions belong to the IEC and are committed to eventual harmonisation of electrotechnical standards, there are still significant differences in details and special requirements and necessity for verification in a local test station which can so add to costs that a product from outside the region can be priced out of the market. It appears also that those countries which are most vociferous in wanting their own products admitted to other world markets with as low tariffs as possible and without testing other than to their own local requirements in their own country tend to be those with the most standards barriers to reciprocal trade. However, progress in the last quarter of the 20th century tends to indicate, with occasional minor setbacks, a trend towards a world-wide set of harmonised electrotechnical standards with common wording and interpretation in the early 21st century. It is also remotely possible that in that century, test certificates and approvals to an IEC standard from an internationally recognised test authority in any region might be recognised as good and sufficient proof of compliance with the appropriate electrotechnical standards in any other region in the world without further local testing.

#### 49.2.6 Communication with organisations concerned with standards

It is clear from the above that anyone wishing to export products has first to penetrate the minefield of local standards regulations imposed either by government or by local traders in the target region. Also any contractor wishing to undertake a construction project, large or small, must apprise himself of all the standards mandatory in the region where his project is to be completed, since such compliance will be implicit in the contract, even if not specifically elaborated.

Appropriate addresses for enquiries in the various lands or international organisations are to be found in Section 49.5.1 (addresses of organisations concerned with standards).

However, the best source of information in the UK on standards matters is the British Standards Institution which runs a service of Technical Help to Exporters which was a popular free enquiry service, originally supported by DTI for the BOTB. However, in response to requests from users of the service and others to make it more comprehensive, the service has been considerably extended in its scope. This greatly expanded service, however can no longer be provided free of charge because of the possible incalculable very large cost of an open-ended service, and the considerably improved service is now self financing. With the advance of IT systems at the beginning of the 21st century, the internet is developing as the best and quickest route to information on standards. How this source is developing is detailed in Section 49.2.6.1.

#### 49.2.6.1 *The impact of the Internet on the distribution of standards*

Any reader interested in standards who is not connected with the Internet should install the facility as soon as possible, with the fastest means of access available. Year 2000 saw the commencement of a big change in the distribution of standards and related material. At the beginning of the millennium more than 10 000 users had registered with the new service WEBSITE: [bsonline.techindex.co.uk](mailto:bsonline.techindex.co.uk), email: [bsonline@techindex.co.uk](mailto:bsonline@techindex.co.uk)

This service, known as 'British Standards On-line' provides subscribers anywhere in the world with new and existing standards from its database. This method ensures that all documents transmitted are updated with the latest up-to-the-minute revisions, which previously might appear much later due to the delay in typesetting and printing. In addition, the user of the standard gets immediate access to the standards information he requires without any postal distribution delays. It is still necessary to pay for standards, because the work of standards publication is largely supported by sale of the standards. In previous years, free distribution of international standards might have led to vastly escalating publishing costs. In future years, however, if printing ceased to be used altogether, and some reliable system of financing standardisation work could be agreed, it might be possible to make all standards free on-line. At the time of writing this chapter there is no remote possibility of such a move, and the sale of standards is essential to support the continuation of the service.

In addition, most standardising bodies have installed websites where the latest freely distributed information is displayed, and from some of which standards can be purchased over the Internet. The two most important sites for UK users are the British Standards Website <http://www.bsi-global.com> and the IEC Website <http://www.iec.ch> which are good sources of general information on the standardisation of electrical products. Throughout the text of this chapter readers may find many other websites and e-mail addresses which may be used to gather further information concerning individual aspects of standardisation, and within the major websites more detailed addresses can be specially useful. For example, the IEC created within their website a possibility of viewing a slide presentation of seminars using Microsoft Powerpoint.

The leader of the project team on IEC 80416 promoted the use of 'virtual meetings' over the world-wide web. An interesting idea, though troublesome for those experts sitting in on a meeting when it is the middle of the night in their location!

The use of one system for the circulation of documents has great advantages because there are incompatibilities

between different word-processing products. IEC have operated for several years with document circulation using Microsoft 'Word' for this purpose which can also readily be circulated by e-mail among working group and committee members. This was a step in the right direction but which gave many problems when some committee members invested in a later version of the product, distributed early in the USA, which could not be read on earlier versions and produced hundreds of pages of obscure symbols instead of the document. This matter needs to be standardised. Even at the Houston meeting the IEC provided a battery of PCs all programmed to read Word 6 which were all found to be unable to read documents on disk for the meeting brought by a convenor who had just bought a later version.

BSI committee members, commencing in year 2000 are to have all their committee documents distributed via the Internet. Eventually no paper copies of documents will be distributed to committee members (except of course to those who agree personally to meet the additional cost of providing such a service). The file format adopted by BSI at the time of writing is that of the Acrobat PDF file system which has been found very satisfactory by most users except for users with certain makes of printer which show difficulty in printing graphics in the latest version of Acrobat. PDF files are quite secure, however, and cannot be edited. This is a disadvantage for a committee member wishing to prepare a new draft, but the difficulty may be overcome by copying text into a Word document and then making the desired changes to that.

Committee members can read these files, and only need to print out those in which they have a particular interest or need for a forthcoming meeting.

IEC also distribute documents in PDF format. However they also use FTP sites, for which you have to be an FTP client. Some files are compressed and need to be un-zipped, for example with Winzip.

A further problem at the moment is the long period of time on the Internet sometimes required for downloading. However, contact with the Internet by faster means than the enhanced modem should undoubtedly overcome this difficulty in the future.

## 49.3 The structure and application of standards

The drafting and presentation of British Standards is itself the subject of a British Standard i.e. BS 0: Part 3: 1991 'A Standard for Standards: Part 3. Guide to Drafting and Presentation of British Standards'. In this part of BS 0, strong emphasis is placed on the need for precision in drafting, particularly in relation to titles, scopes, requirements, and test methods appropriate to specifications, and the advice in this standard is still of great value in preparing draft clauses for standards. However, this guidance can now only apply at the drafting stage, because most British (and CENELEC) standards are now to be IEC standards often with identical text. Any wording has therefore to be agreed by all International partners in the agreement, and the final version made into an identically worded British Standard even when it is not in 'good English' as spoken in England. The 1991 revision required alterations to the earlier editions of BS 0: Part 3, in order to accommodate the changes required by the IEC/ISO directives—Part 3: 1989 *Drafting and presentation of International standards* and the CEN/CENELEC Internal Regulations—Part 3: 1990 *Rules for the drafting and presentation of European standards*.

The example given below of structure of British Standards therefore reflects typical IEC structure, which sometimes conflicts with the aspirations of BS 0.

#### 49.3.1 Different types of British Standard documents

British Standards are used to promote standardisation of a wide range of technical matters, terminology and symbols, marking and classification, methods of measuring, testing, analysing, sampling, etc.; methods of declaring, specifying, etc.; specifications for materials or products, specified dimensions, performance, safety requirements, etc.; specification of processes and practices etc.; recommendations on applications of products and processes, and desirable safe procedures.

The type of British Standard document for each of these purposes must obviously vary since the purpose of the document is different, varying from a set of instructions to a code of advice on good practice. There are thus British Standard Specifications, Drafts for Development (where a new technology is rapidly being introduced), Published Documents of information and guidance, British Standard Codes of Practice, Guides, Handbooks, Glossaries, etc. Standards may also be referred to in Regulations to avoid inclusion of detailed technical provisions and criteria in the body of the law.

In the following parts of this section some more detail is given of these different forms of documents produced by the BSI.

##### 49.3.1.1 *British Standard Specifications*

A British Standard Specification is the most well known and understood type of BSI standards publication. It lays down a set of requirements to be satisfied by the product, material, or process in question, and embraces, often by reference, the relevant methods by which compliance may be determined.

The general series of British Standards uses the prefix BS and is numbered sequentially. This is followed by a colon and the part or section number (if any) and then another colon and year of issue (or year of revision when the standard is revised). At one time this nomenclature was mainly restricted to British Standard Specifications, but now is also used for codes of practice (see Section 49.3.1.4). The number has no special significance, although many British Standard committees keep one number for a product (e.g. BS88: Part 4: 1988 has been retained for low-voltage fuses for the protection of semiconductor devices) and only the date is changed when the standard undergoes revision. At the time of writing it is possible that the parts of IEC 20269 corresponding to BS 88 may become Harmonised Documents (prefix HD), but it is unlikely that they will become ENs. This is because the harmonisation document permits a country to choose only those parts of the document which are to be used in that country. If the document becomes a full EN, all parts become the British Standard. Although the performance standards are practically the same for all fuses in IEC 60269, the dimensions are very different. If all the parts of the IEC standard were to be included in the EN, fuses would be supplied which would not fit into any existing UK installation, and users would not want to rip out their installations just in order to replace them with fuses of exactly the same performance but of new dimensions.

The automobile series are indicated by the letters BS AU plus a sequential number with a suffix letter which advances with every amendment (e.g. BS AU 242a: 1998).

The prefix BS ISO indicates the British version of an ISO standard, and BS CISPR similarly a CISPR document.

The prefix PAS implies a product assessment specification issued as an interim measure, and QC in the prefix relates to quality control.

The marine series are indicated by the prefix BS MA and is numbered sequentially.

The aerospace series uses a still different nomenclature, being numbered sequentially within classes, each class being indicated by a letter, e.g. 'F' for fabrics, 'S' for steels, etc. Editions other than the first bear a prefix number to show the edition. e.g. BS 3M 60:1998 is the third edition whereas in the case of BS Z 15:1998 no current standard is superseded.

Amendments became numbered sequentially under the prefix AMD, although earlier amendments were numbered as published documents (e.g. in BS 3036 Amendment No. 3 was classified as PD 5141, whereas Amendment No. 4 is AMD 2463).

Every British Standard used to be also classified according to the Universal Decimal Classification (UDC) (details in BS 1000). The UDC number was assigned at the manuscript stage and for older British Standards it can be found in small print beneath the BS number on the front cover. Every BSI publication for sale (except amendments) carries also an International Standard Book Number (ISBN) on the outside back cover. This appears usually near the top left-hand side of the back cover (e.g. on the rear cover of BS 88: Section 2.2:1988 you will find 'ISBN 0 580 16846 8').

Other general information, outside the main body of the standard, tends also to be printed on the inside and outside of the front and back cover. A group number may also be included which indicates the purchase price of the standard.

In the case of a dual numbered standard where there is identical text, the international or regional document number is printed beneath the British Standard number on the top right-hand corner of the front cover. The following example is a European Standard (EN) which is now a part of BS88:

BS EN 60269-3:1995  
BS 88 Section 3.1:1995  
IEC 269-3 :1987

In this example, in the numbering of the EN it can also be detected that the standard is derived from IEC 269-3. The general series of British Standards have white covers, which identifies them from other types of British Standard publication. This will have decreasing relevance as distribution goes electronic.

##### 49.3.1.2 *Drafts for development*

Drafts for Development (DDs) can be regarded as equivalent to the 'provisional' or 'tentative' standards that are issued in certain countries outside the UK. They are published when guidance is urgently needed, for example in a new and rapidly developing technology, but where such guidance, though theoretically sound, has not yet been subjected to enough practical application to justify the publication of a British Standard. DDs are particularly advantageous for setting a framework for new test methods where extensive use of the tests is needed to establish satisfactory repeatability and reproducibility. The IEC equivalent to a DD is the Technical Trend Document (TTD). An example is the dual numbered document:

DD 183:1989  
IEC 127-4 TTD

Drafts for Development may be converted into British Standards of any type or withdrawn when sufficient experience has been obtained and considered by the appropriate committee.

Drafts for Development are bound in vivid orange covers to distinguish them from other British standard publications. After 1992 IEC ceased publication of TTDs, and only a few DDs were current at the start of the millennium.

#### 49.3.1.3 *Published documents*

Published Documents (PD) are miscellaneous documents containing supplementary information relating to standardisation. A good example is PD 5688 covering the use of 'SI Units'. This is a useful little booklet which was published by BSI when the metric system was being introduced into British Standards and everyday life in the UK. It gives a brief account of the way the SI system of units has evolved, tabulates the basic units and the principal supplementary and derived units and a few conversion factors relating SI units to the imperial units. (The SI system of units is used in all IEC Standards as well as in British Standards.)

Published Documents were all published in blue covers, except for the Education Section of PDs which had yellow coloured covers.

#### 49.3.1.4 *Codes of practice and guides*

Codes of Practice have the main function of recommending good accepted practice as followed by competent practitioners. Codes of Practice assemble the results of practical experience and scientific investigation in a form that enables the reader to make immediate use of proven developments in particular branches of industry.

Before 1975, Codes of Practice were numbered in a separate CP series with a red cover. Nowadays, new and revised Codes of Practice are each given a new number in the BS series, retaining the title '*British Standard Code of Practice for ...*'.

In contrast to British Standard Specifications, British Standard Guides and Codes of Practice are written in the form of guidance only, and are not intended to provide objective criteria by which compliance may be judged. Consequently the word 'must' is never used in a Code of Practice, and 'shall' is replaced by 'should' because none of the requirements are mandatory. Neglect of safety measures prescribed in Codes of Practice and Guides might now however be taken as evidence of liability in the case of an accident.

Care is taken by drafting committees to ensure that Codes of Practice do not become textbooks, the principles behind a particular practice being discussed or explained only when absolutely necessary. Specific recommendations for avoiding certain existing practices are made only where tacit approval of these practices would otherwise be assumed by the reader or if the practices in question may be hazardous. Where appropriate, a code offers a series of options and identifies the implications of accepting them.

#### 49.3.1.5 *Glossaries and methods*

British Standard Glossaries are documents bringing together agreed sets of terms and definitions for reference. They normally contain a contents list, classified sections giving terms and definitions numbered by section and subsection in a special code which assists retrieval of

information, and an alphabetic index referring to the same special code.

British Standard Methods comprise a variety of standards describing formalised ways of performing given tasks. The methods of doing this are clearly stated and explanations given of any calculations etc., necessary to complete each task. British Standard methods can be included in specifications that require them, or alternatively may be published as separate standards with a general BS reference. This is a useful arrangement when the methods are required to be called up in two or more other standards.

#### 49.3.1.6 *Handbooks*

British Standards Handbooks comprise texts taken from a number of British Standards, complete and/or in part, together with related material previously published elsewhere relating to a particular field. Since a handbook might contain only an extract from a British Standard, problems of interpretation may arise. In any such case, the full text of the British Standard in question should be consulted.

An example of a Handbook was published around the time of 'metrication' mentioned above, the British Standard Handbook No. 18 '*Metric Standards for Engineering*', which brought together in one volume all the information then currently available on metric standards for general engineering. When first published it was a 580 page book with all available standardised metric information. Comparison of this with the little booklet PD 5686 mentioned above will give some concept of the difference between a Handbook and a Published Document.

#### 49.3.1.7 *Regulations*

A Regulation is a binding document which contains legislative, regulatory or administrative rules and which is adopted and published by an authority legally vested with the necessary power. References made to standards in regulations may have one of two effects:

- (1) *Standards made mandatory*: the standard or the part of the standard which is referred to must be followed, or a specific result in a standard test must be achieved in order to obey the statutory requirement. This means that the text in the standard ceases to be voluntary in the context of the legal requirement.
- (2) *Standards deemed to satisfy*: in this case, compliance with the standard is indicated as one way of fulfilling a regulatory requirement. It is possible to choose another route to fulfil the requirement, but those doing so may be required to prove that their alternative complies with the regulation.

Until recently, Regulations might call up British Standards, but are not British Standards. The separation of the regulatory authority and the Standardisation body has needed modification to fit in with the arrangements with CENELEC in co-ordination of Electrical Regulations. Under EEC Directives, European Standards, dual numbered with British Standards cease to be voluntary, and thus effectively become Standard Regulations. This may require changes to the present UK organisation of the regulatory process.

The principal example of this is the case of the *IEE Wiring Regulations—Regulations For Electrical Installations*, popularly known as the 'wiring rules'. These are at present drawn up by the Wiring Regulations Committee of the Institution

of Electrical Engineers. The parallel international work takes place in IEC, which is the international equivalent of the electrical aspects of BSI. The international work on regulations for electrical installations is undertaken by IEC TC64 and the position of the UK regulatory system would fit better into the system if parallel work was carried out by BSI committees issuing standards which take into account CENELEC harmonisation documents. More detail of the problems of co-ordination with International Standards (such as IEC 60364—'Electrical Installations of Buildings') was made in the preface to the 15th edition (amended) of the IEE wiring regulations. Such a reorganisation would not necessarily change the organisations or expertise used in doing the technical work but the Regulations have had to become harmonised standards. These difficulties were resolved in the year 1990/91 by the formation of BSI committee PEL/64 and its subcommittees matching equivalent IEC/TC64 and CENELEC TC64 committees and sub-committees.

In 1997, the 16th edition of the wiring regulations was also published as the second edition of BS 7671.

### 49.3.2 International equivalents of British Standard documents

As has been noted in Section 49.3.1.1 and Section 49.3.1.2 and elsewhere there are equivalent IEC and European Standards to the more important electrical British Standards. These are indicated by the dual numbering system. As time progresses, however, the distinctions between all such documents tend to decrease, and national deviations diminish. This is particularly the case within Europe, where CENELEC regulations stipulate conditions giving European Standards the status of a national standard without any alteration in the member states.

Many standards current in North America do not have direct equivalents elsewhere. If the USA with its North American bloc could move a little faster in aligning its national standards with IEC, we could see most national deviations vanishing by the year 2050.

### 49.3.3 Structure of a typical standard

Since most electrotechnical British Standards are directly derived from IEC standards, the structure and wording of the standards originates in IEC decisions rather than independent national decisions. The following is the structure of a typical IEC standard specification:

- (a) Foreword (followed by preface and introduction where appropriate), giving the background to the specification and its international development;
- (b) Scope;
- (c) Object;
- (d) Definitions;
- (e) Conditions For Operation in Service;
- (f) Classification;
- (g) Characteristics;
- (h) Marking;
- (i) Standard Conditions for Construction; and
- (j) Tests.

This structure has been criticised in the past in that it sometimes leads to a certain degree of repetition in different clauses. However this disadvantage is offset by the considerable advantage that all the requirements are clearly stated in

each clause, and *all* the test requirements are gathered together in the final section rather than being distributed throughout the text. It is thus perfectly clear exactly what has actually been tested and what the product has achieved if it successfully complies with the specification.

### 49.3.4 Implementation of standards

The implementation of standards is controlled by factors seen above to be changing with the growth of international regulation. British Standards have historically always been *voluntary* in their implementation. However, the changes implied by the EEC Directives are shown above to make them *mandatory* when they become ENs. A similar situation is seen in Section 49.3.1.7 to exist with Regulations.

A British Standard Specification forms part of the trade description of a product when quoted by a BS number or when compliance with it is claimed. Marking with a BS number constitutes a unilateral claim that the product complies with *all* the requirements of the BS quoted. The person making such a claim is responsible for its accuracy under the Trade Descriptions Act 1968. To support their claims, manufacturers may have their products certified (see Section 49.4) as complying with the requirements of the appropriate British Standard Specification.

The existence of a British Standard Specification facilitates the preparation of contracts, and any British Standard Specification invoked in a contract becomes legally binding on the contracting parties. However, the compliance with the British Standard does not of itself confer immunity from legal obligations. The user is only guaranteed that the product supplied complies with all the requirements of the standard, and must satisfy himself that these are sufficient to fulfil the tasks for which he is purchasing the product. Many British Standard Specifications contain options and other matters which need to be clarified in any contract to ensure that the correct variant of the British Standard is being specified.

As explained above, British Standard Codes of Practice, Guides and similar recommendations are written in the form of guidance only, and are not intended to provide objective criteria by which compliance may be judged. Such publications are not appropriate for simple reference in contracts.

There are three methods of reference to British Standards used in Regulations and elsewhere:

- (1) *Reference to standards by exact identification (strict reference)*: one or more specific British Standard(s) are designated in such a way that later revisions of any such British Standard will not be applied unless the reference is modified. The British Standard is usually indicated by its number and date. This is the method of reference normally used in the UK.
- (2) *Reference to standards by undated specification (undated reference)*: one or more specific British Standard(s) are designated in such a way that later revisions of any such British Standard will be applied without the reference needing to be changed. In this case the British Standard is usually designated by its number only.
- (3) *General reference to standards*: reference is made in a general way to present and future standards, which means that the relevant reference includes a general clause so that all the present and future standards in a specific field are regarded as meeting the aims of the document containing the reference (e.g. the document could be a regulation).

## 49.4 Testing, certification and approval to standard recommendations

To confirm compliance with British Standards it is necessary to test and to mark the appropriate products to identify compliance with the appropriate British Standard and/or that the manufacture is maintained at an acceptable level of quality. BSI operates four certification marking systems:

- (1) The '*kitemark*', the BSI's certification mark indicates not only compliance with the appropriate standard, but also compliance with a rigorous program of surveillance, inspection and follow-up testing at regular intervals.
- (2) The '*safety mark*', which was introduced in 1974 to provide manufacturers with a means of demonstrating compliance with a British Standard specifically related to safety.
- (3) The '*registered firm symbol*', operated for manufacturers who produce goods which are not at present covered by a British Standard.
- (4) The '*BS 9000 mark*' for electronic components certified under the BS 9000 system.

In its certification activities, BSI does not have, or seek, a monopoly position, but responds to UK needs and aims to provide a service which can be used by industry. Through the Quality Assurance Council the BSI cooperates with other organisations concerned with certification of compliance with standards. The more important of these are:

- (1) British Electrotechnical Approvals Board (BEAB);
- (2) British Approvals Service for Electric Cables (BASEC);
- (3) Association of Short-Circuit Testing Authorities (ASTA);
- (4) British Approvals Service for Electrical Equipment for Flammable Atmospheres (BASEEFA).

The BSI has compiled a register of test houses of assessed capability indicating their fields of testing.

The BSI Certification and Assessment Department is responsible not only for the certification of products but also for the assessment of the capabilities of the firms in manufacturing and service industries. The growing realisation of the importance of quality and reliability in goods and services has caused rapid growth in the percentage of firms seeking registration in schemes such as BS 5750. Registration and maintenance to such a quality standard has a dual advantage. Compliance is not only an attraction to customers, it is also a benefit to the efficient business of the registered firm improving its competitiveness and ensuring the maintenance of that quality by independent assessment to the British Standard.

The BSI Test House centred at Hemel Hempstead provides a wide range of testing facilities which are generally available to clients world-wide and embraces tests which are electrical, electronic, mechanical, chemical, photometric, automotive, etc. ([www.inspectorate.com](http://www.inspectorate.com))

BSI also carry out import/export inspections, arranging for inspection before shipment at the place of manufacture. The BSI inspectorate is accredited by the following organisations in the UK:

- (1) BSI,
- (2) BASEC,
- (3) Department of the Environment (Property services agency)
- (4) Department of Transport,

and it also has accreditation from the following overseas organisations:

- (1) Canadian Standards Association (CSA),
- (2) Centre Technique du Bois (*France*),
- (3) Institute for Industrial Research and Standards (IIRS) (*Eire*),
- (4) Instituto del Marchio di Qualita (IMQ) (*Italy*),
- (5) Staatliches Materialprüfungsamt (MPA) (*Germany*),
- (6) Standards Association of Australia (SAA),
- (7) Standards Association of New Zealand (SANZ),
- (8) Statens Planverk (*Sweden*),
- (9) Technische Überwachungs Verein (TUV),
- (10) Underwriters Laboratories Inc. (UL),
- (11) Underwriters Laboratories of Canada (ULC)
- (12) Verband Deutscher Elektrotechniker (VDE) (*Germany*).

**BEAB** certifies household appliances and all home laundry equipment, heating and cooking appliances, refrigerators and freezers, home sound and vision equipment, etc. for compliance with relevant British Standards, for example the many parts of BS 3456. These are mostly already in agreement with CENELEC HDs and the ENs which are superseding parts of BS 3456.

Many retailers in the UK large and small will only stock BEAB-approved appliances.

**BASEC** provides a certification scheme for manufacturers of electric cables and flexible cords, and ensures that ongoing quality control procedures are adequate to ensure consistently high standards. BSI provides the assessment and inspection facilities (but not the operations management service which it provided in earlier years).

**ASTA** operates a certification and product marking scheme for circuit-breakers, fuses, fuse-links, fuse-boards, switches, isolators, starters, transformers, reactors and electrical wiring accessories. It offers a number of classes of test certificate, including a certificate of complete compliance with the requirements of a relevant standard.

**BASEEFA** certifies electrical equipment using any of the recognised forms of explosion protection, and certifies equipment intended for zone II areas. Certification is against recognised standards, where these are available, and otherwise to standards prepared by BASEEFA.

International Standards are prepared with great care, and every attempt is made to avoid ambiguity in specifying tests. However, where any possible ambiguity becomes apparent in the practical performance of the tests, the above bodies assess the most appropriate interpretation of the test. Such interpretations are today often agreed internationally by groups representing test authorities so that tests are of equal severity wherever carried out.

## 49.5 Sources of standards information

Many libraries throughout the UK have stocks of British Standards and some also stock foreign standards. The most comprehensive source of information, however, is the BSI which has established an extensive standards information service.

**BSI library and enquiry service** The BSI Library contains a full set of all current and superseded British Standards, a collection of International Standards and complete sets of standards from 80 foreign standardisation bodies. This is one of the world's largest collections of standards, comprising over half a million documents. Documents are available

on loan to members of BSI at a small charge. Tel: 0208 996 7004 fax: 0208 996 7005

*BSI PLUS (private list updating service)* Available to BSI subscribing members. PLUS monitors and updates subscribers' standards library automatically.

*BSI enquiry service* This deals with direct enquiries concerning British Standards, international regional and foreign standards. e-mail: [info@bsi.org.uk](mailto:info@bsi.org.uk) or look in at the website <http://www.bsi-global.com>

*BSI catalogue* This publication, up-dated annually, lists all published British Standards and other special series, together with short abstracts.

*BSI update STANDARDS* These are issued monthly cumulatively up-dating the latest catalogue and gives details of all new and revised British Standards, amendments, withdrawals, renewals, drafts issued and new work started, as well as details of IEC and CENELEC documents.

*BSI business STANDARDS* This publication is issued bi-monthly, and in addition to articles and general information on current standards topics, it gives BSI information on topics such as the Reader Enquiry Service (Tel: 020 8996 9001), a comprehensive updated directory of BSI senior staff and services, details of membership services and of the British Standards Society, and details of events such as the communication days 2000 and the training services of BSI Business Solutions Ltd.

*BSI annual report* This is published each year in October, and it gives a review of the year's work and a statement of accounts.

#### 49.5.1 Addresses of organisations concerned with standards

*British Standards Institution*  
Head Office; BSI Standards  
389 Chiswick High Road  
London W4 4AL  
United Kingdom  
Tel: +44 (0) 181-996 9000  
Fax: +44 (0) 181-996 7400  
e-mail: [info@bsi.org.uk](mailto:info@bsi.org.uk)

*Hemel Hempstead*  
Maylands Avenue  
Hemel Hempstead HP2 4SQ  
United Kingdom  
Tel: +44 (0) 1442 230442  
Fax: +44 (0) 1442 231442  
e-mail: [info@bsi.org.uk](mailto:info@bsi.org.uk)

Units 1, 5 and 6  
Finway Road  
Hemel Hempstead  
Herts  
HP2 7PT
